[a] Based on 70 percent volatile content of sludge, and a sludge specific gravity of 1.02 (concentration effects neglected).

[b] Hydraulic detention time, d.

The amount of volatile solids destroyed in a high-rate complete-mix digester can be roughly estimated by the following empirical equation (Liptak, 1974):

$$V_d = 13.7 \ln(\text{SRT}_{\text{des}}) + 18.9 \tag{13–14}$$

where V_d = volatile solids destruction, %

SRT_{des} = time of digestion, d (range 15 to 20 d)

The equation does not account for variation in the sludge feed to digestion and the digestion mixing and other operating conditions and should be used to obtain a rough estimate only, and it appears that the equation overestimates volatile solids destruction. Typical volatile solids destruction ranges as a function of SRT are provided in Table 13–30. Because the untreated sludge feed can be measured easily, this method is also used commonly. In plant operation, calculation of volatile solids reduction should be made routinely as a matter of record whenever sludge is drawn to processing equipment or drying beds. Alkalinity and volatile acids content should also be checked daily as a measure of the stability of the digestion process.

In calculating the volatile solids reduction, the ash content of the sludge is assumed to be conservative; that is, the number of pounds of ash going into the digester is equal to that being removed. Digester VSR can be calculated based on two different methods. The first method is the mass balance method, which is shown below.

$$R_{\text{VSS}} = \frac{M_{\text{VS in feed}} - M_{\text{VS in digested sludge}} - M_{\text{VS in surpernatent}}}{M_{\text{VS in feed}}} \times 100 \tag{13–15}$$

Table 13–30

Estimated volatile solids destruction in high-rate complete-mix mesophilic anaerobic digestion

Digestion time, d	Volatile solids destruction, %
30	50–65
20	50–60
15	45–50

where R_{VSS} = volatile solids destruction, %
$M_{\text{VS in feed}}$ = mass flowrate of volatiles in digester feed, kg/d
$M_{\text{VS in digested sludge}}$ = mass flowrate of volatiles out of digester, kg/d
$M_{\text{VS in surpernatent}}$ = mass flowrate of volatiles in digester decant stream, kg/d

It should be noted that in modern high rate digesters, there is no decant so the $M_{\text{VS in surpernatent}}$ number goes to zero. Digester VSR can also be calculated with the simplified Van Kleeck formula given below.

$$R_{\text{VSS}} = \frac{W_{\text{VS in feed}} - W_{\text{VS in digested sludge}}}{W_{\text{VS in feed}} - (W_{\text{VS in digested sludge}})(W_{\text{VS in feed}})} \times 100 \tag{13–16}$$

where $W_{\text{VS in feed}}$ = Weight fraction of digested sludge volatile content per total dry solids
$W_{\text{VS in digested sludge}}$ = Weight fraction of volatiles out of digester per total dry solids

It should be noted that the Van Kleeck formula assumes that there is no supernatant withdrawal or accumulation of grit inside the digester so in practice the results may not be 100 percent accurate. A typical example calculation of volatile solids reduction is presented in Example 13–6.

EXAMPLE 13–6 **Determination of Volatile Solids Reduction** From the following analysis of untreated and digested biosolids, determine the total volatile solids reduction achieved during digestion. It is assumed that (1) the weight of fixed solids in the digested biosolids equals the weight of fixed solids in the untreated sludge and (2) the volatile solids are the only constituents of the untreated sludge lost during digestion.

	Volatile solids, %	Fixed solids, %
Untreated sludge	68	32
Digested sludge	50	50

Solution

1. Determine the weight of the digested solids. Because the quantity of fixed solids remains the same, the weight of the digested solids based on 1.0 kg of dry untreated sludge, as computed below, is 0.64 kg.

$$\text{Fixed solids in untreated sludge} = \frac{0.32\text{ kg}}{(0.32 + 0.68)\text{ kg}} 100 = 32\%$$

Let X equal the weight of volatile solids after digestion. Then

$$\text{Fixed solids after digestion} = \frac{0.32\text{ kg}}{(0.32 + X)\text{ kg}} 100 = 50\%$$

$$\text{Weight of volatile solids after digestion, } X\text{ kg} = \frac{0.32\text{ kg}}{0.5} - 0.32 = 0.32\text{ kg}$$

$$\text{Weight of digested solids} = 0.32\text{ kg} + 0.32\text{ kg} = 0.64\text{ kg}$$

2. Determine the percent reduction in total and volatile suspended solids.
   a. Percent reduction of total suspended solids

$$R_{\text{TSS}} = \frac{(1.0 - 0.64)\text{ kg}}{1.0\text{ kg}} 100 = 36\%$$

b. Percent reduction in volatile suspended solids using both methods
Using the mass balance method [Eq. (13–15)]

$$R_{\text{VSS}} = \frac{(0.68 - 0.32)\text{ kg}}{0.68\text{ kg}} 100 = 52.9\%$$

Using the Van Kleeck method [Eq. (13–16)]

$$R_{\text{VSS}} = \frac{0.68 - 0.5}{0.68 - 0.5(0.68)} 100 = 52.9\%$$

Population Basis. Digestion tanks are also designed on a volumetric basis by allowing a certain number of cubic meters per capita (cubic feet per capita). Detention times range from 10 to 20 d for high-rate digesters (U.S. EPA, 1979). These detention times are recommended for design based on total tank volume, plus additional storage volume if sludge is dried on beds and weekly sludge withdrawals are curtailed because of inclement weather.

Typical design criteria for heated anaerobic digesters based on population are shown in Table 13–28. The criteria are applied only where analyses and volumes of sludge to be digested are not available. The capacities shown in Table 13–28 should be increased 60 percent in a municipality where the use of food-waste grinders is universal and should be increased on a population-equivalent basis to allow for the effect of industrial wastes.

Selection of Tank Design and Mixing System

Most anaerobic digestion tanks are either cylindrical, conventional German design, or egg-shaped (see Fig. 13–20). The most common shape used in the United States is a shallow, vertical cylinder with a floating cover [see Fig. 13–20(a)] or fixed cover [see Fig. 13–20(b)]. Rectangular tanks were used in the past, but they experienced great difficulty in mixing the tank contents uniformly. German designers have worked on optimizing the shape of digesters, and two basic types have emerged: the conventional German digester and the egg-shaped digester. The conventional German digester [see Fig. 13–20(c)] is a deep cylindrical vessel with steeply sloped top and bottom cones (Stukenberg et al., 1992). The egg-shaped digester, shown on Fig. 13–20(d), is similar in appearance to an upright egg, and the design is sometimes modified to a sphere-cone shape. Egg-shaped tanks have been used extensively in Europe, especially in Germany, and are growing in popularity in the United States. Essentially all of the modern digester designs in the United States are of either the cylindrical or egg-shaped type. Cylindrical and egg-shaped digesters and the mixing systems used for each type of tank are discussed in the following paragraphs. Advantages and disadvantages of each type of digester are summarized in Table 13–31.

Proper mixing is one of the most important considerations in achieving optimum process performance. Various systems for mixing the contents of the digesters have been used; the most common types involve the use of (1) gas injection, (2) mechanical stirring, and (3) mechanical pumping. Some digester installations use a combination of gas mixing and recirculation by pumping. The advantages and disadvantages of the various mixing systems are summarized in Table 13–32; typical design parameters are shown in Table 13–33.

Cylindrical Tanks. Cylindrical sludge digesters are seldom less than 6 m (20 ft) or more than 38 m (125 ft) in diameter. The water depth should not be less than 7.5 m (25 ft) at the sidewall because of the difficulty in mixing shallow tanks, and the depth may be as

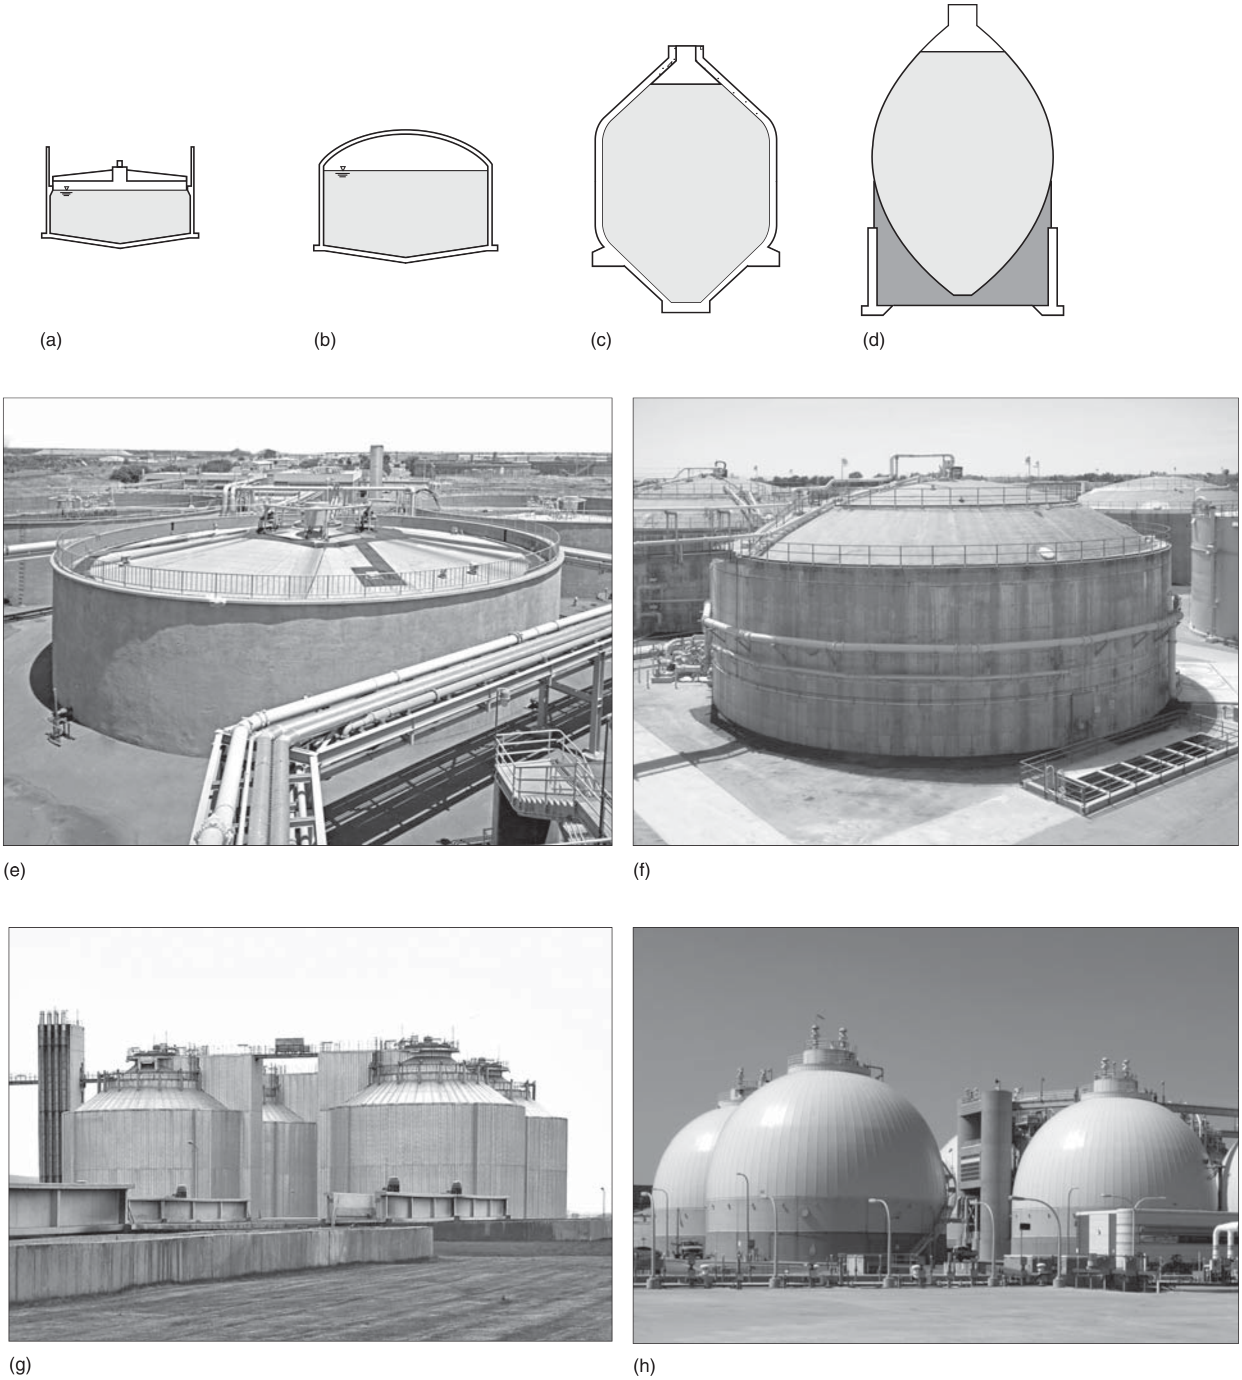

Figure 13–20

Typical shapes of anaerobic digesters: (a) and (e) cylindrical with floating cover, (b) and (f) cylindrical with fixed cover, (c), (g), and (h) conventional German design with reinforced concrete construction [note digesters in (g) and (h) are clad in a metal sheath], and (d) egg-shaped with steel shell (see also Figs. 13–24 and 13–25).

Table 13–31
Comparison of cylindrical and egg-shaped digesters[a]

Type of digester	Advantages	Disadvantages
Conventional	• Reactor shape results in large volume for gas storage • Reactor can be equipped with gas holder covers • Low profile • Conventional construction techniques can be applied; construction costs can be competitive	• Reactor shape results in inefficient mixing and dead spaces • Poor mixing results in grit accumulation • Large surface area provides space for scum accumulation and foam formation • Cleaning is required for removal of grit and scum accumulation; digester may be required to be taken out of service
Egg-shaped	• Minimum grit accumulation • Reduced scum formation • Higher mixing efficiency • More homogeneous biomass is obtained • Lower operating and maintenance costs; cleaning frequency significantly reduced • Smaller footprint; less land area is required • Foaming is minimized (except for gas mixing)	• Very little gas storage volume; external gas storage is required if as is recovered • High profile structures; may be aesthetically objectionable • Difficult access to top-mounted equipment; installation requires a high stair tower or an elevator • Greater foundation requirements and seismic considerations • Foaming of gas-mixed digester may be a problem in collecting gas • Higher construction costs • Construction limited to specialty contractors

[a] Adapted, in part, from Brinkman and Voss (1998).

much as 15 m (50 ft). The floor of the digester is usually conical with the bottom sloping to the center, with a minimum slope of 1 vertical to 6 horizontal where the sludge is drawn off (see Fig. 13–21). An alternative design uses a “waffle” bottom to minimize grit accumulation and to reduce the need for frequent digester cleaning (see Fig. 13–22).

Gas-injection systems used in cylindrical tanks are classified as unconfined or confined [see Figs. 13–23(a) and (b) on page 1518]. Unconfined gas systems collect gas at the top of the digesters, compress the gas, and then discharge the gas through a pattern of bottom diffusers or through a series of radially placed top-mounted lances. Unconfined gas systems mix the digester contents by releasing gas bubbles that rise to the surface, carrying and moving the sludge. These systems are suitable for digesters with fixed, floating, or gas holder covers. In confined gas systems, gas is collected at the top of the digesters, compressed, and discharged through confined tubes. Two major types of confined systems are the gas lifter and the gas piston [see Figs. 13–23(c) and (d)]. The gas lifter system consists of submerged gas pipes or lances inserted into an eductor tube or gas lifter. Compressed gas is released from the lances or pipes, and the gas bubbles rise, creating an air-lift effect. In the gas piston system, gas bubbles are released intermittently at the bottom of a cylindrical tube or piston. The bubbles rise and act like a piston, pushing the sludge to the surface. These systems are suitable for fixed, floating, or gas holder covers.

Mechanical stirring systems commonly use low-speed turbines or mixers [see Figs. 13–23(e) and (f)]. In both systems, the rotating impeller(s) displaces the sludge, mixing

Table 13–32

Summary of advantages and disadvantages of various anaerobic digester mixing systems

Type of mixer	Advantages	Disadvantages
All systems	• Increased rate of biosolids stabilization	• Corrosion and tear of ferrous metal piping and supports • Equipment wear by grit • Equipment plugging and operational interference by rags
Gas injection:		
Unconfined:		
Cover-mounted lances	• Lower maintenance and less hindrance to cleaning than bottom-mounted diffusers. Effective against scum buildup	• Corrosion of gas piping and equipment • High maintenance for compressor • Potential gas-seal problem • Compressor problems if foam gets inside, solids deposition • Plugging of gas lances • Entire tank contents are not mixed
Bottom-mounted diffusers	• Better movement of bottom deposits than cover-mounted lances	• Corrosion of gas piping and equipment • High maintenance for compressor • Potential gas-seal problem • Foaming. Incomplete mixing • Scum formation • Diffuser plugging • Bottom deposits can alter mixing patterns • Requires digester dewatering for maintenance
Confined:		
Gas lifters	• Better mixing and gas production and better movement of bottom deposits than cover mounted lances. Lower power requirements than cover mounted lances	• Corrosion of gas piping and equipment • High maintenance for compressor • Potential gas-seal problem • Corrosion of gas lifter • Lifter interferes with digester cleaning • Scum buildup • Does not provide good top mixing • Requires digester dewatering for maintenance if bottom mounted
Gas pistons	• Good mixing efficiency • Less susceptible to plugging due to rags or fibrous material • Provides surface agitation for management of scum layer • Can contain optional heating jacket	• Corrosion of gas piping and equipment • High maintenance for compressor • Potential gas-seal problem • Equipment internally mounted • Pistons interfere with digester cleaning • Requires digester dewatering for maintenance • Cannot operate at varying liquid levels

(*continued*)

Table 13–32 (*Continued*)

Type of mixer	Advantages	Disadvantages
Mechanical stirring: Low-speed turbines	• Good mixing efficiency	• Wear of impellers and shafts • Bearing failures. Interferences of impellers with rags • Requires oversized gear boxes • Gas leaks at shaft seal • Long overhung loads
Low-speed mixers	• Breaks up scum layers	• Not designed to mix entire tank contents • Bearing and gear box failures • Impeller wear. Interference of impellers by rags
Linear motion mixing	• Lower energy consumption compared to other technologies • High mixing efficiency • Capable of operating at various liquid levels • Suitable for retrofits • Equipment maintenance can be completed without taking digester out of service • Minimal mechanical complexity	• Limited number of installations in the United States • May require maintenance platform and equipment hoist • No redundancy • Sole supplier
Mechanical pumping:		
Internal draft tubes	• Good top-to-bottom mixing • Reversibility provides variable mixing dynamics • Provides surface agitation for management of scum layer	• Sensitive to liquid level • Corrosion and wear of impeller • Bearing and gear box failures • Requires oversized gear box • Structural modifications required for retrofit
External draft tubes	• Same as internal draft tube • Draft tube maintenance easier than internal type • Can contain optional heating jacket	• Same as internal draft tube
Pumps	• Good mixing control. Scum layer and sludge deposits can be recirculated. Pumps easier to maintain than compressors • Conductive for FOG addition	• Impeller wear • Plugging of pumps by rags[a] • Bearing failures • High electrical consumption • Decreased efficiency at higher solids concentrations • High mixing energy may contribute to foaming

[a] Impact from plugging with rags can be minimized or eliminated by using chopper pumps.

the digester contents. Low-speed turbine systems usually have one cover-mounted motor with two turbine impellers located at different sludge depths. A low-speed mixer system usually has one cover-mounted mixer. Mechanical stirring systems are most suitable for digesters with fixed or floating covers. Another type of mechanical mixer that is new to the market (as of writing this book) is a linear motion mixer that consists of a ring-shaped disc

Table 13–33

Typical design parameters for anaerobic digester mixing systems[a]

Parameter	Type of mixing system	Typical values[b]	
		U.S. customary units	SI units
Unit power	Mechanical systems	0.025–0.04 hp/10^3 gal of digester volume	0.005–0.008 kW/m^3 of digester volume
Unit gas flow[c]	Gas mixing		
	Unconfined	4.5–5 $ft^3/10^3\ ft^3\cdot min$	0.0045–0.005 $m^3/m^3\cdot min$
	Confined	5–7 $ft^3/10^3\ ft^3\cdot min$	0.005–0.007 $m^3/m^3\cdot min$
Velocity gradient, G[d]	All	50–80 s^{-1}	50–80 s^{-1}
Turnover time of tank contents	Confined gas mixing and mechanical systems	20–30 min	20–30 min

[a] Adapted from U.S. EPA (1987).

[b] Actual design values may differ depending on the type of mixing system, manufacturer, and digestion process or function.

[c] Quantity of gas delivered by the gas injection system divided by the digester gas volume.

[d] See Eq. (5–3) in Chap. 5.

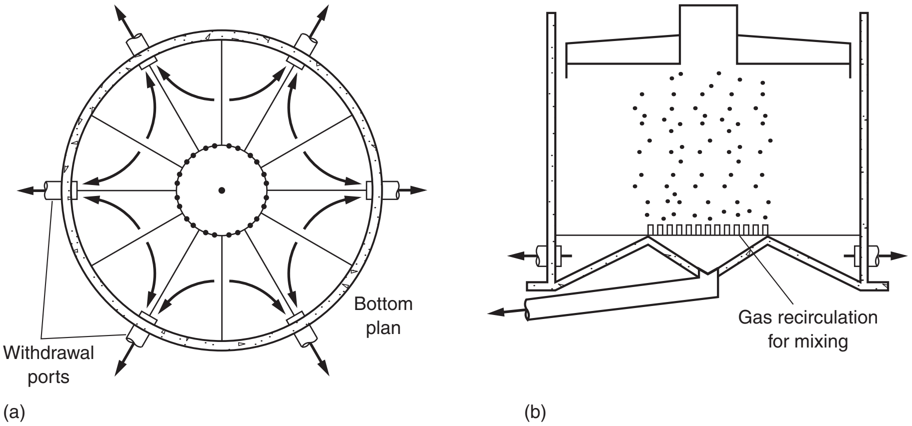
Typical waffle bottom anaerobic digester: (a) plan view (b) section.



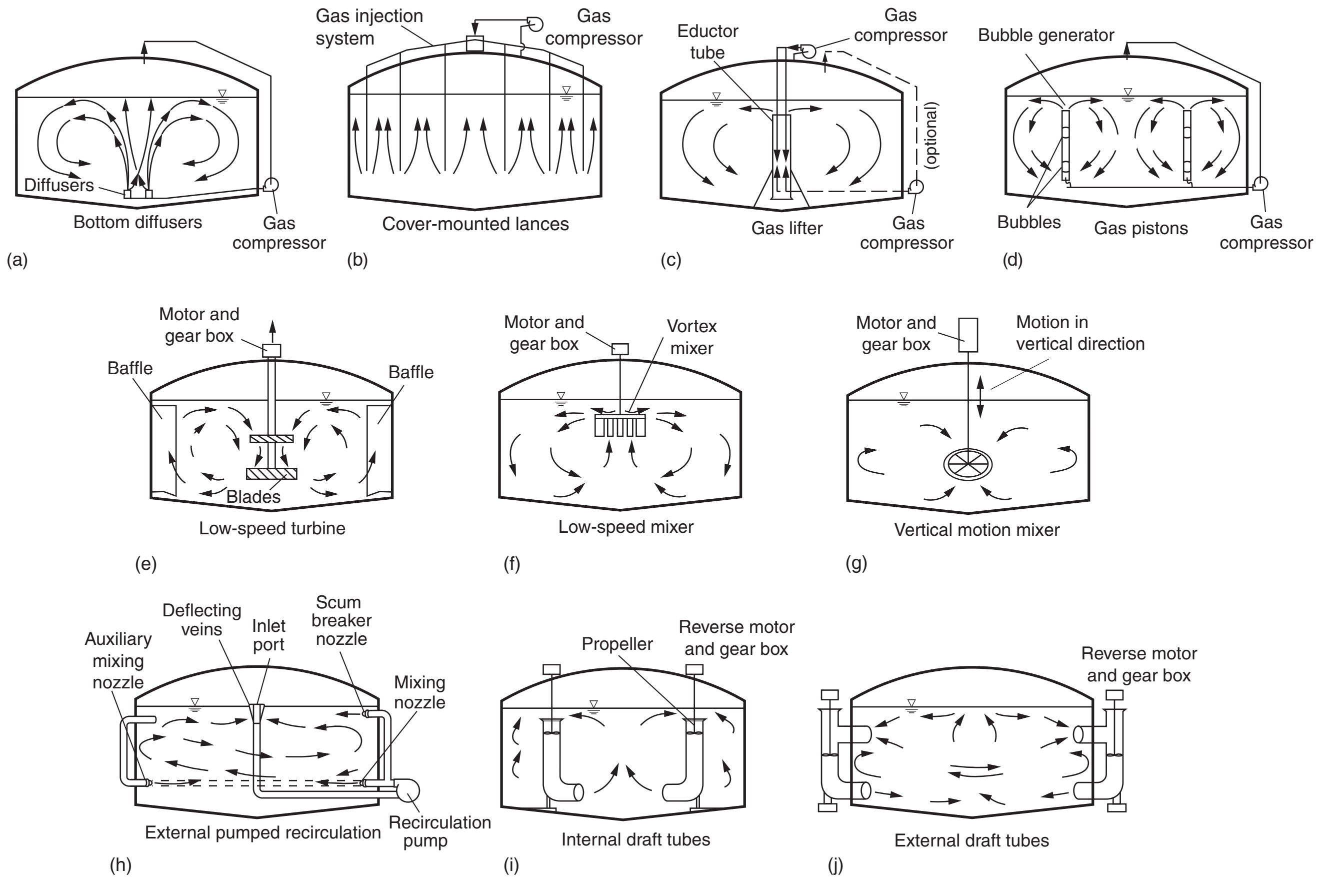


Figure 13–23

Devices used for mixing contents of anaerobic high rate digesters (a) and (b) unconfined gas injection systems; (c) and (d) confined gas injection systems, (e), (f), and (g) mechanical mixing systems; and (h), (i), and (j) mechanical pumping systems.

that oscillates up and down creating strong axial and lateral agitation needed for mixing of the digester contents [see Fig. 13–23(g)].

Most mechanical pumping systems consist of propeller-type pumps mounted in internal or external draft tubes, or axial-flow or centrifugal pumps and piping installed externally [see Figs. 13–23(h), (i), and (j)]. Mixing is promoted by the circulation of sludge. Mechanical pumping systems are suitable for digesters with fixed covers.

Egg-Shaped Tanks. The purpose of the egg-shaped design is to enhance mixing and to eliminate the need for cleaning. The digester sides form a steep cone at the bottom so that grit accumulation is minimized [see Figs. 13–20(d) and 13–24(a)]. Other advantages cited for the egg-shaped design include better control of the scum layer and smaller land-area requirements. Steel construction is more common for egg-shaped tanks in the United States; reinforced concrete construction requires complex formwork and special construction techniques. The structures are relatively high as compared to other treatment plant structures [see Fig. 13–24(b)], and may require an elevator for access to the top of the structure. In Boston, MA (see Fig. 13–18), and Baltimore, MD, the heights of the digesters were over 40 m (130 ft).

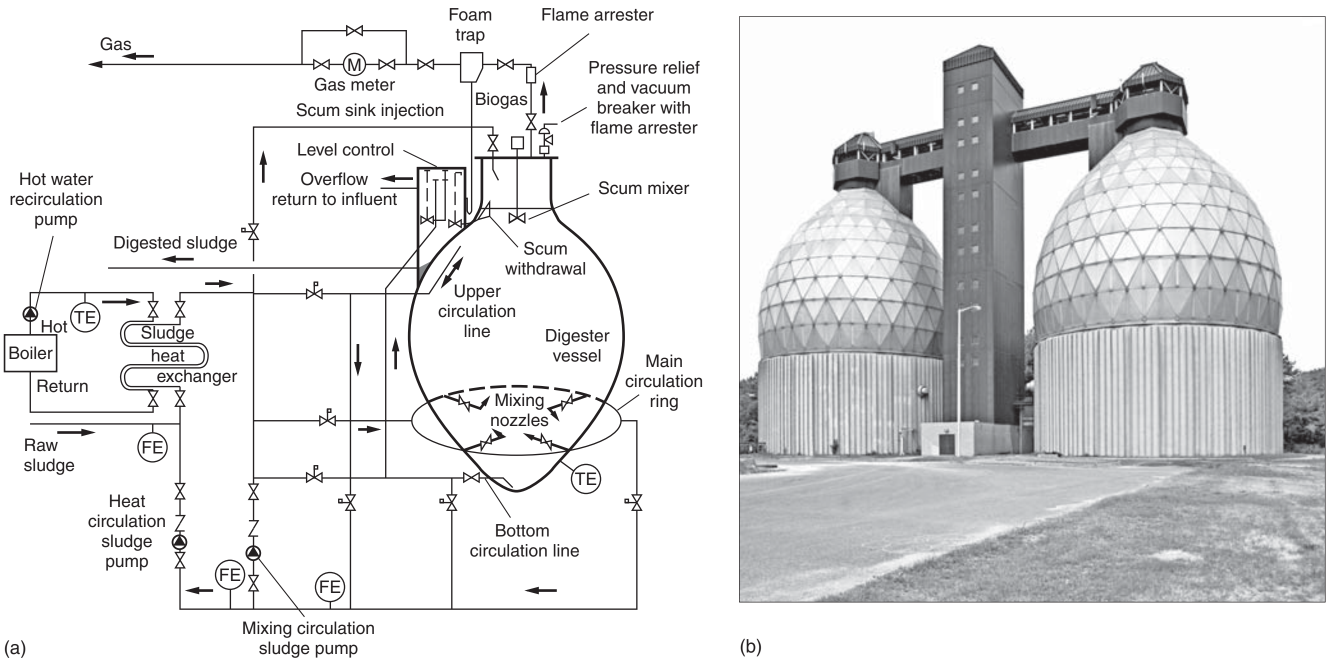

Figure 13–24

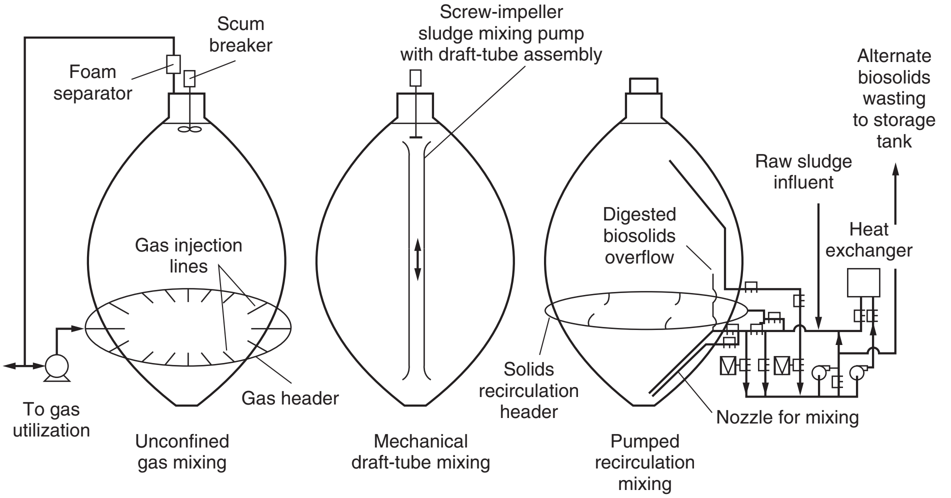
Egg-shaped anaerobic digester: (a) schematic diagram from Walker Process catalogue (b) pictorial view.

Egg-shaped digester mixing systems are similar to those for cylindrical tanks and consist of unconfined gas mixing, mechanical draft-tube mixing, or pumped recirculation mixing (see Fig. 13–25). Gas mixing is considered by some to be relatively ineffective in mixing the digester contents below the level of the injection nozzles. The mechanical draft tube and pumped recirculation mixing systems, however, are considered able to provide sufficient energy to mix even the sludge in the bottom cone of the digester. The mechanical draft-tube

Figure 13–25

Mixing systems for egg-shaped anaerobic digesters. (From Stukenberg et al., 1992.)



mixer, which can be operated in either an up- or down-pumping mode, also provides a positive means of mixing at the surface to control scum and foam (Stukenberg et al., 1992).

Recirculation mixing is generally more effective when the sludge is taken from the bottom and discharged near the gas-liquid interface or above the gas-liquid interface to break up scum that may have accumulated. Recirculation mixing is also effective for foam control in gas-mixed digesters.

Any or all of the mixing systems may be used, and all may be operated during any one day, although gas and mechanical draft-tube mixing are seldom used at the same time. Most digesters are fitted with a gas lance or hydraulic jet near the bottom of the cone to stir any accumulated grit.

A combination jet-pump draft-tube mixing system is also used that permits mixing in three zones of the digester. One jet pump is attached to the bottom of the centrally located vertical draft tube, and a second jet pump is attached to the top. In this configuration, the draft tube can function for pumping sludge upward or downward for periodic blending of bottom sludge and scum with the tank contents. A third pump is located at the vessel perimeter to create a swirling action. External recirculation pumps are also provided for sludge heating and additional circulation of the tank contents. The system is designed to circulate the tank volume 10 times per d (Clark and Ruehrwein, 1992).

Methods for Enhancing Sludge Loading and Digester Performance

Opportunities for enhancing the performance of anaerobic digesters include thickening the digester feed sludge or thickening a portion of the digesting sludge to increase the SRT. Recirculating a portion of the digested sludge and cothickening with untreated primary and waste sludge was reported originally by Torpey and Melbinger (1967). The solids concentration in the feed sludge improved and the performance of the digester, as measured by volatile solids destruction, increased significantly. The thickening system was installed at wastewater plants in New York City. In a study by Maco et al. (1998), the effects of thickening digested biosolids, either thickened separately or combined with prethickening of untreated sludge, increased the SRT of the digestion process and the production of biogas and decreased the hydraulic retention time.

The value of thickening the feed sludge to the digester is indicated by data presented in Table 13–29. For example, for a 15-d hydraulic retention time and an average TSS of 3 percent, the volatile solids loading factor in Table 13–29 is 1.4 $kg/m^3·d$. By improving the feed sludge TSS to 6 percent, the VSS loading can be increased to 2.9 $kg/m^3·d$, near the middle of the sludge loading range given in Table 13–28. In this hypothetical example, a doubling in digester capacity is achieved. In evaluating digested biosolids recycling to reduce the size and number of digesters or increase the sludge processing capacity of existing digesters, sludge rheology and sludge handling equipment require evaluation. While most digesters can accommodate increases in solids concentrations, the limits imposed by pumping and mixing systems require careful evaluation (Maco et al., 1998).

Sludge pretreatment prior to anaerobic digestion can enhance the solids loading and the digester performance. Pretreatment is practiced through adding energy in the form of mechanical, electrical, or ultrasonic. Combining heat with pressure to cause thermal hydrolysis has been practiced successfully. These methods of sludge pretreatment are presented later in this section.

Gas Production, Collection, and Use

Gas from anaerobic digestion contains about 65 to 70 percent CH_4 by volume, 25 to 30 percent CO_2, and small amounts of N_2, H_2, H_2S, water vapor, and other gases. Digester gas has a specific gravity of approximately 0.86 relative to air. Because production of gas is one of the best measures of the progress of digestion and because digester gas can be used as fuel, the designer should be familiar with its production, collection, and use.

Gas Production. The volume of methane gas produced during the digestion process can be estimated using Eq. (13–12), discussed previously. Total gas production is usually estimated from the percentage of volatile solids reduction. Typical values vary from 0.75 to 1.12 m^3/kg (12 to 18 ft^3/lb) of volatile solids destroyed. Gas production can fluctuate over a wide range, depending on the volatile solids content of the sludge feed and the biological activity in the digester. Excessive gas production rates sometimes occur during startup and may cause foaming and escape of foam and gas from around the edges of floating digester covers. In egg-shaped and shallow cylindrical digesters, foaming can clog the gas outlet unless foam control is provided. If stable operating conditions have been achieved and the foregoing gas production rates are being maintained, a well-digested sludge can be obtained.

Gas production can also be estimated crudely on a per capita basis. The normal yield is 15 to 22 $m^3/10^3$ persons·d (0.6 to 0.8 ft^3/person·d) in primary plants treating normal domestic wastewater. In secondary treatment plants, the gas production is increased to about 28 $m^3/10^3$ persons·d (1.0 ft^3/person·d).

Gas Collection. In cylindrical digesters, gas is collected under the cover of the digester. Three principal types of covers are used: (1) floating, (2) fixed, and (3) membrane. Floating covers fit on the surface of the digester contents and allow the volume of the digester to change without allowing air to enter the digester [see Fig. 13–26(a)]. Gas and air must not be allowed to mix, or an explosive mixture may result. Explosions have occurred in wastewater treatment plants. Gas piping and pressure-relief valves must include adequate flame traps. The covers may also be installed to act as gas holders for a limited storage of gas. High-rate digesters produce about two volumes of gas per volume of digester capacity/d (Speece 2001). Floating covers can be used for single-stage digesters or in the second stage of two-stage digesters.

Fixed covers provide a free space between the roof of the digester and the liquid surface [see Fig. 13–26(b)]. Gas storage must be provided so that (1) when the liquid volume is changed, gas, and not air, will be drawn into the digester; otherwise an overflow weir with a U-shaped trap needs to be provided to maintain a liquid seal, and (2) gas will not be lost by displacement. Gas can be stored either at low pressure in external gas holders that use floating covers or at high pressure in pressure vessels if gas compressors are used. Gas not used should be burned in a flare. Gas meters should be installed to measure gas produced and gas used or wasted.

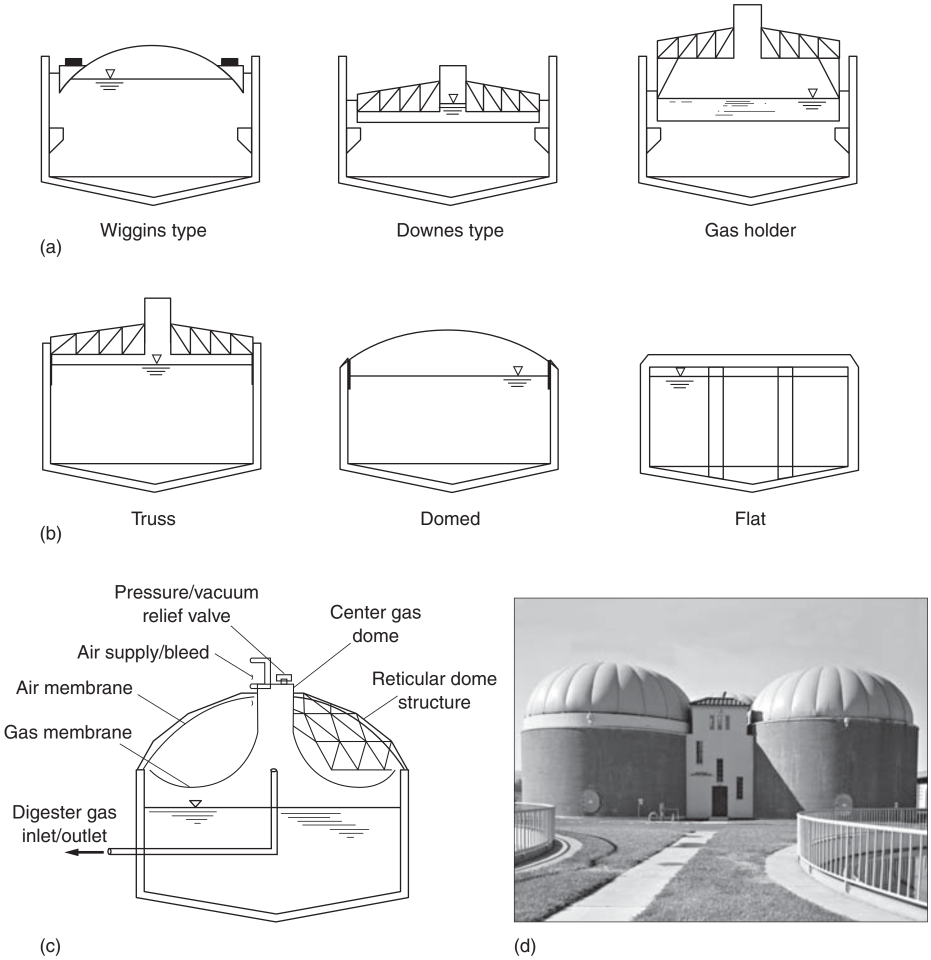
Another development in gas holder covers for cylindrical tanks is the membrane cover [see Fig. 13–26(c)]. This cover consists of a support structure for a small center gas dome and flexible air and gas membranes. An air-blower system is provided to pressurize the air space between the two membranes and vary the air space volume. Only the gas membrane and the center gas dome are in contact with the digester contents. The gas membrane is made from a flexible polyester fabric.

In egg-shaped digesters, the volume available for gas storage is small. For efficient utilization of digester gas, supplemental external storage may be required.

Gas Pretreatment and Use. Methane gas at standard temperature and pressure (20°C and 1 atm) has a lower heating value of 35,800 kJ/m^3 (960 Btu/ft^3). Lower heating value is the heat of combustion less the heat of vaporization of any water vapor present. Because digester gas is only 65 percent methane, the lower heating value of digester gas

Figure 13–26

Types of anaerobic digester covers: (a) floating, (b) fixed, and (c) and (d) schematic and view of membrane gas cover.



is approximately 22,400 kJ/m^3 (600 Btu/ft^3). By comparison, natural gas, which is a mixture of methane, propane, and butane, has a heating value of 37,300 kJ/m^3 (1000 Btu/ft^3). Digester gas can be used as a fuel for boilers to provide heat for digestion and other parts of the plant if surplus heat is available. Digester gas can also be used in cogeneration and when purified can be used as a natural gas substitute.

Because digester gas contains hydrogen sulfide, nitrogen, particulates, and water vapor, the gas frequently has to be cleaned before use. These impurities can significantly impact the operation and performance of equipment that utilizes the gas, especially cogeneration equipment. Proper design of a digester gas use system requires careful consideration of possible pretreatment requirements. The primary constituents of digester gas that require pretreatment are moisture, hydrogen sulfide, mercaptans, and siloxanes.

Pretreatment for Removing Moisture. Digester gas is typically saturated with water vapor. Common practice and regulatory codes require designing for removal of the moisture that condenses in the digester gas piping system using sediment traps and drip traps. Piping should be provided with a minimal slope of 10 mm/m (1/8-in./ft) to low points at which sediment traps or drip traps are located. Consideration should be given to access these devices for removal of the collected condensate. Automatic drip traps are available but are not allowed in some jurisdictions. A significant amount of the moisture in the gas will be condensed simply through the cooling in the piping system at ambient temperatures, which can then be removed by the appropriate traps. Long runs of piping or travel through other pretreatment systems can be advantageous for reducing the moisture content of the gas.

Some gas use systems may require additional removal of moisture from the gas. Chilling of the gas (reducing the dew point) is commonly used in systems where very dry gas is required. This treatment step is usually associated with systems where activated carbon is supplied for removal of other contaminants or where the gas use system requires a very dry gas. As cooling of the gas is costly to operate, this system should only be included after careful consideration of the costs and benefits obtained through that level of treatment.

Pretreatment for Removing Hydrogen Sulfide. Hydrogen sulfide can damage piping systems and digester gas use equipment. The hydrogen sulfide combines with the condensate and forms a weak sulfuric acid. Piping materials such as stainless steel or lined ductile iron pipe should be considered to resist the corrosion and erosion that can be caused by the slightly acidic condensate. Cement lined ductile iron pipe should not be used as the cement lining is readily destroyed by the condensate. Additional wall thickness ductile iron pipe has been used successfully providing an allowance for some corrosion and erosion.

A significant amount of the hydrogen sulfide is removed along with the condensate. This removal may be adequate for some digester gas uses like boilers, although even then the boiler may incur additional maintenance due to the presence of the hydrogen sulfide. Several systems are commonly used for removal of hydrogen sulfide from digester gas. Historically, iron sponge impregnated into wood chips has been used. The sulfide combines with the iron to form iron sulfide, a solid. These systems can also include methods to regenerate the iron in place.

There are several other commercially available processes for removal of hydrogen sulfide that include a liquid phase oxidation process, biological scrubbers or treatment systems, chemical systems, activated carbon, adsorptive resins, and others. Most, aside from the biological systems, resins, and activated carbon, use some form of iron chemistry. Systems that remove moisture through chilling will also remove a significant amount of the hydrogen sulfide in the condensate. However, consideration of condensate handling must be assessed. If returned to the treatment plant, consideration needs to be given to the ultimate fate of the hydrogen sulfide.

Pretreatment for Removing Siloxanes. Siloxanes are silicon containing volatile organic compounds. Siloxanes are used as carriers or conditioners in antiperspirants, skin care products, deodorants, liquid soaps, and hair care products and are now ubiquitous in the environment and wastewater. They are hydrophobic and tend to attach to the sludge produced during treatment. Once in an anaerobic digester, the conditions of mixing and heating tend to cause the siloxanes to volatilize into the digester gas. Wherever digester gas is burned, such as in a boiler, engine, or turbine, silicon dioxide (SiO_2), an inert white powder, is formed. Silica dioxide is the base material for glass, sandpaper, and grinding tools. The silicon dioxide can build up in the combustion equipment causing significantly increased maintenance or total equipment failure.

Sampling and testing procedures for siloxanes has not been standardized. Also, the allowable levels of siloxanes for gas use equipment vary by type and manufacturer of equipment. A proper design requires careful assessment and consideration of the siloxane composition of the gas and required cleaning for use. Sampling and testing program would be best for obtaining design information.

Siloxanes can be removed primarily in condensate through chilling or adsorption on a media or activated carbon. Return of the condensate to the treatment plant has been

Table 13–34

Typical electricity and heat generation efficiency from various co-generation systems[a]

Co–generation system	Electricity generation efficiency, %	Heat recovery efficiency,%
Internal combustion engine	37–42	35–43
Lean burn internal combustion engine	30–38	41–49
Conventional turbine	26–34	40–52
Recuperated Turbine	36–37	30–45
Microturbine	26–30	30–37
Molten carbonate fuel cell	40–45	30–40
Phosphoric acid fuel cell	36–40	NA

[a] Adapted from U.S. EPA (2010).

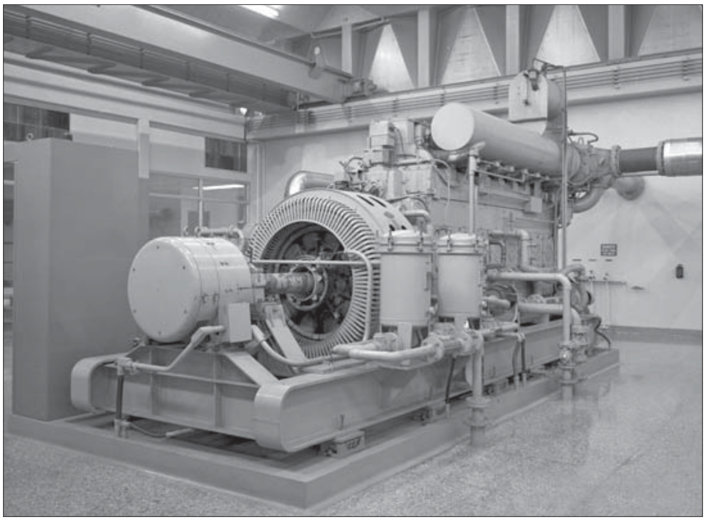
determined to be acceptable as a significant amount of the siloxane will be removed from the plant through volatilization from an aeration tank and in the final solids disposition. Media are regenerated through steam or other processes.

Digester Gas Use in Cogeneration. Cogeneration is generally defined as a system for generating electricity and producing another form of energy (usually heat in the form of steam or hot water). Cogeneration systems are also known as combined heat and power (CHP) systems. Most common at wastewater facilities are internal combustion engines or microturbines connected to generators. Several larger facilities also use turbines. Fuel cells are also used to create electricity with the heat recovered for process uses. Typical efficiencies for these processes are provided in Table 13–34. A typical internal combustion engine is shown on Fig. 13–27.

Design of a cogeneration system must consider variations in gas production, use of all of the gas or allowing occasional flaring of excess gas, and redundancy. These considerations are also impacted by the cost of electricity. It will be cost-effective to provide a more robust system when the electrical savings are greater due to higher electrical rates. Gas storage may also be considered when large variations in gas production are anticipated

Figure 13–27

Internal combustion engines for cogeneration at the Back River Wastewater Treatment facility in Baltimore, MD.



(due to industrial loadings or feed of supplemental organic material to the anaerobic digesters) or to maximize electricity generation at facilities where time of day electrical charges are significantly higher than off peak rates. The level of gas cleaning required for the cogeneration systems can vary widely and also needs to be considered in the system design.

The design of a cogeneration system must also consider air pollution impacts. Several jurisdictions have significant restrictions on combustion of fuels. Permitting aspects for cogeneration systems can impact the cost-effectiveness or ability to implement a specific system or device. Fuel cells have the lowest air emissions but the highest cost of the systems listed in Table 13–34.

Digester Gas Use as a Natural Gas. Digester gas is purified to enable its use as a substitute for natural gas. Besides the removal of H_2S, siloxanes, and water vapor, the additional removal of carbon dioxide (CO_2) is required to upgrade the digester gas to natural gas pipeline quality. Purified digester gas can have a methane content of 95 percent plus and can be modified slightly to meet pipeline quality methane for sale or use as natural gas. Purified digester gas can also be compressed to become compressed natural gas (CNG) for use as vehicle fleet fuel in natural gas burning engines. CNG plants can be useful in areas where air pollution is an issue and natural gas fleet vehicles are already in operation. Use of CNG can also be a substantial cost savings in areas where gasoline prices are higher. Several technologies are available for gas purification. The common technologies for gas purification are water adsorption, chemical adsorption, pressure swing adsorption (PSA), and cryogenic separation.

Digester Heating

The heat requirements of digesters consist of the amount needed (1) to raise the incoming sludge to digestion tank temperatures, (2) to compensate for the heat losses through walls, floor, and roof of the digester, and (3) to make up the losses that might occur in the piping between the source of heat and the tank. The sludge in digestion tanks is heated by pumping the sludge through external heat exchangers and back to the tank.

Analysis of Heat Requirements. In computing the energy required to heat the incoming sludge to the temperature of the digester, it is assumed that the specific heat of most sludges is essentially the same as that of water. The assumption that the specific heats of sludge and water are essentially the same has proved to be acceptable for engineering computations. The heat loss through the digester sides, top, and bottom is computed using the following expression:

$$q = UA\Delta T \tag{13–17}$$

where q = heat loss, J/s (Btu/h)
U = overall coefficient of heat transfer, J/m^2·s·°C (Btu/ft^2·h·°F)
A = cross-sectional area through which the heat loss is occurring, m^2 (ft^2)
ΔT = temperature drop across the surface in question, °C (°F)

In computing the heat losses from a digester using Eq. (13–17), it is common practice to consider the characteristics of the various heat transfer surfaces separately and to develop transfer coefficients for each one. The application of Eq. (13–17) in the computation of digester heating requirements is illustrated in Example 13–7.

Heat-Transfer Coefficients. Typical overall heat-transfer coefficients are reported in Table 13–35. As shown, separate entries are included for the walls, bottom, and top of the digester. Digestion tank walls may be surrounded by earth embankments that serve as

Table 13–35

Typical values for the overall coefficients of heat transfer for computing digester heat losses[a]

Item	U.S. customary, Btu/ft²·°F·h	SI units, W/m²·°C
Plain concrete walls (above ground)		
300 mm (12 in.) thick, not insulated	0.83–0.90	4.7–5.1
300 mm (12 in.) thick with air space plus brick facing	0.32–0.42	1.8–2.4
300 mm (12 in.) thick wall with insulation	0.11–0.14	0.6–0.8
Plain concrete walls (below ground)		
Surrounded by dry earth	0.10–0.12	0.57–0.68
Surrounded by moist earth	0.19–0.25	1.1–1.4
Plain concrete floors		
300 mm (12 in.) thick in contact with moist earth	0.5	2.85
300 mm (12 in.) thick in contact with dry earth	0.3	1.7
Floating covers		
With 35 mm (1.5 in.) wood deck, built–up roofing, and no insulation	0.32–0.35	1.8–2.0
With 25 mm (1 in.) insulating board installed under roofing	0.16–0.18	0.9–1.0
Fixed concrete covers		
100 mm (4 in.) thick and covered with built–up roofing, not insulated	0.70–0.88	4.0–5.0
100 mm (4 in.) thick and covered, but insulated with 25 mm (1 in.) insulating board	0.21–0.28	1.2–1.6
225 mm (9 in.) thick, not insulated	0.53–0.63	3.0–3.6
Fixed steel covers 6 mm (0.25 in.) thick	0.70–0.95	4.0–5.4

[a] Adapted in part from U.S. EPA (1979).

insulation, or they may be of compound construction consisting of approximately 300 mm (12 in.) of concrete, insulation, or an insulating air space, plus brick facing or corrugated aluminum facing over rigid insulation. The heat transfer from plain concrete walls below ground level and from floors depends on whether they are below the groundwater level. If the groundwater level is not known, it may be assumed that the sides of the tank are surrounded by dry earth and that the bottom is saturated earth. Because the heat losses from the tank warm up the adjacent earth, it is assumed that the earth forms an insulating blanket 1.5 to 3 m (5 to 10 ft) thick before stable ambient earth temperatures are reached. In northern climates, frost may penetrate to a depth of 1.2 m (4 ft). Therefore, the ground temperature can be assumed to be 0°C (32°F) at this depth and to vary uniformly above this depth to the design air temperatures at the surface. Below the frost depth, normal winter ground temperatures can be assumed, which are 5 to 10°C (10 to 20°F) higher at the base of the wall. Alternatively, an average temperature may be assumed for the entire wall below grade.

The loss of heat through the roof depends on the type of construction, the absence or presence of insulation and its thickness, the presence of air space (as with floating covers between the skin plate and the roofing), and whether the underside of the roof is in contact with sludge liquor or gas.

Radiation from roofs and aboveground walls also contributes to heat losses. At the temperatures involved, the effect is small and is included in the coefficients normally used, such as those given in the foregoing discussion. For the theory of radiant-heat transmission, the reader is referred to McAdams (1954). Heat requirements for a digester are determined in Example 13–7.

When external heaters are installed, the sludge is pumped at high velocity through the tubes while water circulates at high velocity around the outside of the tubes. The circulation promotes high turbulence on both sides of the heat transfer surface and results in higher heat transfer coefficients and better heat transfer. Another advantage of external heaters is that untreated cold sludge on its way into the digesters can be warmed, intimately blended, and seeded with sludge liquor before entering the tank. Heat exchangers require cleaning periodically to maintain heat transfer efficiency.

Digestion tanks have also been heated using internal heating systems. Some arrangements have included pipes mounted to the interior face of the digester wall and mixing tubes equipped with hot-water jackets. Because of inherent operating and maintenance problems with this type of heating system, internal heating is not recommended. Reported problems include caking of sludge on the heating surface and the inability to inspect or service the equipment unless the tank is dewatered (WEF, 1987).

EXAMPLE 13–7 **Estimation of Digester Heating Requirements** A digester with a capacity of 90,700 wet kg/d (200,000 lb/d) of thickened sludge is to be treated by circulation of sludge through an external hot water heat exchanger. Assuming that the following conditions apply, find the heat required to maintain the required digester temperature. If all heat were shut off for 24 h, what would be the average drop in temperature of the tank contents?

1. Concrete digester dimensions:
   Diameter = 20 m
   Side depth = 7 m
   Middepth = 10 m
2. Heat-transfer coefficients:
   Dry earth embanked for entire depth, $U = 0.68\ \text{W/m}^2\cdot{}^\circ\text{C}$
   Floor of digester in moist earth, $U = 2.85\ \text{W/m}^2\cdot{}^\circ\text{C}$
   Fixed Concrete Insulated Roof exposed to air, $U = 1.5\ \text{W/m}^2\cdot{}^\circ\text{C}$
3. Temperatures:
   Air = −5°C
   Earth next to wall = 0°C
   Incoming sludge = 10°C
   Earth below floor = 5°C
   Sludge contents in digester = 35°C
4. Specific heat of sludge 4200 J/kg·°C

Solution

1. Compute the heat requirement for the sludge.

$$q = (90{,}700\ \text{kg/d})[(35 - 10)^\circ\text{C}](4200\ \text{J/kg}\cdot{}^\circ\text{C})$$

$$= 95.2 \times 10^8\ \text{J/d}$$

2. Compute the area of the walls, roof, and floor.

   Wall area $= \pi(20)\,(7) = 439.6\ \text{m}^2$

   Floor area $= \pi(10)\,[10^2 + (10 - 7)^2]^{1/2} = 327.8\ \text{m}^2$

   Roof area $= \pi(10^2) = 314\ \text{m}^2$

3. Compute the heat loss by conduction using Eq. (13–17).

   $q = UA\Delta T$

   a. Walls:

   $$q = 0.68\ \text{W/m}^2\cdot{}^\circ\text{C}\ (439.6\ \text{m}^2)(35 - 0^\circ\text{C})(86{,}400\ \text{s/d}) = 9.0 \times 10^8\ \text{J/d}$$

   b. Floor:

   $$q = 0.85\ \text{W/m}^2\cdot{}^\circ\text{C}\ (268.2\ \text{m}^2)(32 - 5^\circ\text{C})(86{,}400\ \text{s/d}) = 5.32 \times 10^8\ \text{J/d}$$

   $$q = 2.85\ \text{W/m}^2\cdot{}^\circ\text{C}\ (327.8\ \text{m}^2)(35 - 5^\circ\text{C})(86{,}400\ \text{s/d}) = 24.2 \times 10^8\ \text{J/d}$$

   c. Roof:

   $$q = 1.5\ \text{W/m}^2\cdot{}^\circ\text{C}\ (314\ \text{m}^2)[35 - (-5^\circ\text{C})](86{,}400\ \text{s/d}) = 16.2 \times 10^8\ \text{J/d}$$

   d. Total losses:

   $$q_t = (9.0 + 24.2 + 16.2) \times 10^8\ \text{J/d} = 49.4 \times 10^8\ \text{J/d}$$

4. Compute the required heat-exchanger capacity.

   Capacity = heat required for sludge and heat required for digester

   $$= (95.2 + 49.4) \times 10^8\ \text{J/d} = 144.6 \times 10^8\ \text{J/d}$$

5. Determine the effect of heat shutoff.

   a. Digester volume $= \pi\left(\frac{D^2}{4}\right)h_s + \pi\left(\frac{D^2}{12}\right)h_c$

   $$= \pi\left(\frac{20^2}{4}\right)(7) + \pi\left(\frac{20^2}{12}\right)(10 - 7) = 2198 + 314$$

   $$= 2512\ \text{m}^3$$

   b. Weight of sludge $= (2512\ \text{m}^3)(10^3\ \text{kg/m}^3)$

   $$= 2.51 \times 10^6\ \text{kg}$$

   c. Drop in temperature $= \dfrac{(144.6 \times 10^8\ \text{J/d})(1\text{d})}{(2.51 \times 10^6\ \text{kg})(4200\ \text{J/kg}\cdot{}^\circ\text{C})} = 1.37^\circ\text{C/d}$

Heating Equipment. The contents of the digester can be heated by tube-in-tube, spiral-plate, or water-bath external heat exchangers. The tube-in-tube and spiral-heat exchangers are similar in design. A tube-in-tube exchanger consists of two concentric pipes, one containing the circulating sludge and the other containing hot water. Flow through the pipes is countercurrent. Spiral-plate heat exchangers [see Fig. 13–28(a) and (b)] are composed of two long strips of plate that are wrapped to form a pair of

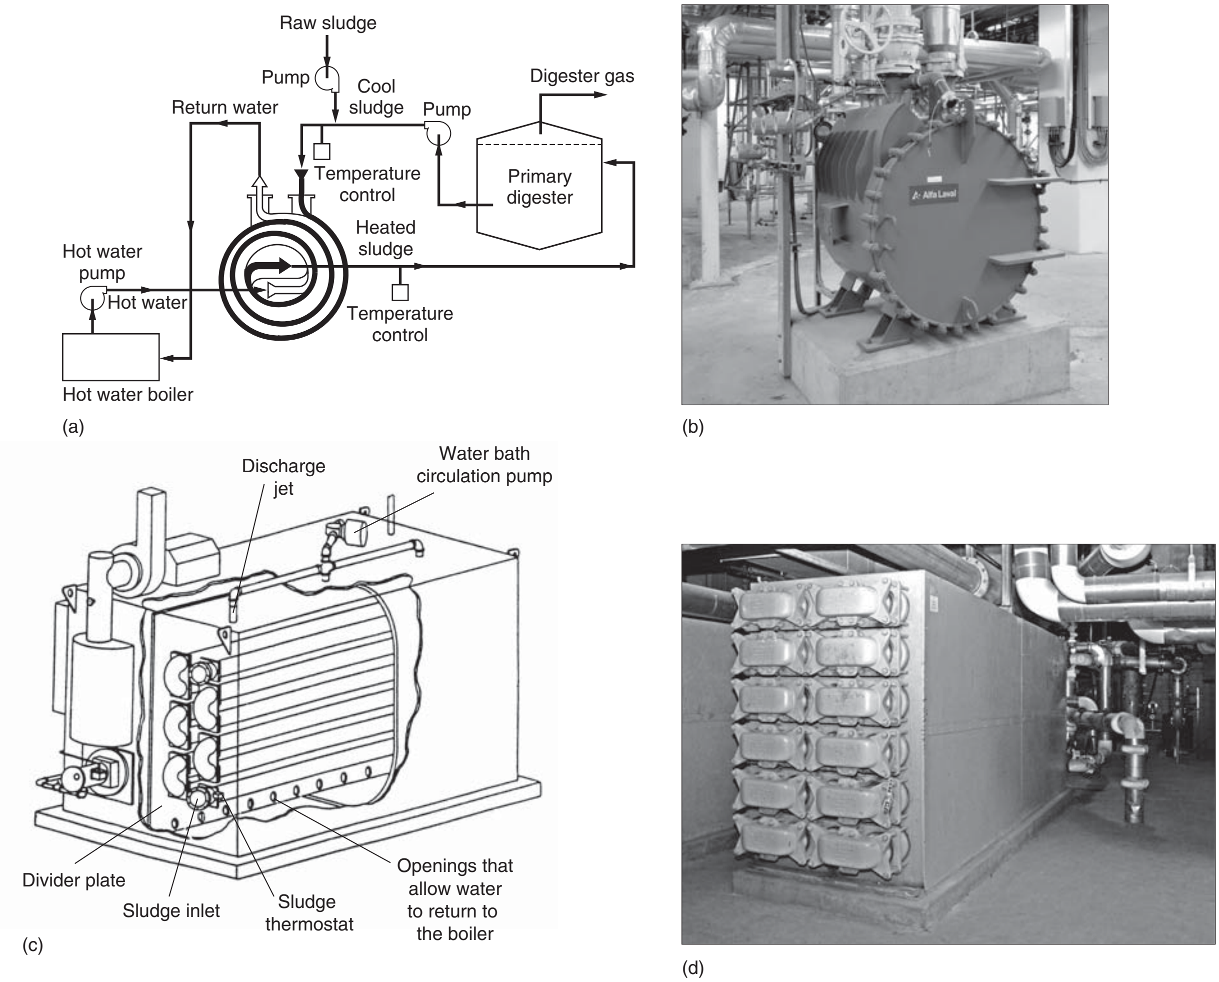


Figure 13–28

Heat exchangers used for heating digesting sludge: (a) schematic diagram of a spiral type, (b) view of a spiral type and (c) schematic of a water bath type heat exchanger, and (d) view of a water bath type heat exchanger.

concentric passages. The flow regime is also countercurrent. Water temperatures are kept generally below 68°C (154°F) to prevent caking of the sludge. Heat-transfer coefficients for external heat exchangers range from 0.9 to 1.6 $W/m^2 \cdot °C$ (WEF 2010a).

Operation of a water-bath heat exchanger involves circulation of the sludge through a heated water bath [see Fig. 13–28(c) and (d)]. The heat transfer rate is increased by pumping hot water in and out of the bath. Recirculation pumps allow the sludge feed to be heated before introduction to the digester.

Boilers and cogeneration systems are used typically to supply heat to the circulating water in the heat exchangers. Boilers can be fueled by digester gas; however, natural gas or fuel oil may be used as auxiliary fuel for times when sufficient digester gas is not available, such as for digester startup. If a cogeneration system is provided that uses digester gas to fuel an internal-combustion engine for generating electricity or powering pumps or blowers, heat from the engine jacket water can be used in the heat exchanger.

Options for staged anaerobic digestion: (a) staged mesophilic digestion, (b) temperature phased thermophilic-mesophilic digestion, (c) temperature phased mesophilic-thermophilic digestion, (d) acid/gas phased digestion with mesophilic acid-phase, (e) acid/gas phased digestion with thermophilic acid phase, and (f) staged thermophilic digestion. (Adapted from Schafer and Farrellm 2000 and Moen, 2000.)

Advanced Anaerobic Digestion

Advanced anaerobic digestion processes were developed to increase the volatile solids reduction during anaerobic digestion and/or produce high quality Class A biosolids for beneficial use of the generated biosolids. Among the advanced anaerobic digestion processes are the thermophilic digestion, staged thermophilic digestion, staged mesophilic digestion, acid/gas phase digestion and temperature phased digestion. These digestion options are shown on Fig. 13–29 and are discussed below. Typical SRTs are also noted on Fig. 13–29.

Thermophilic Anaerobic Digestion. Thermophilic digestion occurs at temperatures between 50 and 57°C (120 and 135°F), conditions suitable for thermophilic bacteria. Because biochemical reaction rates increase with temperature, doubling with every 10°C (18°F) rise in temperature until a limiting temperature is reached, thermophilic digestion is much faster than mesophilic digestion. Advantages and disadvantages of thermophilic digestion when compared to mesophilic digestion are provided in Table 13–36. Single-stage thermophilic digesters have been used only in limited applications; for municipal sludge treatment, they have been mainly used as the first stage of a temperature-phased anaerobic digestion process (Moen, 2000).

Although there may be greater reductions in pathogens in thermophilic digestion than in mesophilic digestion, U.S. federal regulations controlling land application of biosolids do not classify thermophilic digestion as a process to further reduce pathogens (PFRP). Both mesophilic and thermophilic digestion are classified as processes to significantly

Table 13–36

Advantages and disadvantages of thermophilic anaerobic digestion as compared to. mesophilic anaerobic digestion

Advantages	Disadvantages
1. Improved pathogen destruction, Class A sludge production is possible[a]	1. If not batch treatment process will require EPA certification for Class A PFRP
2. Reaction rate is increased which can reduce volume requirements (capital savings)	2. Increased thermal energy requirements[b]
3. May improve overall VSR and increase digester gas production	3. Biosolids may not dewater as well[c]
4. Components and design are essentially the same as conventional mesophilic digesters	4. Higher odor potential in dewatered cake[c]
	5. Increased ammonia concentration in dewatering sidestream
	6. Process may not be as stable
	7. More complex system due to heat recovery requirements
	8. May be more susceptible to foaming

[a] To meet Class A with thermophilic digestion, the process must incorporate batch thermophilic tanks that can meet the time/temperature requirements under Alternative 1. Otherwise, the process will require site specific testing under Alternative 3.

[b] Many plants incorporate a heat recovery loop where thermophilic sludge is cooled and the energy is utilized to preheat the raw sludge. Incorporating the heat recovery loop reduces thermal energy requirements but increases the cost and complexity of the digestion system.

[C] To improve dewatering and reduce odor potential many plants incorporate a mesophilic digestion stage prior to dewatering.

reduce pathogens (PSRP). Therefore, single-stage thermophilic digestion has significant limitations, as cited above.

Staged Thermophilic Digestion. A staged thermophilic digestion process [see Fig. 13–29(f)] uses a large reactor followed by one or more smaller reactors to reduce pathogen short circuiting and achieve a Class A sludge. At the Annacis Island Wastewater Treatment Plant in Vancouver, BC, the first stage is followed by three subsequent stages. Volatile solids reductions for the digestion system are reported to be on the order of 63 percent (Schafer and Farrell, 2000b).

Staged Mesophilic Digestion. Although digestion performed in two tanks coupled in series has been done in the past, little information is available about the operation of two-stage heated and mixed high-rate digesters. Researchers Torpey and Garber found that there were few benefits in volatile solids reduction and gas production in two series tanks as compared to a single-stage high-rate process (Torpey and Melbinger, 1967; Garber, 1982). More recent testing indicates that two-stage mesophilic digestion may produce more stable, less odorous biosolids that are easier to dewater (Schafer and Farrell, 2000a). Staged mesophilic digestion is shown on Fig. 13–29(a).

Acid/Gas Phased Digestion. In the acid/gas (AG) digestion process, anaerobic digestion proceeds through the three distinct phases of digestion described earlier—hydrolysis, fermentation (acidogenesis), and methanogenesis—but the process is divided into two separate steps. In the first stage, known as the acid phase digester, solubilization of particulate matter occurs (hydrolysis), and volatile acids are formed (acidogenesis). The first stage is conducted at a pH of 6 or less and at a short SRT conducive to the production of high concentrations of volatile acids (> 6000 mg/L). The second stage, known as the gas phase, is conducted at a neutral pH and a longer SRT to suit the environmental conditions for the methane-generating bacteria and maximize gas production. Advantages of this method of digestion are (1) greater volatile solids reduction can be achieved, (2) digester foaming can be controlled, and (3) either stage can be operated at mesophilic or thermophilic temperatures [see Figs. 13–29(d) and (e)]. More than 30 full-scale plants using the AG process are in operation at the time of writing of this text (2012) (Wilson et al., 2008). Total volatile solids reductions range from 50 to 60 percent. Most acid/gas systems produce Class B biosolids and operate in the mesophilic range for both phases and termed AGMM. However, at the Belmont Wastewater Plant in Indianapolis, IN, where a thermophilic acid phase and mesophilic gas phase system was pilot tested, it was found that the process was effective in meeting Class A requirements for pathogen reduction (Schafer and Farrell, 2000a).

The design of an AG digestion system requires control of the organic loading to the acid phase to prevent the formation of methanogens. Control is provided through control of the detention time. Ideal detention time is between 1 to 2 d. Due to the low SRT, volatile solids leading rates for the acid phase digestion are an order of magnitude greater than conventional digestion and range from 24 to 40 kg VS/m^3·d (1.5 to 2.5 lb/d·ft^3) (WEF, 2012). The methane phase can then be a little as 10 d. Regulatory approval of this short a detention time maybe required to retain Class B digested sludge quality. The original concept for this process recommended a plug flow acid phase reactor. Current designs have used a tall cylindrical tank with level control to enable good mixing while maintaining the high organic loading. There will be very little gas produced in this process and the gas will contain little, if any, methane. This gas may be burned separately or combined with the methane phase digester gas, but is often wasted and not otherwise used. Counterintuitive to typical biological processes, operation requires increasing the loading (by decreasing the detention time) when the process begins to become less acidic and/or methane begins to be produced.

Temperature-Phased Digestion. Temperature-phased anaerobic digestion (TPAD), shown on Figs. 13–29(b) and (c), was developed in Germany and is an approach that incorporates the advantages of thermophilic digestion and mitigates the disadvantages through the addition of a mesophilic phase that enhances stabilization. The design of the temperature-phased process utilizes the advantage of the greater thermophilic digestion rate, which generally is four times faster than mesophilic digestion. The TPAD process has shown the capability for absorbing shock loadings better, as compared to single-stage mesophilic or thermophilic digestion. The process can operate in either of two modes, thermophilic-mesophilic or mesophilic-thermophilic. In the thermophilic-mesophilic mode, shown on Fig. 13–29(b), the thermophilic phase is designed to operate at 55°C (130°F) with a 3 to 5 d detention time. The mesophilic phase is designed to operate at 35°C (95°F) with a 10 d or greater detention. The total average detention time of 15 d compares to the typical 10 to 20 d range of the single-stage high-rate mesophilic digestion process. The volatile suspended solids (VSS) destruction efficiencies of the TPAD process are on the order of 15 to 25 percent greater than single-stage mesophilic digestion (Schafer and Farrell, 2000b).

Through greater hydrolysis and biological activity in the thermophilic phase, the system tends to have greater VSS destruction and gas production. Foaming is also reduced. The mesophilic phase provides additional VSS destruction and conditions the sludge for further processing. The main advantages of the mesophilic phase are (1) the destruction of odorous compounds (mostly fatty acids) that are common to the thermophilic digestion process and (2) the improved stability of the digestion operation. The process is also reported to be capable of meeting Class A sludge requirements (WEF, 2010a).

A second temperature-phased digestion process shown on Fig. 13–29(c) has a mesophilic stage that precedes the thermophilic stage. Limited results from full-scale and pilot testing show that the volatile solids reduction is greater than that from single-stage mesophilic digestion (Schafer and Farrell, 2000b). Design considerations for the temperature-phased anaerobic digestion process include selection of the heating and mixing systems to ensure proper temperature control of each stage, sizing of the gas-handling equipment to meet the greater gas production rates, and control of the pumping systems for digester feed and heating (WEF, 2010a).

Sludge Pretreatment for Anaerobic Digestion

Pretreatment of sludge prior to anaerobic digestion is used to increase the solids loading, increase the volatile solids reduction, increase biogas production and in some cases produce Class A biosolids. Sludge pretreatment results in increased hydrolysis through the application of some form of energy to the sludge. The form of pretreatment can be chemical, physical, electrical, or thermal. This section discusses two main categories of pretreatment: thermal hydrolysis and physical-chemical and electrical pretreatment.

Thermal Hydrolysis Pretreatment. Thermal hydrolysis (TH) is a thermal conditioning process that operates at lower temperatures in the range 150–200°C and functions as a pretreatment step before anaerobic digestion. The cited benefits of the process include (1) break down of longer organic polymer chains to shorter chain organic matter to increase digestion and gas production, (2) production of Class A product under the time and temperature stipulations of the EPA Part 503 biosolids rule, (3) enhancement of digested biosolids dewatering characteristics achieving in many cases greater than 30 percent cake solids with mechanical dewatering, (4) produce good quality product in terms of odor and texture, and (5) significant reduction of digestion volume through reducing treated sludge viscosity allowing higher solids concentrations to be pumped and mixed during digestion.

At present (ca. 2013), two commercially available TH processes are available; one is called Cambi™ and is provided by Cambi AS, Norway; the other is called Exelys™ and is provided by Veolia Water Systems, France. The two systems operate under the same treatment parameters; however, the first system is batch based, and the second system is a plug flow design that is a modification of Veolia's batch TH process (Biothelys™). The Cambi™ system is the most widely used system for thermal hydrolysis and is considered fully developed system; however, comparison with other systems may be warranted (Abu-Orf and Goss, 2012). The focus of the information in this section is mainly on the batch TH system as provided by Cambi™.

Description of the TH Batch System as Provided by Cambi™. The Batch TH process is a well established process outside North America with more than two dozen installations (2012) processing sludge from 3.3 to 250 dry tonne/d (3.6 DT/d to 275 DT/d). The process is gaining interest in North America with the first installation expected at Blue Plains Advanced Wastewater Treatment Plant in 2014. The process appears to be cost effective and meets the future needs of Blue Plains (Abu-Orf et al., 2009). As illustrated on Fig. 13–30, the thermal hydrolysis step consists of three basic units: the pulper, the reactor and the flash tank that defines a process train. In reality there is more to the process train than those three units. The sludge needs to pass through some type of screening process ahead of the TH to remove damaging materials from the sludge stream. Furthermore, the sludge must be pre-dewatered to slightly higher than 16 percent total solids. The dewatered sludge is then transferred to a silo or bin that is large enough to provide equalization,

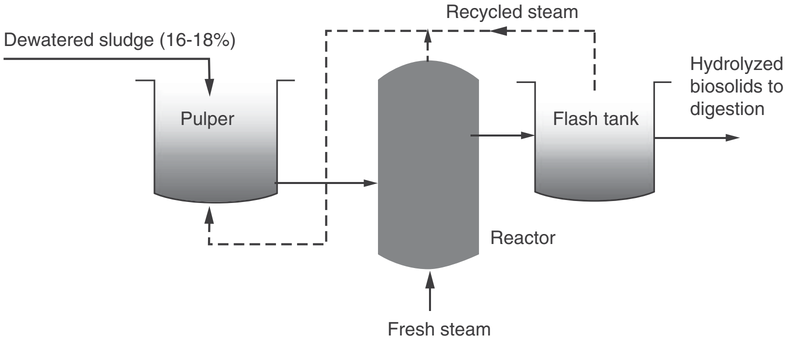

Figure 13–30

Main components of batch thermal hydrolysis system.

allowing the TH process to operate at a uniform flowrate. The sludge can then be transferred to the pulper tank via augers in the bottom of the storage bin and pumps. The concentration of solids to the pulper is diluted to a concentration between 14.5 and 16.5 percent TS using dilution water (typically plant effluent). The sludge is mixed in the pulper and preheated using steam that is recycled back from the flash tank. The preheated sludge is pumped to the reactor vessel where it will be heated using fresh stream to about 165°C (329°F) and a pressure of approximately 8–9 bar (120–130 $\text{lb}_f/\text{in.}^2$) gauge After the appropriate hydrolyzing time, the sludge is transferred from the reactor to the flash tank. The flash tank receives treated sludge with a solids concentration about 3 points less due to the steam injection and dilution.

The treated sludge temperature at this point is too hot to feed a mesophilic digester and requires cooling and dilution if needed. Again, the water used for dilution is required to lower the concentration of the treated sludge to between 8 and 12 percent for feeding into the digester. The temperature must also be reduced to about 42–44°C by heat transfer. The sludge at 8 to 12 percent TS is then transferred to the digestion facility. Finally, the digested biosolids are transferred to final dewatering before being distributed for beneficial reuse. The final product has very good stacking properties and is low in odor, making it very suitable for soil blending and for land application. In addition to the process train, there must be a source of fresh steam for heating the reactors, so there will be at least a boiler as part of the train. Usually, the biogas generated from the digestion process is processed via a combined heat and power (CHP) facility for producing electricity and a majority of the necessary steam for the TH process. The amount of waste heat from the CHP system typically provides 75–95 percent of the total steam energy requirements so a supplemental standby boiler that operates on digester gas or an auxiliary fuel source is required.

Reactor Operation Scheme. The TH reactors operate in a batch mode with a typical volume of 12 m^3 (424 ft^3) and receive approximately 7.6 m^3 (268 ft^3) ($\sim$70 percent of total volume) of sludge in each batch. Once the sludge is transferred, approximately one tonne of fresh steam is injected per one dry tonne of sludge (from Cambi™ Specifications). After the reaction period elapses, the sludge is released to the flash tank. When the steam is released from the reactors, it passes to the pulper and preheats the incoming sludge. The pulper and the flash tanks are usually sized twice the size of one reactor. The batch steps for a typical 90 min cycle for each reactor are shown in Table 13–37. The theoretical amount of steam required can be estimated by the following equation:

$$\frac{M_{\text{steam}}}{M_s} = \frac{\left(C_{\text{PS}} + \dfrac{C_{\text{PW}}}{W_s} - C_{\text{PW}}\right)(T_H - T_{\text{raw}})}{H - C_{\text{PW}}(T_H - T_{\text{ref}})} \tag{13–18}$$

Table 13–37

Steps for 90 min batch cycle operation

Step	Action	Time, min	Description
1	Fill	15	Fill reactor with 7.6 m^3 of sludge
2	Steam injection	15	Inject steam in the Reactor
3	React	30	Hold reactor at 160°C and 620 kP (90 $lb/in.^2$)
4	Steam out	15	Release steam to pulper
5	Empty	15	Transfer sludge to flash tank by pressure release.

where

M_{steam} = mass of live steam fed to the process

C_{PS} = specific heat of dry sludge fraction, 1.5 kJ/kg°C (0.36 Btu/lb·°F)

C_{PW} = specific heat of water, 4.18 kJ/kg·°C (1 Btu/lb·°F)

T_H = temperature out of the thermal hydrolysis system. For Cambi™, this temperature corresponds to the temperature out of the flash tank which is approximately 105–110°C (220–230°F)

T_{raw} = raw sludge temperature, typically 10–25°C (50–77°F)

H = enthalpy of steam which is approximately 2785 kJ/kg (1200 Btu/lb) at 12 bar (175 $lb_f/in.^2$)

T_{ref} = reference temperature, typically 0°C (32°F)

For example, sludge at 10°C that is dewatered to 16 percent TS by weight would require the following amount of steam for the hydrolyzed sludge to reach a temperature of 110°C:

$$\frac{M_{\text{stream}}}{M_s} = \frac{\left[(1.5\ \text{kJ/kg}\cdot{}^\circ\text{C}) + \dfrac{(4.18\ \text{kJ/kg}\cdot{}^\circ\text{C})}{0.16} - (4.18\ \text{kJ/kg}\cdot{}^\circ\text{C})\right][(110 - 10)^\circ\text{C}]}{(2785\ \text{kJ/kg}) - (4.18\ \text{kJ/kg}\cdot{}^\circ\text{C})[(110 - 0)^\circ\text{C}]}$$

$$= 1.0\ \text{kg steam/kg sludge}$$

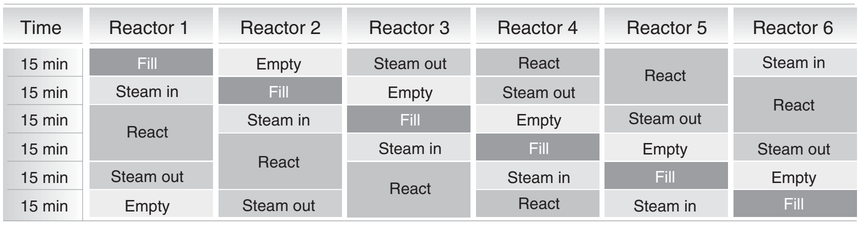
It should be noted that Eq. (13–18) is based on some simplifying assumptions such as no heat loss and that all flash steam is recovered and condensed successfully in the pulper. In reality some losses would be expected, and sizing for a design should be conducted carefully with the vendor.

Reactor System Sizing. The overall system sizing is based on a single reactor capacity. Usually it is assumed that sludge is delivered to the reactor at 14.7 percent. The reactor capacity is based on the cycle time and the concentration of the sludge in the reactor. For a standard 90 min cycle as described in Table 13–37 and 7.6 m^3/batch of sludge at a 14.7 percent solids concentration, the capacity of a single reactor is about 17.88 dry tonne/d (19.66 dry ton/d). Design size of the reactor is usually based on 95 percent reactor availability. The throughput capacity of train is dependent on the number of reactors within each train. Single reactor capacity can be increased by increasing the solids concentration (maximum would be 17 to 17.5 percent) or shortening the cycle time without compromising the reaction time that is necessary to achieve Class A biosolids according to Part 503 Regulations. In addition, Cambi™ is currently (2012) developing alternative reactor sizes allowing the system to be tailored to sizes at small to medium sized plants. An aerial view of a Cambi™ process installation in Davyhulme, Manchester UK, in which the thermal hydrolysis reactors are visible is shown on Fig. 13–31(a).

Figure 13–31

The Cambi™ process (a) Aerial view of installation in Davyhulme, Manchester, UK. The Cambi™ reactors are visible in the center of the photograph. The 8 × 7600 m^3 digesters, shown on the lower right, which originally processed 40,000 tonne/y of dry solids now process 92,000 tonne/y with the installation of the Cambi™ thermal hydrolysis pretreatment process (courtesy of Cambi™) and (b) schematic of the operation of a six reactor process, based on a 90 min cycle time.

(a)



Time	Reactor 1	Reactor 2	Reactor 3	Reactor 4	Reactor 5	Reactor 6
15 min	Fill	Empty	Steam out	React	React	Steam in
15 min	Steam in	Fill	Empty	Steam out		React
15 min	React	Steam in	Fill	Empty	Steam out	
15 min		React	Steam in	Fill	Empty	Steam out
15 min	Steam out		React	Steam in	Fill	Empty
15 min	Empty	Steam out		React	Steam in	Fill

(b)

Reactor Sequence Operation. The preferred smallest Cambi process train will have two reactors; otherwise it will be a batch operation. With two reactors the train works as a continuous operation. Based on solids residence of 90 min within each reactor, a sketch portraying the sequential status of a six reactor Cambi™ process, as selected by the Blue Plains Advanced Wastewater Treatment Plant, is shown on Fig. 13-31(b) (Abu-Orf et al., 2009). Process staggering allows continuous operation of all major mechanical equipment.

As shown on Fig. 13-31(b), one reactor would always be filling, one would always be receiving steam, one would always be releasing steam, and one would always be emptying treated sludge. Based on this operating sequence the sludge feed pumps and the steam plant would always be operating and that only valves would be opening and closing to direct the flow to and from the reactors.

Physical, Chemical, and Electrical Pretreatment. These pretreatment processes are generally applied to sludge produced from secondary treatment process as these sludges typically do not digest well anaerobically. Pretreatment of these sludges is accomplished through application of ultrasonic waves, mechanical shear, electrical pulse, pressure drop, or electrical field. The application of these different treatment methods has resulted in various degrees of success in enhance sludge digestion. For the application of the pretreatment process to be practically effective the amount of sludge entering the digester from secondary treatment must be more or at least same as the sludge produced from primary treatment.

A description of six sludge pretreatment technologies is presented in Table 13–38. Pretreatment technologies use pulse power, pressure drop combined with mechanical

Table 13–38

Description of commercially available physical, chemical and electrical technologies for pretreatment of secondary sludges prior to anaerobic digestion[a]

Technology/ manufacturer	Description	Advantages	Disadvantages
OpenCel/OpenCel, USA	Pulsed Power Technology, as offered by Open Cel®, exposes biological sludge to high voltage bursts between 20 and 100 microseconds to lyses cell membranes	Relatively low energy requirements Imparts usable heat to secondary sludge Low space requirements Low pressure operation	Relatively new Limited number of installations in North America Offered by only one manufacturer
Crown Disintegration/ Siemens, USA	Pretreatment is applied to only a portion of the secondary sludge, which includes grinding and mixing followed by pressurization. The high pressure drop causes cavitation of the sludge and rupturing of the cell membrane	Similar technology offered by other manufacturers Low space requirements Approximately 20 installations worldwide, all in Europe. Small footprint	Relatively high energy requirements. No operating facilities in North America. High pressure system 1200 kPa (175 $lb_f/in.^2$) with wear parts
Sludge Squeezer/ Huber, USA	Technology imparts a high pressure drop to a portion of the secondary sludge in a two stage process. In the first stage the sludge flocs are mechanically ruptured. In the second stage the flocs are mixed into the sewage sludge via a hydrodynamic flow field and homogenized	Similar technology offered by other manufacturers Low space requirements Approximately 3 installations, all in Europe	Relatively high energy requirements No operating facilities in North America High pressure system 1200 kPa (175 $lb_f/in.^2$) with wear parts
MicroSludge/ MicroSludge, Canada	A portion of the secondary sludge is pretreated with lime to soften cell membrane, then undergoes grinding and mixing followed by pressurization up to 1200 kPa (175 $lb_f/in.^2$). When the pressure is released, the biological cells are exposed to high shear forces which is hypothesized to rupture the cell membranes. The process includes course and fine screens for the thickened sludge and conditioned sludge, respectively, as well as a gas liquid separator to release ammonia gas formed at high pH	Small footprint Reduction in dewatering cost (polymer and electrical) Benefit for digester heating from 45°F rise of processed sludge Reduced digester mixing energy due to reduced viscosity and volume	Relatively high energy requirements. Requires lime addition High pressure system 1200 kPa (175 $lb_f/in.^2$) with wear parts. No operating facilities in North America
Sonolyzer/ Ovivo, USA	Based on ultrasonic treatment of secondary sludges, which consists of applying high frequency sound waves to the sludge matrix, causing cavitation and disintegration of the cell membranes	Intensively studied over the last 15 y. >25 installations worldwide	Relatively high energy requirements. Only one manufacturer currently in the North America
Electrokinetic Disintegration/ Sud-Chemie AG, Germany	The sludge is run through a series of pipes containing an internal electrical high voltage field and as it moves, the cellular structure is weakened and cracked which allows the bacteria to more effectively digest the sludge	Optimizes digestion Increase gas production Increase settling of sludge Several installations in Europe	High energy requirement Operation with high voltage

[a] The information in this table is current ca. 2013.

Table 13–39

Factors favoring direct co-digestion of organic feedstocks (WEF, 2010b)[a]

Category	Description
Technical	• Remove nuisance wastes from the collection system, especially if a waste is causing stoppage, odor or damage. • Remove organic loadings and nuisance factors from headworks and liquid treatment train. • Increase use of existing digester capacity, especially with co-digestion of wastes that are synergistic with wastewater sludge in terms of increasing the volatile solids loading rate. • Improve knowledge of how to handle organic wastes. • Provide a reliable outlet for organic wastes.
Economical	• Develop a new revenue stream from tipping fees for organic wastes. • Produce more biogas for combined heat and power systems, or thermal dryer systems, or other beneficial uses. • Reduce cost of operation, maintenance, and odor control in the liquid treatment train, from headworks to final clarifiers. • Avoid or defer construction of additional liquid train treatment capacity. • Increase the throughput rate of the sludge processing train.
Environmental	• Earn carbon credits, where applicable. • Reduce land application of organic wastes that contribute to methane production rather than carbon sequestration. • Reduce emission of greenhouse gases, particularly methane, coincidental to increasing energy recovery from waste materials.

[a] Adapted from WEF (2010b).

disintegration or chemical treatment, ultrasonic waves, and electrokinetic disintegration. These technologies have different advantages and disadvantages (see Table 13–38). One important observation is that these pretreatment technologies are used more widely in Europe than in North America. The main reason for the increased usage of pretreatment options is that treatment facilities in Europe benefit greatly from the small to moderate increase in biogas production from applying these technologies through green energy credit and other incentives for generating additional green energy from biosolids.

Co-digestion with Other Organic Waste Material

Anaerobic digestion has been applied traditionally as a single substrate, single purpose treatment process and is commonly used in municipal, industrial and agricultural treatment facilities. Most municipal wastewater treatment plants have reported an excess digestion capacity of 15 to 30 percent (Hansen, 2006). These facilities may be able to process with their existing digester capacity a wide range of organic material with municipal sludge and increase their biogas production. The process of digesting more than one substrate is called co-digestion. The technical, economical, and environmental drivers for co-digesting organic wastes with municipal sludge are outlined in Table 13–39 (adapted from WEF, 2010b).

Co-digestion or "co-fermentation" is the simultaneous digestion of a mixture of two or more organic substrates, usually a primary substrate such as wastewater sludge together with lesser amounts of one or more secondary substrate, such as organic municipal solid waste (MSW), source separated organic waste, flotation scum layers, glycerin, and brown

Table 13–40

Biogas unit production and methane content[a]

Feedstock type	Gas yield per unit solids destroyed, m^3/kg	Methane content
Fat	1.2–1.6	62–72

grease collected from grease traps. Yellow grease, having other commercial uses, is considered too valuable to be used as a feedstock for co-digestion. When blending organic substrates, the possible outcomes can be synergistic, antagonistic, or neutral based upon methane production that is greater than, less than, or the same as that observed when each material is digested alone. The successful co-digestion of any organic feedstock requires careful management (Zitomer et al., 2008).

Anaerobic digestion process appears to become more stable when a variety of substrates are co-digested causing improved digester performance (Braun and Wellinger, 2003; Schafer and Lekven, 2008; STOWA, 2006). The addition of certain organic substrate to the anaerobic digestion system can stimulate biological activity and improve digestion performance in terms of biogas production as illustrated on Fig. 13–32.

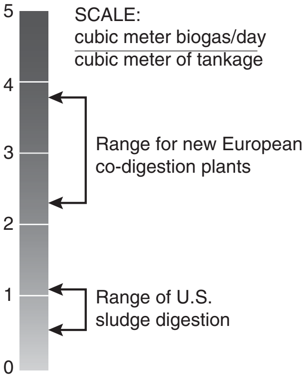

Figure 13–32

Gas production efficiency comparison. (Adapted from Schafer and Lekven, 2008.)

Co-digestion of Liquid, High Strength Organic Wastes. Co-digestion of fats, oils, and grease (FOG) is the most common among high strength liquid organic wastes due to its observed high biogas yield. Other liquid organic wastes are suitable for co-digestion including whey from cheese production or residual glycerin from biodiesel production. Biogas production and methane content from the degradation of some organic wastes are presented in Table 13–40. Detailed waste characterization data for selected high-energy organic feedstocks for co-digestion is presented in Table 13–41.

FOG is mostly referred to as material that is collected in interceptors or grease traps of restaurants and cafeterias. Separately collected unprocessed FOG generally has a high residual water content. Brown grease (often also referred to as trap grease) is obtained after the residual water content of the collected FOG is removed. In general, unprocessed FOG is comprised of a brown grease content of around 10 percent by volume; the remaining 90 percent is water (NREL, 2008).

Table 13–41

Characteristics of selected high-energy organic feedstocks[a]

Component	Unit	Restaurant interceptor grease	Biodiesel glycerin	Polymer dewatered FOG	Lime dewatered FOG
Total solids	% solids	1.8–21.9	14.7	42.4	49.1
Volatile solids	% solids	1.2–21.6	14.0	40.9	37.4
Volatile solids/total solids	%	88.9–98.6	95.2	96.5	76.5

Figure 13–33

City of San Francisco waste water treatment plant FOG receiving station.

Considerations for FOG Co-digestion. WWTPs that co-digest pretreated FOG and other high strength (liquid) organic wastes had to make modifications to their existing facilities design to accommodate delivery, storage, dosing, and mixing of the delivered material (WEF, 2010b). The actual co-digestion program and its process design may vary from plant to plant. While some facilities feed the pretreated FOG directly into the digester, most co-digestion programs use one or more separate holding tanks for treated FOG storage. In this case the received FOG (see Fig. 13–33) may be stored temporarily and added to the digester through combining with the influent sludge or combined with the digested sludge through existing heat exchange recycling system.

Additional components of the pretreatment train may include a rock trap or screen for contaminate removal, chopper pump for tank mixing, tank air ventilation, or activated carbon for odor control. Some co-digestion programs may also be designed to receive only substrate that has already been pretreated off-site. A dosing pump automatically and steadily feeds the FOG into the anaerobic digester. The treated FOG addition should be increased gradually to minimize lag effects and increase process stability. The gradual increase in FOG addition should also prevent any sudden surge in gas production that may result in solids flotation or digester stratification (WEF, 2010b).

Once the biomass in the digester has been acclimated to the FOG addition, an increase in both overall biogas production as well as methane content has been reported. For a successful FOG co-digestion program and plant operation, adequate injection, effective digester heating and mixing (to avoid dead zones) were found to be important process factors. To take full advantage of the anticipated increase in digester gas production extra co-generation capacity for power and heat production may be required.

Co-digestion of Organic Solid Wastes. Anaerobic digestion technologies were commercially developed for source-separated organic waste (SSO) and the organic fraction of MSW (OFMSW) in Europe around 1990 and are now in use worldwide. As the technologies for the treatment of SSO and OFMSW become more developed, the number of plants that co-digest these material will increase. SSO and OFMSW have been found suitable for co-digestion with municipal solids with promising gas yields. The amount of biogas that can be produced from co-digesting SSO and other organic substrates can be found in Braun and Wellinger (2003).

East Bay Municipal Utility District (EBMUD) in California is leading the effort on co-digestion of organic solid wastes. Funded in part through an U.S. EPA Region 9 grant, bench-scale studies were conducted to determine biodegradability, methane gas production,

Table 13–42

Inputs and outputs of the Co-digestion Economic Analysis Tool (CoEAT) of EPA

Inputs (including financial data)	Outputs
1. Feedstock type and generation	1. Fixed and recurring costs
2. Collection and Transportation	2. Savings from solids waste diversion
3. Processing	3. Capital investment
4. Digestion infrastructure	4. Biogas production and energy values
5. Disposal of biosolids	5. Methane reduction from landfills

and the required minimum mean residence time when feeding pulped SSO to the digesters. The results show that three to three and a half times more methane was produced from co-digestion when compared to digesting only sludge for a given digester volume. The EBMUD has developed and patented its in-house food-waste recycling process that has been operating since early 2000 and is accepting approximately 36 tonne/d (79,400 lb/d) of pretreated (crushed and screened) food scraps for co-digestion (Peck, 2008; Gray et al., 2008a; Gray et al., 2008b).

Cost-Effectiveness of Co-digestion. Cost effectiveness of co-digestion of organic wastes depends on many factors. The important factors for cost consideration include waste type, location and distance from plant, tipping fee, required on-site pretreatment, digestion capacity, method of beneficial use of the generated biogas, and electricity prices. Region 9 of the U.S. EPA developed a co-digestion economic analysis tool (CoEAT) based on the extensive research and experience of EBMUD. The CoEAT is designed for use by decision makers and is considered the initial step in assessing the economic feasibility of food waste co-digestion at wastewater treatment plants for the purpose of biogas production. The input and output information for the CoEAT program is presented in Table 13–42. The types of organic wastes considered includes residential food waste, commercial food waste, FOG, food processing waste (fruit, vegetables, breads, rendering byproducts), dairy waste—milk solids, and agricultural waste (fruit and vegetable trimmings).

13–10 AEROBIC DIGESTION

Aerobic digestion may be used to treat (1) waste activated sludge only, (2) mixtures of waste activated sludge or trickling-filter sludge and primary sludge, or (3) waste sludge from extended aeration plants. Aerobic digestion has been used primarily in plants of a size less than 0.2 m^3/s (5 Mgal/d), but in recent years the process has been employed in larger wastewater treatment plants with capacities up to 2 m^3/s (50 Mgal/d) (WEF, 2010a). In cases where separate sludge digestion is considered, aerobic digestion of biological sludge may be an attractive application. Advantages and disadvantages of conventional aerobic digestion as compared to anaerobic digestion are provided in Table 13–43.

As discussed in Sec. 13–2 and Table 13–12, aerobic digestion is one of the processes defined to meet PSRP requirements for Class B biosolids. To meet Class B requirements for pathogen reduction, the regulations state the solids retention times must be at least 40 d at 20°C and 60 d at 15°C. In many instances, plants that have facilities designed for SRTs less than 40 d and wish to meet the Class B requirements for pathogen reduction have had to add additional storage capacity or thickeners. If the design engineer uses aerobic digestion for stabilization and does not meet the above SRTs, it will be necessary to monitor the performance of the process to demonstrate that the pathogen reduction

Table 13–43

Advantages and disadvantages of aerobic digestion

Advantages	Disadvantages
1. Volatile solids reduction in a well-operated aerobic digester is approximately equal to that obtained anaerobically	1. High power cost is associated with supplying the required oxygen
2. Lower BOD concentrations in sidestreams than anaerobic digestion	2. Does not produce methane for energy recovery
3. Produces an odorless, humuslike, biologically stable end product	3. Aerobically digested biosolids produced have poorer mechanical dewatering characteristics than anaerobically digested biosolids
4. Allows recovery of the basic fertilizer values in the biosolids	4. The process is affected significantly by temperature, location, tank geometry, concentration of feed solids, type of mixing/aeration device, and type of tank material
5. Simple technology requiring few special skills for reliable operation	5. Process consumes alkalinity
6. Low capital cost for small facilities	
7. Easy to construct of readily available parts	
8. Suitable for digesting nutrient-rich waste activated sludges	
9. No risk for explosions	

[a] Adapted, in part, from WEF (2012).

criterion has been met. Monitoring is also required to demonstrate that the volatile solids reduction requirements are met for compliance to the vector attraction criterion (U.S. EPA, 2003).

Process Description

Aerobic digestion is similar to the activated sludge process. As the supply of available substrate (food) is depleted, the microorganisms begin to consume their own protoplasm to obtain energy for cell maintenance reactions. When energy is obtained from cell tissue, the microorganisms are said to be in the endogenous phase. Cell tissue is oxidized aerobically to carbon dioxide, water, and ammonia. In actuality, only about 75 to 80 percent of the cell tissue can be oxidized; the remaining 20 to 25 percent is composed of inert components and organic compounds that are not biodegradable. The ammonia is subsequently oxidized to nitrate as digestion proceeds. Nonbiodegradable volatile suspended solids will remain in final product from aerobic digestion. Considering the biomass wasted to a digester and the formula $C_5H_7NO_2$ is representative for cell mass of a microorganism, the biochemical changes in an aerobic digester can be described by the following equations:

Biomass destruction:

$$C_5H_7NO_2 + 5O_2 \rightarrow 4CO_2 + H_2O + NH_4HCO_3 \tag{13–19}$$

Nitrification of released ammonia nitrogen:

$$NH_4^+ + 2O_2 \rightarrow NO_3^- + 2H^+ + H_2O \tag{13–20}$$

Overall equation with complete nitrification:

$$C_5H_7NO_2 + 7O_2 \rightarrow 5CO_2 + 3H_2O + HNO_3 \tag{13–21}$$

Using nitrate nitrogen as electron acceptor (denitrification):

$$C_5H_7NO_2 + 4NO_3^- \rightarrow 5CO_2 + 2N_2 + NH_3 + 4OH^- \tag{13–22}$$

With complete nitrification/denitrification:

$$2C_5H_7NO_2 + 11.5O_2 \rightarrow 10CO_2 + N_2 + 7H_2O \tag{13–23}$$

As given by Eqs. (13–19) through (13–21), the conversion of organic nitrogen to nitrate results in an increase in the concentration of hydrogen ions and subsequently a decrease in pH if sufficient buffering capacity is not available in the sludge. Approximately 7 kg of alkalinity, expressed as $CaCO_3$, are destroyed per each kg of ammonia oxidized. Theoretically, approximately 50 percent of the alkalinity consumed by nitrification can be recovered by denitrification. If the dissolved oxygen is kept very low (less than 1 mg/L), however, nitrification will not occur. In practice, cycling of the aerobic digester between aeration and mixing has been found to be effective in maximizing denitrification while maintaining pH control. In situations where the buffering capacity is insufficient, resulting in pH values below 5.5, it may be necessary to install alkalinity feed equipment to maintain the desired pH.

Where activated or trickling-filter sludge is mixed with primary sludge and the combination is to be digested aerobically, direct oxidation of the organic matter in the primary sludge and oxidation of the cell tissue will both occur. Aerobic digesters can be operated as batch or continuous flow reactors (see Fig. 13–34). Three proven variations of the process are most commonly used: (1) conventional aerobic digestion, (2) high-purity oxygen aerobic digestion, and (3) autothermal aerobic digestion (ATAD). Aerobic digestion accomplished

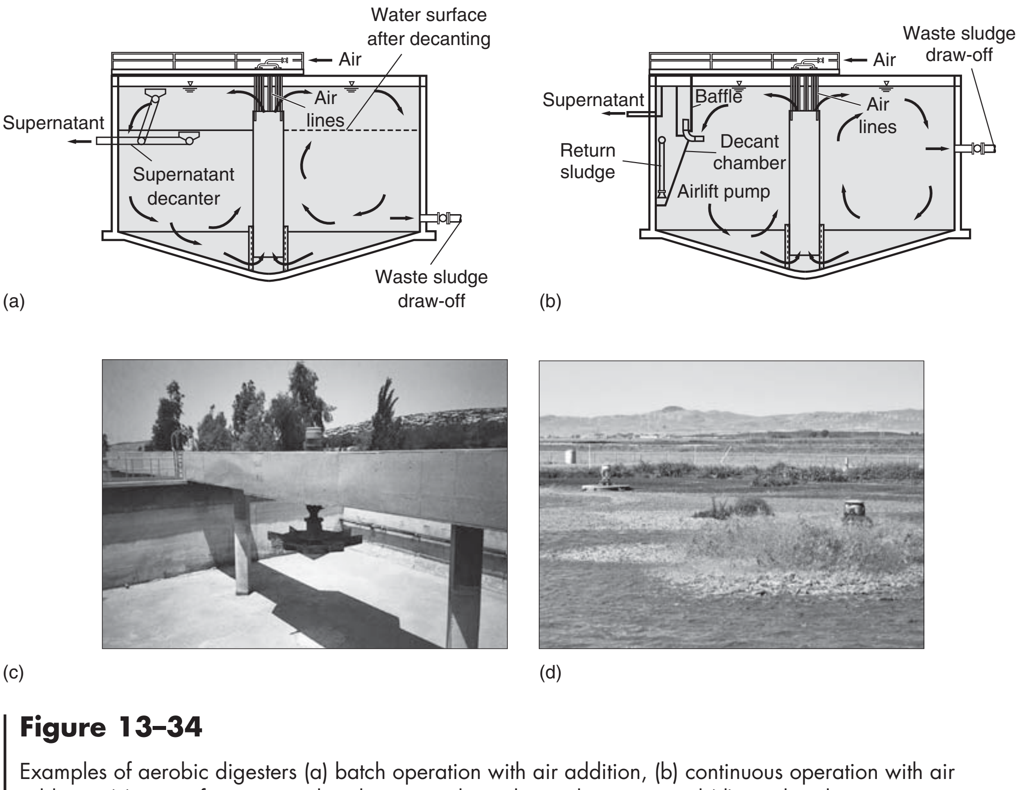

Figure 13–34

Examples of aerobic digesters (a) batch operation with air addition, (b) continuous operation with air addition, (c) view of empty aerobic digester with mechanical aerator, and (d) aerobic digester in lined earthen basin.

with air is the most commonly used process, so it is considered in greater detail in the following discussion.

Conventional Air Aerobic Digestion

Factors that must be considered in designing conventional aerobic digesters include temperature, solids reduction, tank volume, feed solids concentration, oxygen requirements, energy requirements for mixing, and process operation. Typical design criteria for aerobic digestion are presented in Table 13–44.

Temperature. Because the majority of aerobic digesters are open tanks, digester liquid temperatures are dependent on weather conditions and can fluctuate extensively. As with all biological systems, lower temperatures retard the process while higher temperatures accelerate it. In considering the temperature effects, heat losses should be minimized by using concrete instead of steel tanks, placing the tanks below grade instead of above grade or providing insulation for above-grade tanks, and using subsurface instead of surface aeration. In extremely cold climates, consideration should be given to heating the sludge or the air supply, covering the tanks, or both. The design should provide for the necessary degree of sludge stabilization at the lowest expected liquid operating temperature and should provide the maximum oxygen requirements at the maximum expected liquid operating temperature.

Volatile Solids Reduction. A major objective of aerobic digestion is to reduce the mass of the solids for disposition. This reduction is assumed to take place only with the

Table 13–44

Design criteria for aerobic digesters[a]

	U.S. customary units		SI units	
Parameter	**Units**	**Value**	**Units**	**Value**
SRT[b]	d		d	
At 20°C		40		40
At 15°C		60		60
Volatile solids loading	lb/ft^3·d	0.1–0.3	kg/m^3·d	1.6–4.8
Oxygen Requirements:				
Cell tissue[c]	lb O$_2$/lb VSS destroyed	~ 2.3 1.6–1.9	kg O$_2$/kg VSS destroyed	~ 2.3 1.6–1.9
BOD in primary sludge				
Energy requirements for mixing				
Mechanical aerators	hp/10^3 ft^3	0.75–1.5	kW/10^3 m^3	20–40
Diffused air mixing	ft^3/10^3 ft^3·min	20–40	m^3/m^3·min	0.02–0.040
Dissolved oxygen residual in liquid	mg/L	1–2	mg/L	1–2
Reduction volatile suspended solids	%	38–50	%	38–50

[a] Adapted, in part, from WEF (1995a); Federal Register (1993).

[b] To meet pathogen reduction requirements (PSRP) of 40 CFR Part 503 regulations.

[c] Ammonia produced during carbonaceous oxidation oxidized to nitrate.

biodegradable content of the sludge, although there may be some destruction of the nonorganics as well. Volatile solids reductions ranging from 35 to 50 percent are achievable by aerobic digestion. Optional criteria for meeting vector attraction requirements of 40 CFR Part 503 are (1) a minimum of 38 percent reduction in volatile solids during biosolids treatment or (2) less than a specific oxygen uptake rate (SOUR) of (1.5 mg O_2/h)/g of total sludge solids at 20°C (U.S. EPA, 1999).

The change in biodegradable volatile solids in a completely mixed digester can be represented by a first-order biochemical reaction at constant-volume conditions:

$$r_M = -k_d M \tag{13–24}$$

where r_M = rate of change of biodegradable volatile solids (M) per unit of time (Δmass/time), MT^{-1}

k_d = reaction rate constant, T^{-1}

M = mass of biodegradable volatile solids remaining at time t in the aerobic digester, M

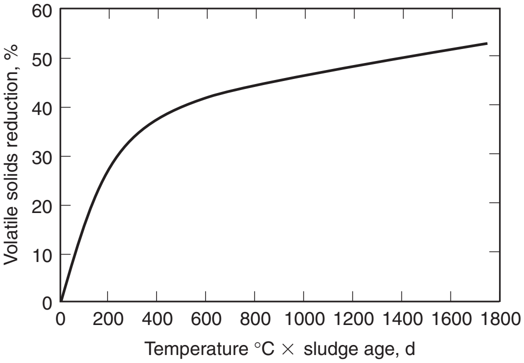
The time factor in Eq. (13–24) is the solid's retention time (SRT) in the aerobic digester. Depending on how the aerobic digester is being operated, time t can be equal to or considerably greater than the theoretical hydraulic residence time (t). Use of the biodegradable portion of the volatile solids is based on the fact that approximately 20 to 35 percent of the waste activated sludge from wastewater treatment plants with primary treatment is not biodegradable. The percentage of nonbiodegradable volatile solids in waste activated sludge from contact stabilization processes (no primary tanks) ranges from 25 to 35 percent (WEF, 2010a).

The reaction rate term k_d is a function of the sludge type, temperature, and solids concentration. Representative values for k_d may range from 0.05 d^{-1} at 15°C to 0.14 d^{-1} at 25°C for waste activated sludge. Because the reaction rate is influenced by several factors, it may be necessary to confirm decay coefficient values by bench-scale or pilot-scale studies.

Solids destruction is primarily a direct function of both basin liquid temperature and the SRT (sometimes referred to as sludge age), as indicated on Fig. 13–35. The data were derived from both pilot-and full-scale studies. The plot on Fig. 13–35 relates volatile solids reduction to degree-days (temperature times sludge age). Initially, as the degree-days increase, the rate of volatile solids reduction increases rapidly. As the degree-days approach 500, the curve begins to flatten. To produce well-stabilized biosolids, at least 550 degree-days are recommended for the aerobic digestion system (Enviroquip, 2000). The use of Fig. 13–35 is demonstrated in Example 13–8, the design of an aerobic digester.

Figure 13–35

Volatile solids reduction in an aerobic digester as a function of digester liquid temperature and digester sludge age.



Tank Volume and Detention Time Requirements. The tank volume is governed by the detention time necessary to achieve the desired volatile solids reduction. In the past, SRTs of 10 to 20 d were the norm for the design of aerobic digestion systems (Metcalf & Eddy, 1991). To meet the pathogen reduction requirements of 40 CFR Part 503 regulations, the SRT criteria (see Table 13–44) in conventional aerobic digesters take precedence over the vector attraction criteria of 38 percent solids reduction for sizing the tank volume.

The digester tank volume can be calculated by Eq. (13–25) (WEF, 2010a):

$$V = \frac{Q_i(X_i + YS_i)}{X(k_d P_v + 1/\text{SRT})} \tag{13–25}$$

where V = volume of aerobic digester, m^3 (ft^3)
Q_i = influent average flowrate to digester, m^3/d (ft^3/d)
X_i = influent suspended solids, mg/L
Y = fraction of the influent BOD consisting of raw primary solids, (expressed as a decimal)
S_i = influent BOD, mg/L
X = digester suspended solids, mg/L
k_d = reaction rate constant, d^{-1}
P_v = volatile fraction of digester suspended solids (expressed as a decimal)
SRT = solids retention time, d

The term YS_i can be neglected if primary sludge is not included in the sludge load to the aerobic digester.

If the aerobic digestion process is operated in a complete-mix, staged configuration (two or three stages), the total SRT should be divided approximately equally among the stages. For more information on staging aerobic digestion, Enviroquip (2000) should be consulted.

Feed Solids Concentration. The concentration of the digester feed solids is important in the design and operation of the aerobic digester. If thickening precedes aerobic digestion, higher feed solids concentrations will result in higher oxygen input levels per digester volume, longer SRTs, smaller digester volume requirements, easier process control (less decanting in batch-operated systems), and subsequently increased levels of volatile solids destruction (WEF 2010a). However, feed solids concentrations greater than 3.5 to 4 percent may affect the ability of the mixing and aeration system in maintaining well-mixed tank contents with adequate dissolved oxygen levels necessary to support the biological process. At feed solids concentrations greater than 4 percent, the aeration equipment must be evaluated carefully to ensure adequate mixing and aeration are achieved. Also at feed solids concentration greater than 4 percent, provisions for removing the heat from the digesters should be practiced.

Oxygen Requirements. The oxygen requirements that must be satisfied during aerobic digestion are those of the cell tissue and, with mixed sludges, the BOD in the primary sludge. The oxygen requirement for the complete oxidation of cell tissue (including nitrification), computed using Eqs. (13–19) and (13–20), is equal to 7 mole/mole of cells, or about 2.3 kg/kg of cells. The oxygen requirement for the complete oxidation of the BOD contained in primary sludge varies from about 1.6 to 1.9 kg/kg destroyed. The oxygen residual should be maintained at 1 mg/L or above under all operating conditions.

Energy Requirements for Mixing. To ensure proper operation, the contents of the aerobic digester should be well mixed. In large tanks, multiple mixing devices should be installed to ensure good distribution of the mixing energy. Typical energy requirements for mixing are given in Table 13–44. In general, because of the large amount of air that must be supplied to meet the oxygen requirement, adequate mixing should be achieved; nevertheless, mixing power requirements should be checked, particularly when feed solids concentrations are greater than 3.5 percent. If polymers are used in the thickening process, especially for centrifuge thickening, a greater amount of unit energy may be required for mixing.

If fine-pore diffused air mixing is used, considerations for selecting the aeration system should include limitations of feed solids concentration on achieving good mixing. Recommendations on feed solids limitations should be obtained from manufacturers of aeration equipment. In addition, the potential for diffuser fouling should be evaluated, especially if the process operation requires decanting.

Process Operation. Depending on the buffering capacity of the system, the pH may drop to a low value of about 5.5 at long hydraulic detention times. The potential drop in pH is due to the increased presence of nitrate ions in solution and the lowering of the buffering capacity due to air stripping. Filamentous growths may also develop at low pH values. The pH should be checked periodically and adjusted if found to be excessively low. Dissolved oxygen levels and respiration rates should also be checked to ensure proper process performance.

Aerobic digesters that do not include prethickening should be equipped with decanting facilities for thickening the digested biosolids before discharge to subsequent operations. Operator control and visibility of the decanting operation are important design considerations. If the digester is operated so that the incoming sludge is used to displace supernatant and the biosolids are allowed to build up, the solids retention time will not be equal to the hydraulic retention time.

EXAMPLE 13–8 **Aerobic Digester Design** Design an aerobic digester to treat the waste sludge produced by the activated sludge treatment plant. Assume that the following conditions apply:

1. The amount of waste sludge to be digested is 2100 kg TSS/d.
2. The minimum and maximum liquid temperatures are 15°C for winter operation and 25°C for summer operation.
3. The system must achieve 40 percent volatile solids reduction in the winter.
4. The minimum SRT for winter conditions is 60 d.
5. Waste activated sludge is concentrated to 3 percent, using a dissolved air flotation thickener.
6. The specific gravity of the waste sludge is 1.03.
7. Sludge concentration in the digester is 70 percent of the incoming thickened sludge concentration.
8. The reaction rate coefficient k_d is 0.06 d^{-1} at 15°C.
9. Volatile fraction of digester TSS is 0.65.
10. No primary sludge is included in the influent to the digester.
11. Diffused-air mixing is used.
12. Air temperature in diffused air system = 20°C.

Solution

1. Compute the volatile solids reduction for winter conditions using Fig. 13–35 and compute the percent volatile solids reduction under summer (maximum) conditions.
   a. For winter conditions, the degree-days from Fig. 13–35 are 15°C × 60 d = 900 degree-days. From Fig. 13–35, the volatile solids reduction is 45 percent, which exceeds the winter requirements of 40 percent.
      To meet the pathogen reduction requirements, the SRT must be 60 d; therefore, the required volume is $68.0\ \text{m}^3/\text{d} \times 60\ \text{d} = 4080\ \text{m}^3$.
   b. During the summer, the liquid temperature will be 25°C, and the degree-days will be 25 × 60 = 1500. From Fig. 13–35, the volatile solids reduction in the summer will be 50 percent.
2. Compute the winter and summer volatile solids reduction based on a total mass of volatile suspended solids.

   Total mass of VSS (VSS_M) = (0.65)(2100 kg/d) = 1365 kg/d

   a. Winter: $1365 \times 0.45 = 614$ kg VSS_M reduced/d
   b. Summer: $1365 \times 0.50 = 682$ kg VSS_M reduced/d
3. Determine oxygen requirements (see Table 13–45 for oxygen requirements).
   a. Winter: $614 \times 2.3 = 1412$ kg O_2/d
   b. Summer: $682 \times 2.3 = 1569$ kg O_2/d
4. Compute the volume of air required per d at standard conditions. For the density of air, see Appendix B–1. Note that air is approximately 23.2% oxygen by weight.

   a. Winter: $$V = \frac{1412\ \text{kg}}{(1.204\ \text{kg/m}^3)(0.232)} = 5055\ \text{m}^3/\text{d}$$

   b. Summer: $$V = \frac{1569\ \text{kg}}{(1.204\ \text{kg/m}^3)(0.232)} = 5617\ \text{m}^3/\text{d}$$

   Assuming an oxygen transfer efficiency of 10 percent, the air flowrates are

   Winter: $$q = \frac{(5055\ \text{m}^3/\text{d})}{(0.1)(1440\ \text{min/d})} = 35.1\ \text{m}^3/\text{min}$$

   Summer: $$q = \frac{(5617\ \text{m}^3/\text{d})}{(0.1)(1440\ \text{min/d})} = 39.0\ \text{m}^3/\text{min}$$
5. Compute the volume of sludge to be disposed of per day using Eq. (13–2).

   $$Q = \frac{2100\ \text{kg}}{(10^3\ \text{kg/m}^3)(1.03)(0.03)} = 68.0\ \text{m}^3/\text{d}$$
6. Compute the air requirement per m^3 of digester volume.

   $$q = \frac{(39.0\ \text{m}^3/\text{min})}{4080\ \text{m}^3} = 0.0096\ \text{m}^3/\text{min}\cdot\text{m}^3$$
7. Check the mixing requirements. Because the air requirement computed in Step 7 is below the range of values given in Table 13–44, mixing requirements will govern the design of the aeration system, unless separate mixing is provided.

Comment The above example is based on a single-stage aerobic digester. If a two-stage or more digester were used, a significant reduction in tank volume is possible. In a multistage arrangement, the air distribution between tanks would vary based on the expected demand as most of the volatile solids reduction will occur in the first stage where the biomass is most active.

Table 13–45

Advantages and disadvantages of ATAD

Advantages	Disadvantages
1. High reaction rate and low retention time requirements when compared to other digestion processes	1. High odor potential
2. Simple operation	2. Potential for poor dewatering characteristics^b
3. Greater reduction of bacteria and viruses are achieved as compared to mesophilic anaerobic digestion	3. Does not nitrify
4. Can meet Class A when the reactor is well mixed and maintained at or above 55°C	4. Requires upstream mechanical thickening
5. Fully enclosed reactors	5. Sidestreams contain high nutrient loads that may require further treatment
6. Lower energy requirements than conventional aerobic digestion	6. Foam control is necessary
	7. Many processes are proprietary
	8. Potential for erosion / corrosion

[a] Adapted, in part, from WEF (2012).

[b] Many newer designs now incorporate product cooling and an additional mesophilic digestion system which is reported to significantly improve dewatering characteristics.

Dual Digestion

Aerobic thermophilic digestion has also been used extensively in Europe as a first stage in the dual digestion process. The second stage is mesophilic anaerobic digestion. Dual digestion has also been tried in the United States using high-purity oxygen in the first stage. Residence times in the aerobic digester range typically from 18 to 24 h, and the reactor temperature ranges from 55 to 65°C. Typical residence time in the anaerobic digester is 10 d. The advantages of using aerobic thermophilic digestion in dual digestion are (1) increased levels of pathogen reduction, (2) improved overall volatile solids reduction, (3) increased methane gas generation in the anaerobic digester, (4) less organic material in and fewer odors produced by the stabilized sludge, and (5) equivalent volatile solids reductions can be achieved in one-third less tankage than a single-stage anaerobic digester. Prior hydrolysis in the aerobic reactor results in increased degradation during subsequent anaerobic digestion and gas production. Approximately 10 to 20 percent of the volatile solids is liquefied in the aerobic digester, while COD reduction is less than 5 percent. Provisions for foam suppression and odor control are required (Roediger and Vivona, 1998).

Autothermal Thermophilic Aerobic Digestion (ATAD)

Autothermal thermophilic aerobic digestion (ATAD), illustrated on Fig. 13–36, represents a variation of both conventional and high-purity oxygen aerobic digestion. In the ATAD process, the feed sludge is generally prethickened, and the reactors are insulated to conserve the heat produced from the oxidation of volatile solids during the digestion process. Thermophilic operating temperatures (generally in the range of 55 to 70°C) can be achieved without external heat input by using the heat released by the exothermic microbial oxidation process. The heat produced per kg of volatile solids destroyed is approximately 20,000 kJ. Because supplemental heat is not provided (other than the heat introduced by aeration and mixing), the process is termed autothermal.

Within the ATAD reactor, sufficient levels of oxygen, volatile solids, and mixing allow aerobic microorganisms to degrade organic matter to carbon dioxide, water, and nitrogen byproducts. The major advantages and disadvantages of ATAD are cited in Table 13–45.

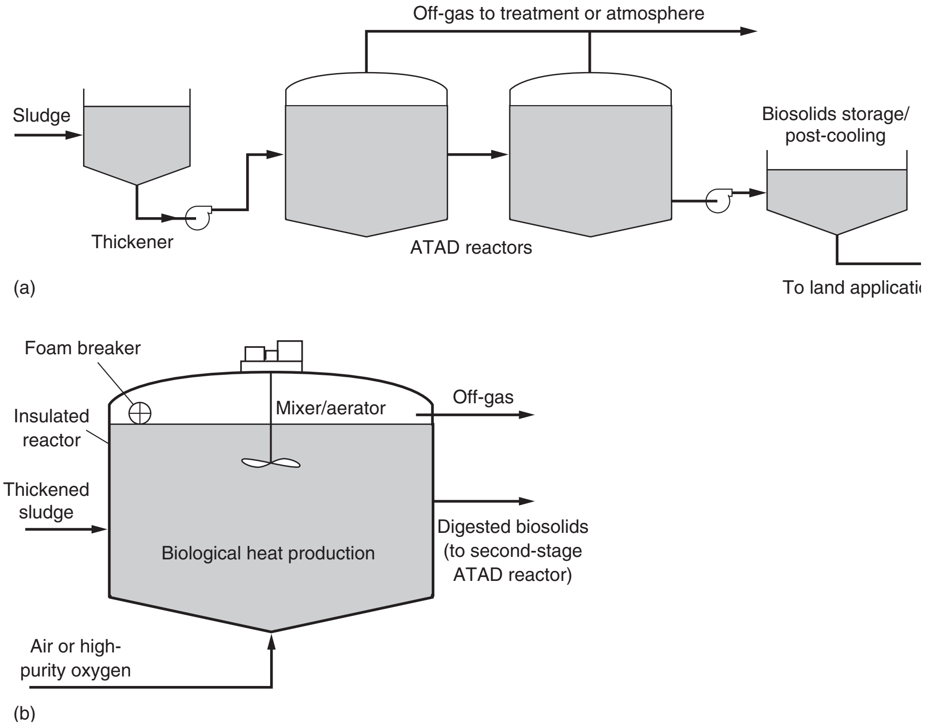


Figure 13–36

Autothermal thermophilic aerobic digester (ATAD) system: (a) process flow diagram and (b) detail of typical reactor.

Because the ATAD system is capable of producing Class A biosolids, it is growing in popularity. In a partial survey of ATAD systems in USA, ~25 ATAD systems were in operation (Meckes, 2011).

Process Theory. The biochemical conditions in thermophilic aerobic digesters differ significantly from conventional aerobic digesters. Because of the high operating temperatures, nitrification is inhibited, and aerobic destruction of volatile solids occurs as described by Eq. (13–19) without the subsequent reactions described by Eqs. (13–20) through (13–23). Additionally, most, if not all, ATAD systems may be operating under microaerobic conditions where oxygen demand exceeds oxygen supply (Stensel and Coleman, 2000). Under microaerobic conditions, proteinaceous cellular material will undergo fermentation where protein is represented as peptone as described by Eq. (13–26) (Chu and Mavinic, 1998):

$$4CH_2NH_2COOH + 4H_2O \rightarrow 3CH_3COOH + 2(NH_4)_2CO_3 \qquad (13\text{–}26)$$

Both Eqs. (13–19) and (13–26) result in the production of ammonia that reacts with water and carbon dioxide to form ammonium bicarbonate and ammonium carbonate to increase alkalinity. Because nitrification does not occur, the pH in the ATAD system will typically range from 8 to 9, higher than in conventional aerobic digesters. Ammonia-nitrogen produced will be present in the off-gas and in solution with concentrations of several hundred mg/L in each. Most of the ammonia nitrogen will be returned to the liquid process in sidestreams from the odor control and dewatering facilities. The acetic acid (or acetate) produced by the fermentation of proteins is one of the volatile fatty acids. Acetic acid will be oxidized subsequently in the presence of sufficient dissolved oxygen as described by Eq. (13–27):

$$CH_3COOH + 2O_2 \rightarrow 2CO_2 + 2H_2O \qquad (13\text{–}27)$$

Anaerobic conditions will occur at times in ATAD systems and will most likely take place in the pre-ATAD sludge holding facilities and in the first-stage ATAD reactors during and immediately after sludge transfers and batch feeding. Under anaerobic conditions, reduced sulfur compounds can be formed that can affect the design and performance of odor-control systems.

Process Design. ATAD systems are designed to have short hydraulic retention times within insulated reactors [see Fig. 13–36(b)]. As long as the ATAD system is well mixed and sufficient oxygen is provided, the temperature in the reactor will rise until a balance occurs; i.e., the heat lost equals the heat input from the exothermic reaction and mechanical energy input. The temperature will continue to rise until the process becomes oxygen mass-transfer-limited.

Factors that must be considered in designing an ATAD system include prethickening, number and type of reactors, postcooling/thickening, feed characteristics, detention time, feed cycle, aeration and mixing, temperature and pH, and foam and odor control. Nearly all of the ATAD systems currently installed in the United States utilize two or more reactors operated in series [see Fig. 13–36(a)]. Design considerations for ATAD systems are presented in Table 13–46; typical design criteria are summarized in Table 13–47.

ATAD systems must be designed to (1) transfer sufficient oxygen to meet the high demand of the reactors and (2) supply the required oxygen while minimizing the latent

Table 13–46

Typical design considerations for an ATAD system[a]

System component	Design consideration
Prethickening system	Thickening or blending facilities may be required to maintain an influent COD to the ATAD reactor greater than 40 g/L
Reactors	Number of reactors; a minimum of two enclosed insulated reactors in series equipped with mixing aeration, and foam control equipment
Screening	Fine screening 6 to 12 mm (0.25 to 0.5 in.) clear openings of raw wastewater or sludge feed stream should be provided for the removal of inert materials, plastics, and rags
Feed cycle	Continuous or batch processing is acceptable, except batch processing provides greater assurance in meeting Class A pathogen reduction requirements
Foam control	Foam suppression is required to ensure effective oxygen transfer and enhanced biological activity. Freeboard of 0.5 to 1.0 m (1.65 to 3.3 ft) is recommended
Post-ATAD storage/ dewatering	Postprocess cooling is necessary to achieve solids consolidation and to enhance dewaterability. A minimum of 20 d detention may be necessary unless heat exchangers are used for cooling the processed biosolids
Odor control	Because of high temperatures in the ATAD system, relatively high concentrations of ammonia are released. Reduced sulfur compounds also result, which can include hydrogen sulfide, carbonyl sulfide, methyl mercaptan, ethyl mercaptan, dimethyl sulfide, and dimethyl disulfide. Odor-control systems may include wet scrubbers, biofilters, or a combination of both (see Chap. 16)
Sidestreams	Liquid sidestreams from odor-control and dewatering systems, when returned to the liquid processing system, may contain constituents that could affect process performance unless accounted for or treated separately

Table 13–47

Typical design parameters for autothermal aerobic digester (ATAD)[a]

	U.S. customary units			SI units		
Parameter	**Units**	**Range**	**Typical**	**Units**	**Range**	**Typical**
Reactor						
HRT	d	4–30	6–8	d	4–30	6–8
Volumetric loading						
TSS, 40 to 60 g/L	lb/10^3 ft^3·d	320–520		kg/m^3·d	5–8.3	
VSS, 25 g/L	lb/10^3 ft^3·d	200–260		kg/m^3·d	3.2–4.2	
Temperature						
Stage 1	°F	95–122	104	°C	35–50	40
Stage 2	°F	122–158	131	°C	50–70	55
Aeration and Mixing						
Mixer type			Aspirating			Aspirating
Oxygen transfer efficiency	lb O_2/kWh		4.4	kg O_2/kWh		2
Energy requirement	hp/10^3 ft^3	5–6.4		W/m^3	130–170	

[a] Adapted, in part, from Stensel and Coleman (2000).

heat loss in the exhaust air. It is difficult to define the oxygen transfer rate in an ATAD system while using typical design procedures used for selecting and sizing aeration equipment for wastewater treatment processes. The oxygen transfer coefficient α (alpha) and the oxygen saturation coefficient β (beta) have not been quantified under the environmental conditions present in an ATAD reactor (Stensel and Coleman, 2000). Factors affecting oxygen transfer are the high temperatures (that would reduce α values) and the foam layer and low dissolved oxygen levels (that might increase oxygen transfer). Nearly all ATAD systems utilize a type of aspirating aerator to introduce oxygen into the reactors. The types include hollow-shaft propeller or turbine aerators, pumped venturi aspirators, and jet aspirators. With all air aspirating systems, the equipment provides both mixing and oxygen transfer. Typical energy requirements for mixing and aeration are given in Table 13–47.

Substantial amounts of foam are generated in the ATAD process as cellular proteins, lipids, and oil and grease materials are broken down and released into solution. The foam layer contains high concentrations of biologically active solids that provide insulation of the reactor and improved oxygen utilization. It is important, therefore, that the foam layer be managed and controlled effectively. Mechanical foam cutters are used most commonly for foam control, but other methods such as spray systems have been employed. A freeboard of 0.5 to 1.0 m is generally recommended for controlling the foam layer (Stensel and Coleman, 2000).

Where ATAD systems are followed by mechanical dewatering, post-ATAD storage is recommended to allow for cooling of the biosolids to improve dewatering performance. Post-ATAD storage coupled with long detention times in the final-stage ATAD reactors may further increase the reduction of volatile solids.

Process Control. The provisions of the 40 CFR Part 503 regulations applicable for meeting the Class A biosolids requirements with the ATAD process are complex because several alternative pathogen-reduction requirements are given. The basic requirements that need to be demonstrated are (1) fecal coliform densities are less than 1000 MPN/g of total solids (dry weight basis), or (2) *Salmonella spp.* bacteria concentrations are below detection limits of 3 MPN/4 g of total solids (dry weight basis). For compliance with these pathogen regulations for Class A biosolids, the withdrawal and feeding of the sludge to the reactors is performed on a batch basis. (In flow-through systems, it is possible that some pathogens might pass through.) Two or more reactors in a series configuration are used typically to ensure that all particles in the reactor are subjected to the time and temperature requirements and that no insufficiently treated biosolids are released to the environment. The ATAD pumping system is designed to withdraw and feed the daily amount of sludge in 1 h or less. The reactor is then isolated for the remaining 23 h each day at a minimum temperature of 55°C.

Improved ATAD Systems

Because many of the first generation ATAD systems suffered from poor performance, odor problems, and high dewatering costs a second generation of ATAD systems has been developed. The differences between the second ATAD generation and previous ATAD installations includes: (1) a single thermophilic stage instead of 2 to 3 stages of shorter detention time; (2) use of pressurized (blower) air for aeration instead of aspirated air; (3) sufficient aeration pressure to maintain aerobic conditions and reduce odor; (4) aeration control based on ORP; (5) non-mechanical foam control; (6) a mesophilic aeration stage following the thermophilic stage. The volume of the first stage thermophilic reactor is approximately two thirds of the total treatment volume. In general, the second generation ATAD systems are reported to provide high volatile solids reduction, a class A biosolids product without offensive odor, and good dewatering with high solids concentration without high chemical demand (Smith et al., 2012). In addition, using a water scrubber and photo catalyter oxidizer for off gas odor control has been reported to be effective (Smith et al., 2012).

The first municipal installation of the second generation ATAD was in 2002 (Scisson, 2009). As of 2012, the largest second generation ATAD began operating at Middletown, OH in May 2009 with a processing capacity of 15 tonne/d (16.5 ton/d) (Pevec, 2010). Based on the performance data from this installation, the system has operated with minimal odor, produces an average volatile solids reduction of about 57 percent, and with centrifuge dewatering cake solids of about 31 percent have been achieved.

High-Purity Oxygen Digestion

High-purity oxygen aerobic digestion is a modification of the aerobic digestion process in which high-purity oxygen is used in lieu of air. The resultant biosolids are similar to biosolids from conventional aerobic digestion. Influent sludge concentrations vary from 2 to 4 percent. Recycle flows are similar to those achieved by conventional aerobic digestion. High-purity oxygen aerobic digestion is particularly applicable in cold weather climates because of its relative insensitivity to changes in ambient air temperatures due to the increased rate of biological activity and the exothermal nature of the process.

While one variation of the high-purity aerobic digestion process uses open tanks, aerobic digestion is usually done in closed tanks similar to those used in the high-purity oxygen activated sludge process. Using closed tanks for high-purity oxygen aerobic digestion will generally result in higher operating temperatures because of the exothermic nature of the digestion process. Maintenance of these higher temperatures in the digester results in a significant increase in the rate of volatile suspended solids destruction.

Where covered tanks are used, a high-purity oxygen atmosphere is maintained above the liquid surface, and oxygen is transferred into the sludge via mechanical aerators. Where an open aeration tank is used, oxygen is introduced to the liquid sludge by a special diffuser that produces minute oxygen bubbles. The bubbles dissolve before reaching the air-liquid interface.

The major disadvantage of high-purity oxygen aerobic digestion is the increased cost associated with oxygen generation. As a result, high-purity oxygen aerobic digestion is cost-effective generally only when used in conjunction with the high-purity oxygen activated sludge system. Also, neutralization may be required to offset the reduced buffering capacity of the system.

PROBLEMS AND DISCUSSION TOPICS

13–1 The water content of waste activated sludge is reduced from 98 to 95 percent. What is the percent reduction in volume by the approximate method and by the more exact method, assuming that the solids contain 70 percent organic matter of specific gravity 1.00 and 30 percent mineral matter of specific gravity 2.00? What is the specific gravity of the 98 and the 95 percent slurry?

13–2 Consider an activated sludge treatment plant with a flowrate of 40,000 m^3/d. The untreated wastewater contains 200 mg/L suspended solids. The plant provides 60 percent removal of the suspended solids in the primary settling tank. If the primary sludge alone is pumped, it will contain 5 percent solids. Assume that 400 m^3/d of waste activated sludge containing 0.5 percent solids is to be transferred to the digester. If the waste activated sludge is thickened in a gravity belt thickener to 6 percent TS, calculate the thickened waste activated sludge volume. Calculate the total reduction in daily volume of biosolids pumped to the digester that can be achieved by thickening the waste activated sludge in a gravity belt thickener as compared with discharging the primary and waste activated sludge directly to the digester. Assume complete capture of the waste activated sludge in the gravity belt thickener.

13–3 For Example 13–4 for gravity thickening, calculate the amount of dilution water required at average design flow using the data provided to maintain a hydraulic loading rate of 12 $m^3/m^2 \cdot d$ for the thickener size computed in the example.

13–4 Determine the required digester volume for the treatment of the sludge quantities specified in Example 13–5 using the (a) volatile solids loading factor, and (b) volumetric per capita allowance methods. Set up a comparison table to display the results obtained using the three different procedures for sizing digesters (two in this problem and one in Example 13–5). Assume the following data apply:

1. Volatile solids loading method
   a. Solids concentration = 5%
   b. Detention time = 15 d
   c. Loading factor = 2.4 kg $VSS/m^3 \cdot d$
   d. Volatile solids concentration = 75%
2. Volumetric loading method
   a. Sewer basin population = 70,000
   b. Per capita contribution = 0.72 g/capita·d
   c. Volume required 50 $m^3/10^3$ capita·d

13–5 A wastewater treatment plant is planning to provide for separate anaerobic sludge digestion for its primary sludge. The plant receives an influent wastewater with the following characteristics:

Average flowrate = 8000 m^3/d

Suspended solids removed by primary sedimentation 200 mg/L

Volatile matter in settled solids = 75%

Water in untreated sludge = 96%

Specific gravity of mineral solids = 2.60

Specific gravity of organic solids = 1.30

Using these data, determine (a) the required digester volume using an SRT of 20 d, and (b) the minimum digester capacity using the recommended loading parameters of kg $VM/m^3 \cdot d$ (kilograms of volatile matter per cubic meter per day).

13–6 A wastewater treatment plant currently dewaters on average 750 kg/d of primary and waste activated sludge to an average solid content of 22 percent TS. The plant currently uses post lime stabilization and on average mixes 300 kg/d of quicklime with their dewatered sludge in a pug mill. What is the theoretical temperature increase after adding quicklime? Discuss the advantages and disadvantage for the plant if they were to switch to anaerobic digestion for sludge stabilization in lieu of lime stabilization.

13–7 A digester is loaded at a rate of 300 kg COD/d. Using a waste-utilization efficiency of 75 percent, what is the volume of gas produced when SRT = 40 d? Assume $Y = 0.10$ and $b = 0.02\ d^{-1}$.

13–8 Volatile acid concentration, pH, or alkalinity should not be used alone to control a digester. How should they be correlated to predict most effectively how close to failure a digester is at any time?

13–9 A digester is to be heated by circulation of sludge through an external hot water heat exchanger. Using the following data, find the heat required to maintain the required digester temperature:

1. U_x = overall heat-transfer coefficient, $W/m^2 \cdot °C$
2. Wall above ground: $U_{air} = 0.85$, wall below ground: $U_{ground} = 1.2$, cover: $U_{cover} = 1.0$
3. Digester is a concrete tank with floating steel cover; diameter = 11 m and sidewall depth = 8 m, 4 m of which is above the ground surface. The tank walls and floor are 300 mm thick.
4. Sludge fed to digester = 15 m^3/d at 14°C
5. Outside temperature = –15°C
6. Average ground temperature = 5°C
7. Sludge in tank is to be maintained at 35°C
8. Assume a specific heat of the sludge = 4200 J/kg·°C
9. Sludge contains 4% solids
10. Assume a cone-shaped cover with center 0.6 m above digester top, and a cone-shaped bottom with center 1.2 m below bottom edge.

13–10 A wastewater treatment plant is considering options for expanding their existing anaerobic digestion system to handle increased sludge production. The plant currently sends 25,000 kg/d of 5 percent thickened sludge to anaerobic digestion for stabilization. The plant currently has three 6200 m^3 digesters but normally only operates two keeping the third as a redundant unit. The digesters are high rate complete mix digesters with no decanting.

a. Using one of the data sets as selected by the instructor determine how much additional digester volume would be required to maintain at least 15 d HRT at future build out with one digester out of service?

b. One option also being considered is adding a thermal hydrolysis process to increase the capacity of the existing anaerobic digesters to avoid building new digester volume. Assuming the solid content going to the digester is 9 percent (after thermal hydrolysis and dilution) would the existing digestion volume be sufficient to meet digestion requirements? What would be the theoretical steam requirement for the thermal hydrolysis system assuming the temperature out of the thermal hydrolysis process is 110°C?

Assume the specific gravity of the thickened sludge and diluted hydrolyzed sludge going to digestion is 1.03.

		Data set			
Item	Unit	1	2	3	4
Future sludge loading	kg/d	55,000	60,000	50,000	58,000
Raw sludge temperature	°C	10	15	20	12

13–11 A small wastewater plant currently utilizes aerobic digestion to stabilize their waste activated sludge prior to Class B liquid land application and they are looking at ways the system can be expanded to handle future loads. The plant currently sends waste activated sludge to a single stage complete mix aerobic digester with no decanting. Using one of the data sets to be selected by instructor, recommend possible options to consider in the upgrade if aerobic digestion is to be maintained. In the example use the following assumptions.

1. The winter and summertime liquid temperatures are 15 and 25 d, respectively
2. The system must be able to achieve $>40\%$ VSR in the winter and meet Class B requirements (SRT > 60 d at 15°C)
3. Specific Gravity of liquid waste activated sludge is 1.01
4. Air temperature in diffused air system is 20°C.
5. Assume a diffused air oxygen transfer efficiency of 10%

In the calculation be sure to comment on volume requirements, SRT, aeration requirements and mixing. Note any perceived advantage or disadvantage with options.

		Data set		
Item	Unit	1	2	3
Current sludge loading	kg/d	500	750	900
Waste activated sludge	% TS	1	0.8	1.3
Future sludge loading	kg/d	1500	2000	3000
Digester volume	m^3	3000	5600	2400
Current blower size	m^3/min	90	165	125

Biosolids Processing, Resource Recovery and Beneficial Use

WORKING TERMINOLOGY

Term	Definition
Aerated static pile composting	A method of composting where the sludge or biosolids and bulking agent are mixed and distributed in a long pile over a grid of air piping which provides the air for reaction.
Belt-filter press	A device that uses a series of porous moving belts revolving over a series of pulleys to drain water from sludge or biosolids.
Carbon footprint	A measure of the impact human activities have on the environment in terms of the amount of greenhouse gases produced, measured in units of carbon dioxide equivalent.
Centrifuge	A dewatering device that relies on centrifugal force to separate particles of varying density (e.g., water and solids).
Composting	A stabilization process that relies on the aerobic decomposition of organic matter in sludge and biosolids by bacteria and fungi.

Term	Definition
Conditioning	A chemical, physical, or biological process designed to improve the thickening or dewatering characteristics of sludge or biosolids.
Decanting	Separating liquid from settled sludge or biosolids by drawing or pouring off the upper layer of liquid after the sludge or biosolids have settled.
Dewatering	A process, usually by belt-filter press or centrifuge that removes a portion of the water contained in solids. Dewatering is distinguished from thickening in that the resulting dewatered cake may be handled as a solid, not as a liquid.
Dissolved-air flotation	A clarification process in which minute bubbles become attached to flocculated material, float to the surface, and are removed by skimming. Heavier solids settle and are removed by mechanical scrapers.
Filter press	A dewatering device in which water is forced from semi-solid materials under high pressure.
Fluidized-bed incinerator	A furnace that uses a high-temperature gas to fluidize solid particles (usually sand and waste sludge and biosolids) to produce and sustain combustion.
Gravity-belt thickener	A thickening device that uses a porous filter belt to promote gravity water drainage.
Heat drying	The application of heat to evaporate water and reduce the moisture content in biosolids below that achievable by conventional dewatering methods.
Humus	Sludge removed from trickling filters.
Incineration	The reduction of the volume of a solid by the thermal destruction of organic matter.
In-vessel composting	A method of composting, mainly proprietary, that occurs inside an enclosed vessel or container.
Mass balance	A method for analyzing physical systems based on the law of conservation of mass.
Multiple-hearth incinerator	An incinerator consisting of numerous hearths that is used for the thermal destruction of organic sludge or biosolids.
Reed bed	A treatment system in which biosolids are used to grow reeds, which in turn utilize the water, nitrogen, and other nutrients to stabilize and dewater the biosolids.
Rheology	The flow properties of a liquid (generally biosolids and sludge) that include elasticity, viscosity, and plasticity.
Rotary drum thickener	A rotating cylindrical screen used to thicken liquid streams of sludge and biosolids.
Rotary press	A sludge or biosolids dewatering device in which the material to be dewatered flows through a channel that is bound between two rotating screens; filtrate passes through the screens and the dewatered material continues through the channel.
Sidestream	A portion of the wastewater flow that has been diverted from the main treatment process flow for specialized treatment (see Chap. 15).
Sludge drying beds	Devices used for the dewatering and drying of sludge and biosolids in which a semi-solid solution is spread over a porous (e.g., sand) or impervious medium and allowed separate and air dry or decant.
Solids	A term often used as a replacement for sludges that have not been stabilized by physical, chemical or biological treatment. The term solids is not used as a substitute for sludge in this chapter. The mass of dry material in sludge is referred to as the solids content.
Thickener	A tank, vessel, or device where residuals or a slurry are concentrated by removing a portion of the water.
Windrow composting	A method of composting where sludge or biosolids are mixed with a bulking agent and arranged in windrows (long piles) that are turned over periodically and remixed mechanically.

Processes used to reduce organic content and to render the processed sludge suitable for reuse or final disposal were considered in Chap. 13. The focus of Chap. 14 is on the many processes used for recovery and beneficial use of biosolids. Before biosolids can be processed or used beneficially, they are typically dewatered to reduce the volume that must be handled. However, to achieve effective dewatering, sludges and biosolids must be conditioned for enhanced water removal. The conditioning of sludge and biosolids is discussed in Sec. 14–1. Commercially available dewatering methods are identified and discussed in Sec. 14–2. Drying the dewatered sludge or biosolids is for the purpose of removing more water and further stabilization; producing granular material that is beneficially used as a fertilizer or energy source is presented in Sec. 14–3. Thermal oxidation of the sludges for destroying harmful constituents and producing ash-like material that can also be used beneficially is discussed in Sec. 14–4. Composting for stabilizing the biosolids and producing fertilizer like material is discussed in Sec. 14–5. Conveyance and storage of biosolids are discussed in Sec. 14–6. The preparation of solids balances for treatment facilities is described in Sec. 14–7. Biosolids resource recovery and energy recovery are covered in Sec. 14–8. The application of biosolids to land and conveyance and storage of biosolids after processing is discussed in Sec. 14–9.

14–1 CHEMICAL CONDITIONING

Sludges and biosolids are conditioned expressly to improve their dewatering characteristics. For proper mechanical dewatering systems such as centrifugation, belt filter press, rotary press, screw press, and pressure filter press, as discussed in Sec. 14–2 , sludges and biosolids must be chemically conditioned. Chemical conditioning results in the flocculation (aggregation) of the sludge and biosolids to achieve efficient solid-liquid separation. Other conditioning methods such as heat treatment and freeze-thaw, have also been used to a limited extent or experimentally and are discussed in previous editions of this textbook. Chemical conditioning uses inorganic chemicals and water soluble polymers, or both. Inorganic conditioners, which include lime, ferric chloride, ferrous sulfate, aluminum sulfate, and aluminum chloride, are used mainly for recessed chamber filter press discussed in Sec. 14–2. However, in certain applications when biosolids are hard to dewater and require high polymer dosages, iron salts are often used (Abu-Orf et al., 2001). Polymers do not increase the dry solids content, while iron salts and lime can increase the dry solids content by 20 to 30 percent. A general discussion of polymers, the most used conditioning agents for mechanical dewatering, is the primary focus of this section. Following a general description of polymers, polymer characteristics, factors affecting conditioning, dosage determination, mixing, and polymer makeup and feeding are also considered.

Polymers

Water-soluble polymers are used most commonly for sludges and biosolids conditioning prior to mechanical dewatering. Polymers are also termed *organic polyelectrolytes* as they dissociate upon addition to water into negatively and positively charged species. Polymers are chains of individual monomer units and linked together in linear, branched, or structured configuration with functional groups located along the chains that determine the charge of the polymer. Because sludges and biosolids are mainly negatively charged, cationic polymers are used most commonly for conditioning. Cationic polyacrylamide (PAM) is the backbone of most, if not all, commercially available polymers for biosolids and sludge conditioning (WEF, 2012). These polymers upon dissociation release anions such as chloride leaving behind long chains of high molecular weight polymeric molecules that are positively charged. These long chains flocculate the suspended solids and the colloidal

Table 14–1

Distribution of polymer charge density and molecular weight[a]

Relative charge density and molecular weight	Charge density, mole %	Relative molecular weight
Very high	> 70–100	> 6,000,000–18,000,000
High	> 40–70	> 1,000,000–6,000,000
Medium	> 10–40	> 200,000–1,000,000
Low	< 10	< 200,000

[a] Adapted from WEF (2012).

material in the sludge biofloc resulting in better solids liquid separation, and is the reason polymers are called flocculants. The form of the cationic PAM can be dry, liquid, or emulsion. The choice of form of polymer to use depends on (1) achieving desired dewatering performance; (2) cost effectiveness; (3) space for storage and handling of the neat product; (4) requirements for polymer make down, aging, and feeding equipment; and (5) safety considerations.

Polymers are proprietary chemicals and vary according to electrical charge, charge density, molecular weight and molecular structure (WEF, 2012). Polymers that are used in sludge or biosolids conditioning are usually cationic, high charge density, and high molecular weight. Degrees of polymer charge density and molecular weight are reported in Table 14–1 (WEF, 2012). The molecular structure can be straight, branched, or structured. In high shear dewatering devices like centrifuges, branched or structured polymers are used. Polymer characterization methods to determine charge density and molecular weight are not commonly practiced in wastewater treatment plants. However, for large treatment facilities that spend significant amounts of money on polymers, onsite characterization is recommended to ensure receiving consistent performing product (Abu-Orf et al., 2009).

Factors Affecting Polymer Conditioning

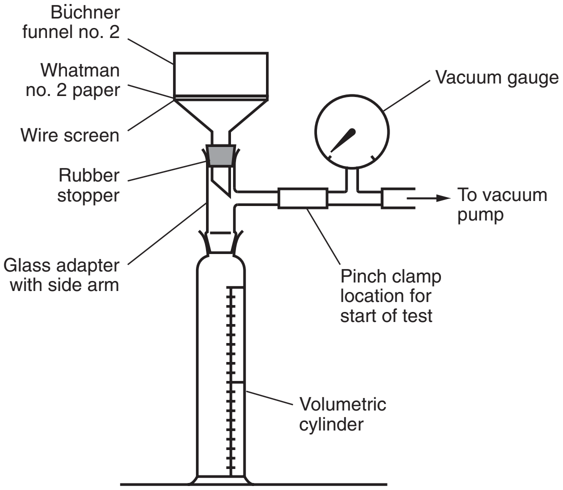
The selection of the type and dosage of polymers depends on the properties of the sludge and biosolids, mixing conditions between the chemicals and the sludge, and dewatering devices to be used. Important sludge and biosolids properties include source, solids concentration, electrical charge of sludge, biopolymer content, and rheology (WEF, 2012). The probable range of polymer doses required can be estimated based on the source of sludge or biosolids (e.g., primary sludge, waste activated sludge, and digested biosolids). Increasing the volatile solids destruction in aerobic and anaerobic digestion increases the polymer demand (Novak et al., 2004). Solids concentrations will affect the polymer dosage and its dispersion. The anionic electrical charge of the sludge or biosolids is an important factor in determining the cationic amount of polymer used. The biopolymer (protein and polysaccharides) content in the sludge and biosolids has a significant impact on polymer dose and dewatering. A linear relationship was found between the colloidal biopolymer content in the biosolids and the optimum polymer dose for dewatering and the dewatering potential (Novak et al., 2004). The method of dewatering affects the selection of the conditioning chemical because of the differences in mixing equipment used by various vendors and the characteristics of particular methods of dewatering.

Polymer Dosage Determination

The polymer dosage required for conditioning can be determined in the laboratory and need to be verified in full-scale trials. Laboratory tests used for selecting polymer dosage include the Buchner funnel test for the determination of specific resistance of filtration

Figure 14–1

Buchner funnel test apparatus used for the determination of the specific resistance of sludges and biosolids.



(see Fig. 14–1), capillary suction time test (CST) (Standard Methods 2012), and the standard jar test (ASTM, 2008). The Buchner funnel test is a method of testing sludge drainability or dewatering characteristics using various conditioning agents. The capillary suction test relies on gravity and the capillary suction of a piece of a standard thick filter paper to draw out water from a small sample of conditioned sludge or biosolids. The standard jar test, the easiest method to use, consists of testing standard volumes of sludge samples (usually 1 L) with different conditioner concentrations, followed by rapid mixing, flocculation, and settling using standard jar test apparatus. Other methods used successfully in laboratory and full scale for determination of optimum polymer dose for conditioning and dewatering include charge of the liquid stream (centrate or filtrate) as measured by streaming current detector (Abu-Orf and Dentel, 1997), viscosity of the liquid stream (Abu-Orf et al., 2003), and rheology of the conditioned sludge or biosolids (Abu-Orf and Ormeci, 2005). Laboratory or pilot-scale testing is recommended to determine the types of polymer and dose required, particularly for sludge and biosolids that may be difficult to dewater.

Mixing

The intimate and uniform mixing of sludge or biosolids and polymer is essential for proper conditioning. The intensity of the mixing must not break the flocculated material after it has formed, and the detention should be kept to a minimum so that sludge reaches the dewatering unit as soon after conditioning as possible. Mixing requirements vary depending on the dewatering method used. A separate mixing and flocculation tank is provided ahead of pressure filters; a separate flocculation tank may be provided for a belt filter press, or the polymer may be added directly to the sludge feed line of the belt filter press unit; and inline mixers are usually used with a centrifuge. It is generally desirable to provide at least two locations for the addition of conditioning chemicals.

In general, it has been observed that the type of sludge has the greatest impact on the quantity of chemical required. Difficult-to-dewater sludges that require larger doses of chemicals generally do not yield as dry a cake and have poorer quality of filtrate or centrate. Sludge types, listed in the approximate order of increasing conditioning chemical requirements, are as follows:

1. Untreated (raw) primary sludge
2. Untreated mixed primary and trickling filter sludge

3. Untreated mixed primary and waste-activated sludge
4. Anaerobically digested primary sludge
5. Anaerobically digested mixed primary and waste activated sludge
6. Aerobically digested mixed primary and waste activated sludge
7. ATAD biosolids
8. Aerobically digested waste activated sludge
9. Untreated waste activated sludge

Typical levels of polymer addition for various types of sludges using belt-filter press centrifuge, rotary press, and screw press dewatering can be found in Sec. 14–2. Actual dosages in any given case may vary considerably from the indicated values. Polymer dosages will also vary greatly depending on the molecular weight, ionic strength, and activity levels of the polymers used. Manufacturers should be consulted for applicability and dosage information.

Conditioning Makeup and Feed

Chemicals are most easily applied and metered in the liquid form. Dissolving tanks are needed if the chemicals are received as dry powder. In most plants, these tanks should be large enough for at least one day's supply of chemicals and should be furnished in duplicate. In large plants, tankage sufficient for one shift is usually adequate. The tanks must be fabricated or lined with corrosion-resistant material. Polyvinyl chloride, polyethylene, and rubber are suitable materials for tank and pipe linings for acid solutions. Metering pumps must be corrosion-resistant. These pumps are generally of the positive displacement type with variable speed or variable stroke drives to control the flowrate.

14–2 DEWATERING

Dewatering is a physical unit operation used to separate the solid matter and water in the sludge or biosolids resulting in a high solids content stream called "cake" and a liquid stream. The liquid stream contains fine, low-density solids and a high concentration of nutrients when anaerobically digested sludge is dewatered and is typically returned to the wastewater treatment system or treated separately (sidestream treatment, see Chap. 15) to reduce nutrient loading to the main treatment system. For effective solids liquid separation, chemical conditioning is required. Increasing the solids content of sludge and biosolids is mainly practiced for one or more of the following reasons:

1. The costs for trucking sludge and biosolids to the ultimate disposition site become substantially lower when the volume is reduced by dewatering.
2. Dewatered sludge and biosolids are generally easier to handle than thickened or liquid sludge. In most cases, dewatered sludge may be shoveled, moved about with tractors fitted with buckets and blades, and transported by belt conveyors.
3. Dewatering is required normally prior to the incineration of the sludge to increase the calorific value by removal of excess moisture.
4. Dewatering is required before composting to reduce the requirements for supplemental bulking agents or amendments.
5. Dewatering is required prior to thermal drying as it is cost effective to remove the water mechanically or by other means, compared to evaporating the water during drying.
6. In some cases, removal of the excess moisture may be required to render biosolids odorless and nonputrescible.
7. Dewatering is required prior to landfilling sludge and biosolids in monofills to reduce leachate production at the landfill site.

In mechanical dewatering devices, mechanically assisted physical means are used to dewater the sludge more quickly. Other dewatering devices rely on the application of electric and heat energy. Following a brief overview of dewatering, each of the major dewatering technologies is considered in this section.

Overview of Dewatering Technologies

To provide a perspective on the discussion of the individual dewatering technologies, it will be useful to first consider the fundamental principles of dewatering; some important factors in the selection of dewatering technologies, including the advantages and disadvantages of the various technologies; and the need for bench and pilot-sate testing.

Fundamental Principles of Dewatering. When considering the dewatering of sludge or biosolids, it is important to consider the various forms of water associated with the biosolids. In a relatively simplified overview, the four types of water associated with sludge, as proposed by Tsang and Vesiland (1990) and others and illustrated on Fig. 14–2(a), are (1) free water, (2) interstitial water, (3) surface water, and (4) bound water. Water not attached to particles that can be removed by gravitational forces, filtration, and centrifugation is known as *free water*. Water trapped within the sludge matrix is known as *interstitial water.* Water bound to the sludge particles by adsorption and adhesion is known as *surface water*. Intercellular and chemically bound water is known as *bound water*. The form of water that can be removed by the various dewatering technologies is illustrated on Fig. 14–2(b). Free and a portion of the interstitial water can be removed by physical means. Electro-dewatering can be used to remove interstitial and a portion of the bound water, depending on the adsorption forces. Thermal drying is required to remove the majority of bound water (Mahmoud et al., 2010).

Important Factors in Technology Selection. The selection of the dewatering device is determined by the type of sludge or biosolids to be dewatered, characteristics of the dewatered product, downstream processing, ultimate disposition, and the space available. The dewatering processes that are used commonly include centrifuges;

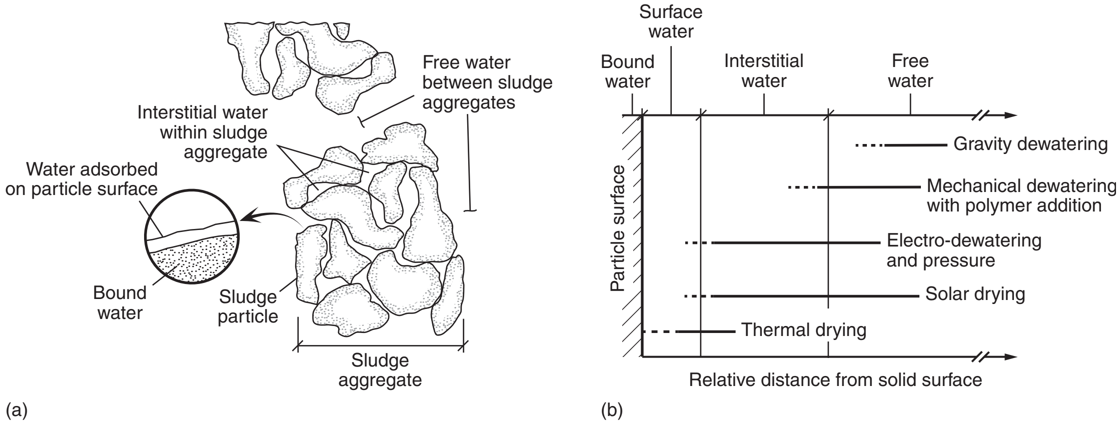


Figure 14–2

Overview of dewatering treated biosolids: (a) different forms of water associated with treated biosolids as proposed by Tsang and Vesiland (1990) and (b) potential operating regions for various technologies used for dewatering biosolids. The dashed portion represents the maximum potential achievable.

belt filter presses; rotary presses; screw presses; recessed-plate filter presses; electro-dewatering, a new innovative process; drying beds; and lagoons. Vacuum filtration, often used in the past for municipal sludge dewatering, has essentially been replaced by alternative mechanical dewatering equipment. The advantages and disadvantages of the various methods of sludge dewatering presented in this chapter are summarized in Table 14–2.

Table 14–2

Comparison of alternative methods for dewatering various types of sludge and biosolids[a]

Dewatering method	Advantages	Disadvantages
Solid bowl centrifuge	• Clean appearance, minimal odor problems, fast startup and shut down capabilities • Easy to install • Produces relatively dry sludge cake • Low capital cost-to-capacity ratio	• Scroll wear potentially a high maintenance problem • Requires grit removal and possibly sludge grinder in the feed stream • Skilled maintenance personnel required • Moderately high suspended solids content in centrate • Cannot observe dewatering zone to optimize/adjust performance
Belt filter press	• Low energy requirements • Relatively low capital and operating costs • Less complex mechanically and is easier to maintain • High pressure machines are capable of producing very dry cake • Minimal effort required for system shut down	• Hydraulically limited in throughput • Requires sludge grinder in feed stream • Very sensitive to incoming sludge feed characteristics • Short media life as compared to other devices using cloth media • Automatic operation generally not advised
Recessed plate filter press	• Highest cake solids concentration • Low suspended solids in filtrate • Simple operation • High solids capture rate	• Batch operation • High equipment cost • High labor cost • Special support structure requirements • Large floor area required for equipment • Skilled maintenance personnel required • Additional solids due to large chemical addition require disposal • Limitations on filter cloth life
Rotary Press	• Low speed 0.5 to 2.5 rev/min • Low noise $<$ 68 dBA • Enclosed design contains odors and aerosols • Relatively low energy use drive motor ranges from 0.56 to 15 kW (0.75 to 20 hp) depending on size of unit • Overdosing polymer does not clog screen and hinder dewatering • Washwater only used during shut down of system • Low shearing force reduces odors in dewatered cake stockpile	• Relatively large footprint per unit volume of dewatering capacity • Capacity limitations will require multiple units for wastewater facilities treatment facilities $> 19{,}000\ \text{m}^3/\text{d}$ (> 5 Mgal/d) • Cannot observe dewatering zone to optimize/adjust performance

(*continued*)

Table 14–2 (*Continued*)

Dewatering method	Advantages	Disadvantages
Screw Press	• Low speed 0.3 to 1.5 rev/min • Low noise < 68 dBA • Enclosed design with hinged access doors contains odors and aerosols • Low energy use drive motor ranges from 0.37 to 3.7 kW (0.5 to 5 hp) depending on size of unit • Overdosing polymer does not clog screen and hinder dewatering • Low shearing force reduces odors in dewatered cake stockpile	• Capacity limitations will require multiple units for wastewater facilities treatment facilities 19,000 m^3/d (> 5 Mgal/d) • Washwater required periodically throughout operating cycle • Cannot observe dewatering zone to optimize/adjust performance
Electro-dewatering	• Automatic operation • Good results for difficult sludge and biosolids • Mechanics are simple and easy to maintain • Odor improvement and pathogen kill on the sludge and biosolids • Some flexibility to incoming sludge characteristics • 3–5 times more energy efficient than dryers	• Batch operation • Moderate to high capital costs • Not particularly suited for larger plant 75,700 m^3/d (20 Mgal/d) and above • Limited final dryness achievable (max 45 to 50 percent DS) • Difficult to predict performance without bench scale testing • New technology • Requires odor treatment for the process off gases • Require predewatering, range of feed between 10 and 25 percent • Operational cost sensitive to local electricity tariff
Sludge drying beds	• Lowest capital cost method where land is readily available • Small amount of operator attention and skill required • Low energy consumption • Little to no chemical consumption • Less sensitive to sludge variability • Higher solids content than mechanical methods	• Requires large area of land • Requires stabilized sludge • Design requires consideration of climatic effects • Sludge removal is labor intensive
Sludge lagoons	• Low energy consumption • No chemical consumption • Organic matter is further stabilized • Low capital cost where land is available • Least amount of skill required for operation	• Potential for odor and vector problems • Potential for groundwater pollution • More land intensive than mechanical methods • Appearance may be unsightly • Design requires consideration of climatic effects

[a] Adapted in part from U.S. EPA (2000).

For smaller plants where land availability is not a problem, drying beds or lagoons are generally used. Conversely, for larger facilities or facilities situated on constricted sites, mechanical dewatering devices are often chosen. Odor control is an important design consideration as the level of odor release varies based on the type of sludge and the mechanical equipment selected. High shear dewatering and conveyance equipment can increase odor release, especially from anaerobically digested sludge (WERF, 2003) (see also Sec. 16–4 in Chap. 16).

Need for Bench and Pilot-Scale Testing. When particular types of sludge or biosolids must be dewatered mechanically, it is often difficult or impossible to select the optimum dewatering device and polymer dosage without conducting bench-scale or pilot studies. Bench-scale testing is usually conducted by manufacturers of dewatering equipment to narrow down the types of polymers and doses to be used in pilot testing. Trailer-mounted, full-size equipment is available from several manufacturers for field-testing purposes. In selecting the type of mechanical dewatering to be used, it is important not to rely on published industry standard performance information and data. Side-by-side pilot testing should be undertaken to select the most cost-effective dewatering device, suitable for the treatment plant sludge or biosolids. With side-by-side testing, dewatering devices can be compared on the same sludge or biosolids, as it is well established that sludge characteristics vary seasonally, if not daily, at some plants. Pilot testing should be designed carefully to determine solids throughput, optimum polymer dose, percent cake solids, and percent solids recovery, which are important factors in comparing capital and operation costs of the various dewatering devices.

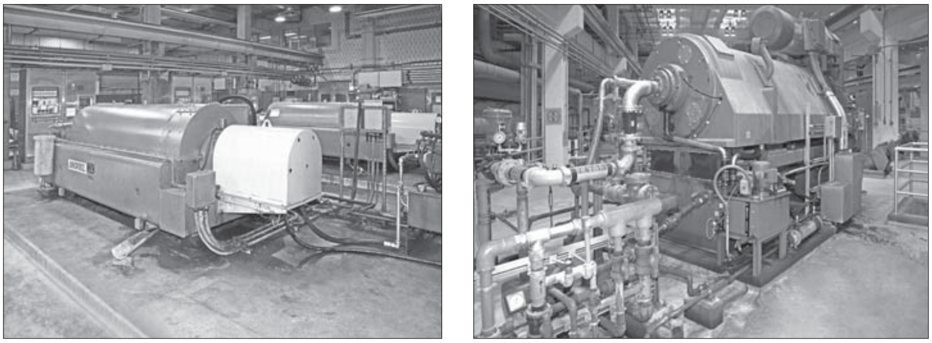
Centrifugation

The centrifugation process is used widely in industry for separating liquids of different density, thickening slurries, or removing solids. The process is applicable to the dewatering of wastewater sludges and has been used widely in both the United States and Europe. Solid-bowl centrifugal devices used for thickening sludge (see Sec. 13–6) may also be used for sludge and biosolids dewatering. In this section, standard solid-bowl and "high-solids" centrifuges are discussed. The high-solids centrifuge is a modification of the standard centrifuge.

Solid-Bowl Centrifuge. In the solid-bowl machine (see Figs. 14–3 and 14–4), biosolids or sludge is fed at a constant flowrate into the rotating bowl, where it separates into a dense cake containing the solids and a dilute liquid stream called "centrate." The centrate is returned to the wastewater treatment system or treated separately, if necessary.

Figure 14–3

View of typical solid bowl centrifuge dewatering installations.



(a)

(b)

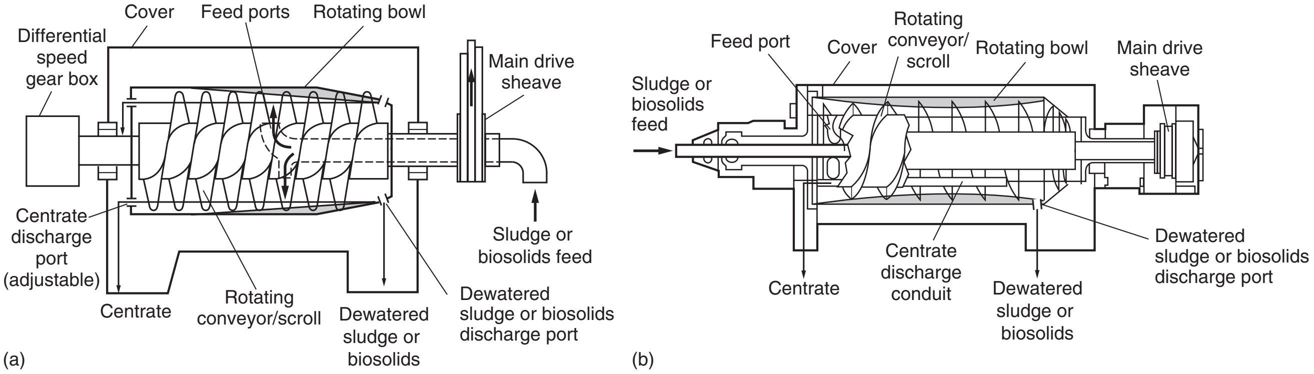


Figure 14–4

Schematic diagrams of two solid bowl centrifuge configurations for dewatering sludge: (a) countercurrent and (b) cocurrent.

The sludge cake is discharged from the bowl by a screw feeder into a hopper or onto a conveyor belt. Depending on the type of sludge or biosolids, solids concentration in the cake varies generally from 20 to 30 percent range. Cake concentrations above 25 percent are desirable for processing by incineration, drying, or by hauling to offsite processing, land application or disposition at a sanitary landfill.

Solid-bowl centrifuges are suitable generally for a variety of dewatering applications. Chemicals for conditioning are added to achieve the desired dewatering performance including cake solids and centrate quality and usually added to the feed line or within the bowl of the centrifuge. Dosage rates for conditioning with polymers vary from 1.0 to 25 g/ kg (2 to 50 lb/ton) of sludge (dry solids basis). Typical performance data for solid-bowl centrifuges are reported in Table 14–3.

Table 14–3

Typical dewatering performance for solid bowl centrifuges for various types of sludge and biosolids[a]

Type of feed	Feed solids, %	Cake solids, %	Polymer use, lb/ton dry TS	Polymer use, g/kg dry TS	Solids capture, %
Untreated sludge					
Primary	4–8	25–50	5–10	2.5–5	95+

[a] Adapted in part from U.S. EPA (2000) and feedback from centrifuge vendors.

High-Solids Centrifuge. High-solids (also called "high-torque") centrifuges are modified solid-bowl centrifuges that are designed to produce a dryer solids cake. These units have a slightly longer bowl length to accommodate a longer "beach" section, a lower differential bowl speed to increase residence time, and a modified scroll to provide a pressing action within the beach end of the unit. In some cases, the high-solids units are capable of achieving solids contents in excess of 30 percent in dewatering municipal wastewater sludges, although a higher polymer usage may be required.

Design Considerations. Centrifugation design is based on either helical or axial flow. Two basic designs of helical centrifuges are used: countercurrent flow and cocurrent flow [see Figs. 14–4 (a) and (b)]. The main difference in the designs is the location of the feed ports, removal of centrate, and internal flow patterns of the liquid and solid phases. In the countercurrent design, the feed slurry enters axially at the junction of the cylindrical conical section; solids travel to the conical end while the liquid phase moves in the opposite direction. In axial flow countercurrent centrifuges, flights are mounted on spokes in the path from the feed zone to the centrate dams. These flights reduce the flow velocity, resulting in enhanced separation. This design allows centrifuges to handle variations of the feed rate without needing to change the dams. As a result, axial flow is the most common type of centrifuge design (WEF, 2012). In the cocurrent design, the solid phase travels the full length of the bowl as does the liquid phase. Cocurrent centrifuge designs are seldom used because of maintenance problems (WEF, 2012).

Process Variables. Process variables affecting centrifuge performance, as measured by the sludge cake solids and TSS recovery, include feed flowrate, rotational speed, differential speed of the scroll, depth of the settling zone, conditioning dose, and the physicochemical properties of the suspended solids and suspending liquid. Important properties are particle size and shape, particle density, temperature, and liquid viscosity.

Selection of units for plant design is dependent on manufacturer's rating and performance data. Several manufacturers have portable pilot units, which can be used for field testing if sludges or biosolids are available. Unfortunately, biosolids or sludges from similar treatment processes but in different localities may differ markedly from each other. For this reason, pilot-plant tests as previously discussed should be conducted whenever possible before final design decisions are made.

Other Design Considerations. The area required for a centrifuge installation is less than that required for other dewatering devices of equal capacity, and the initial cost is lower. Higher power usage costs will partially offset the lower initial cost. Special consideration must also be given in providing sturdy foundations and soundproofing because of the vibration and noise that result from centrifuge operation. An adequate electric power source is required because large motors may be used.

Because centrifuges are enclosed, on-site odor generation may be better contained as compared to other types of dewatering systems. Ventilation of the centrifuge facility to control potential odors and moisture accumulation should be provided, however. On the other hand, cake solids produced from high solids centrifuges are more odorous compared to other dewatering devices, which could adversely affect beneficial use methods such as land application. Moreover, sudden increase in pathogen indicator organisms in cake solids after anaerobic digestion was observed after centrifugation (WERF, 2008a).

Combined Centrifuge Process. Technologies that combine centrifuge dewatering with flash air drying are available commercially. It is reported that these systems are able to process sludges or biosolids with total solids ranging from 2 to 7 percent and produce a

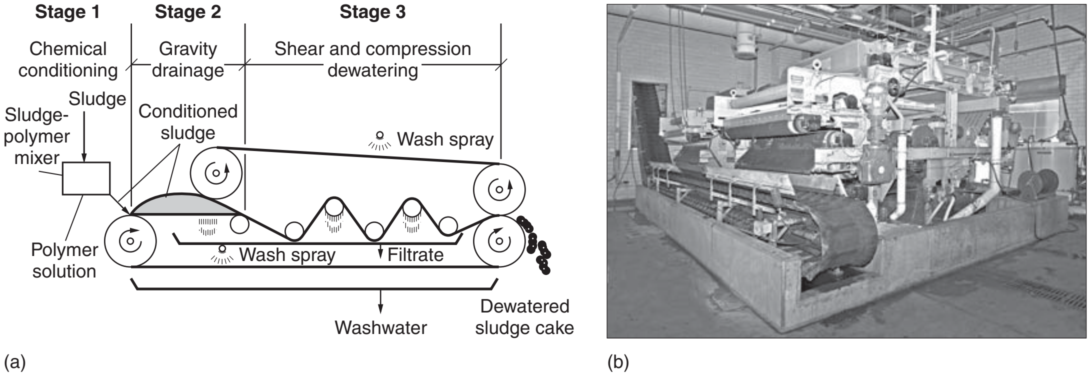

Figure 14–5

Belt press dewatering: (a) schematic of the three basic stages of belt press dewatering (b) view of a typical installation.

product with 60 to 90 percent dryness. Currently (2013), there is no installation in North America.

Belt-Filter Press

Belt-filter presses (BFPs) are continuous-feed dewatering devices that use the principles of gravity drainage and mechanically applied pressure to dewater chemically conditioned sludges or biosolids (see Fig. 14–5). The belt-filter press was introduced in the United States in the early 1970s and has become one of the predominant sludge dewatering devices. It has proven to be effective for almost all types of municipal wastewater sludge and biosolids.

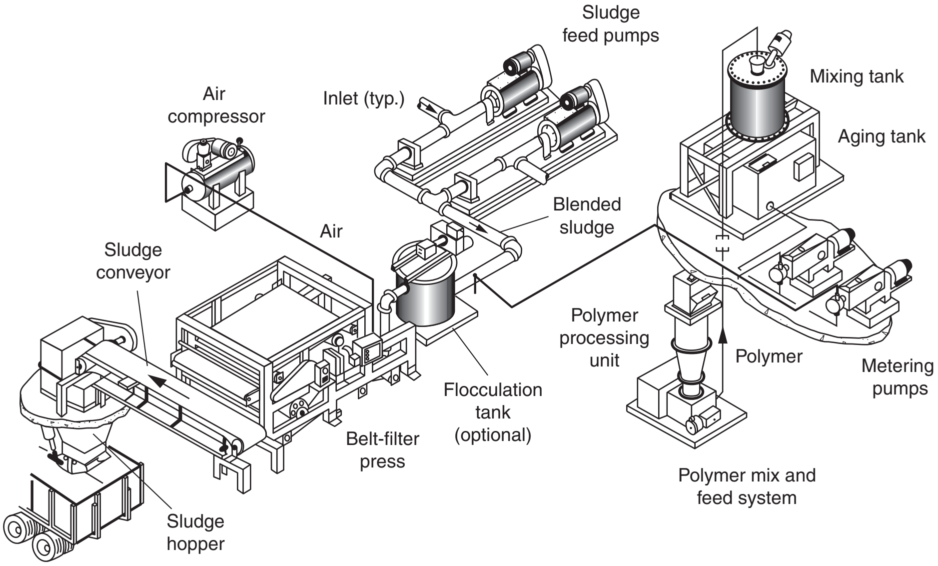
Description. In most types of BFPs, conditioned sludge or biosolids are first introduced on a gravity drainage section where it is allowed to thicken. In this section, a majority of the free water is removed by gravity. Following gravity drainage, pressure is applied in a low-pressure section, where the sludge is squeezed between opposing porous cloth belts. On some units, the low-pressure section is followed by a high-pressure section where the sludge is subjected to shearing forces as the belts pass through a series of rollers. The squeezing and shearing forces thus induce release of additional quantities of water from the sludge. Many vendors also offer systems with three belts which allow for independent control of the gravity section from the pressure section. The three belt system is ideal for dilute sludges. Improved dewatering can be achieved with this design as each zone can be optimized independently. The final dewatered sludge cake is removed from the belts by scraper blades.

System Operation and Performance. A typical BFP system consists of sludge feed pumps, polymer feed equipment, belt filter press, sludge cake conveyor, and support systems (sludge feed pumps, washwater pumps, and compressed air). Most units do not use a conditioning tank. A schematic diagram of a typical two belt-filter press installation is shown on Fig. 14–6.

Many variables affect the performance of the BFP: sludge or biosolids characteristics, method and type of chemical conditioning, pressures developed, machine configuration (including gravity drainage), belt porosity, belt speed, and belt width. The BFP is sensitive to wide variations in sludge characteristics, resulting in improper conditioning and reduced dewatering efficiency. Blending facilities should be included in the system design where

Figure 14–6

Schematic diagram of a complete belt press dewatering system.



the sludge or biosolids characteristics are likely to vary widely. Based on actual operating experience, it has been found that the solids throughput is greater and the cake dryness is improved with higher solids concentrations in the feed sludge or biosolids. Typical BFP performance data for various types of sludge and biosolids are reported in Table 14–4.

Table 14–4

Typical dewatering performance for belt filter presses[a]

[a] Based on feedback from belt filter press vendors.

[b] Polymer needs based on high molecular weight polymer (100 percent strength, dry basis).

Design Considerations. BFPs are available in metric sizes from 0.5 to 3.0 m in belt width. The most common size used for municipal sludge applications is 2.0 m. Solids loading rates vary from 180 to 1600 kg/m·h (400 to 3500 lb/m·h) depending on the sludge type and feed concentrations. Hydraulic throughput based on belt width ranges from 110 to 640 L/m·min (30 to 170 gal/m·min). Design of a BFP is illustrated in Example 14–1.

Safety considerations in design should include adequate ventilation to remove hydrogen sulfide or other gases mainly when dewatering undigested sludges, and equipment guards to prevent loose clothing from being caught between the rollers.

EXAMPLE 14–1 **Belt-Filter Press Design** A wastewater treatment plant produces 75,000 L/d of thickened biosolids containing 3 percent solids. A belt-filter press installation is to be designed based on a normal operation of 8 h/d and 5 d/wk, a belt-filter press loading rate of 275 kg/m·h, and the following data. Compute the number and size of belt-filter presses required and the expected solids capture, in percent. Determine the daily hours of operation required if a sustained 3-d peak solids load occurs.

1. Total solids in dewatered sludge = 22 percent.
2. Total suspended solids concentration in filtrate = 900 mg/L = 0.09 percent.
3. Washwater flowrate = 90 L/min per m of belt width.
4. Specific gravities of sludge feed, dewatered cake, and filtrate are 1.02, 1.07, and 1.01, respectively.

Solution

1. Compute average weekly sludge production rate.

$$\text{Wet biosolids} = (75{,}000\text{ L/d})(7\text{ d/wk})(10^3\text{ g/1 L})(1\text{ kg/}10^3\text{ g})(1.02) = 535{,}500\text{ kg/wk}$$

$$\text{Dry solids} = (535{,}500\text{ kg/wk})(0.03) = 16{,}065\text{ kg/wk}$$

2. Compute daily and hourly dry solids-processing requirements.

$$\text{Daily rate} = (16{,}065\text{ kg/wk})\left(\frac{1\text{ wk}}{5\text{ operating d}}\right) = 3213\text{ kg/d}$$

$$\text{Hourly rate} = \frac{(3213\text{ kg/d})}{(8\text{ h per operating d})} = 401.6\text{ kg/h (8 h operating d)}$$

3. Compute belt-filter press size 3

$$\text{Belt width} = \frac{(401.6\text{ kg/h})}{(275\text{ kg/m·h})} = 1.46\text{ m}$$

Use one 1.5-m belt-filter press and provide one identical size for standby.

4. Compute filtrate flowrate by developing solids balance and flow balance equations.
   a. Develop daily solids balance equation.

Solids in sludge feed = solids in sludge cake + solids in filtrate

$$3213\text{ kg/d} = (S\text{ kg/d})(0.22) + (F\text{ kg/d}) \times (0.0009)$$

$$3213\text{ kg/d} = (0.22)(\text{S}) + (0.0009)(F)$$

where S = sludge cake flowrate (wet), kg/d
F = filtrate flowrate (wet), kg/d

b. Develop mass flowrate equation.

Sludge flowrate + washwater flowrate = filtrate flowrate + cake flowrate
Daily sludge flowrate = (535,500 kg/wk)/(5 d/wk) = 107,100 kg/d
Washwater flowrate = (90 L/min·m)(1.5 m)(60 min/h)(8 h/d)(1 kg/L)(1.0)
= 64,800 kg/d
107,100 kg/d + 64,800 kg/d = 171,900 kg/d = $F + S$

c. Solve the mass balance and flowrate equations simultaneously.
First solve S in terms of F per the flowrate equation in 4.b.

$S = 171{,}900\ \text{kg/d} - F$

Next solve for F from the solids balance equation in 4.a.

$$\begin{aligned}3213\ \text{kg/d} &= 0.22\,(171{,}900\ \text{kg/d} - \text{F}) + 0.0009(\text{F})\\ &= 37{,}818\ \text{kg/d} - 0.2191(\text{F})\\ F &= 157{,}942\ \text{kg/d}\\ &= (157{,}942\ \text{kg/d})/(1\ \text{kg/L})/(1.01) = 159{,}521\ \text{L/d}\end{aligned}$$

5. Determine solids capture.

$$\text{Solid capture} = \frac{\text{solids in feed} - \text{solids in filtrate}}{\text{solids in feed}} \times 100$$

$$= \frac{[(3213\ \text{kg/d}) - (157{,}942\ \text{kg/d})(0.0009)]}{(3213\ \text{kg/d})} \times 100$$

$= 95.6\%$

6. Determine operating requirements for sustained peak biosolids load.

a. Determine peak 3-d load.
From Fig. 3–14 (b), the ratio of peak to average mass loading for 3 consecutive days is 2. The peak load is (75,000 L/d) (2) = 150,000 L/d.

b. Determine daily operating time requirements, neglecting sludge in storage.

$$\begin{aligned}\text{Dry solids per day} &= (150{,}000\ \text{L/d})(1\ \text{kg/L})(1.02)(0.03)\\ &= 4590\ \text{kg/d}\end{aligned}$$

$$\text{Operating time} = \frac{(4590\ \text{kg/d})}{(275\ \text{kg/m·h})(1.5\,\text{m})} = 11.1\ \text{h/d}$$

The operating time can be accomplished by running the standby belt-filter press in addition to the duty press, or operating the duty press for an extended shift.

Comment The value of sludge storage is important in dewatering applications because of the ability to schedule operations to suit labor availability most efficiently. Scheduling sludge dewatering operations during the day shift is also desirable if sludge has to be hauled off-site.

Rotary Press

The rotary press as a dewatering device for municipal sludges and biosolids has been adapted since 1994 with the first installation at the City of Montreal, Canada. Similar to centrifuges and BFPs, the rotary press feed solids are typically conditioned with cationic polymer that is injected into the feed upstream of the inlet to the dewatering unit. A typical process flow diagram for a rotary press system is shown on Fig. 14–7(a). Because rotary press systems are totally enclosed, they provide enhanced safety, odor containment, and relatively low noise levels compared with some other types of sludge or biosolids dewatering systems discussed in this textbook.

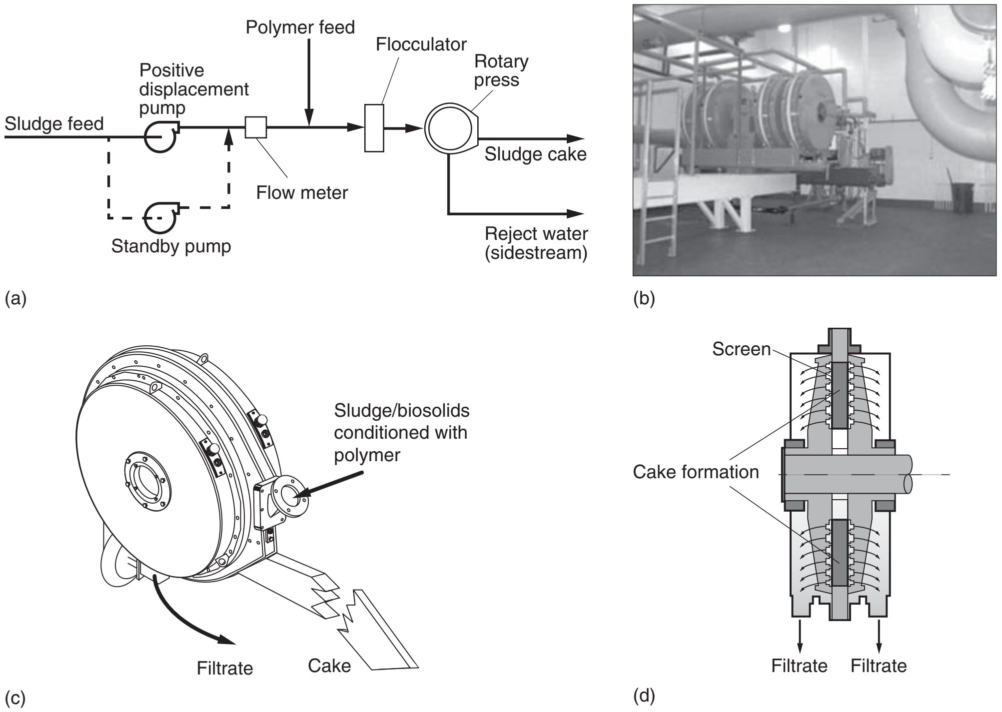

Figure 14–7

Rotary press for sludge dewatering: (a) schematic process flow diagram, (b) view of typical installation (courtesy of Scarborough Sanitart District, Scarborough ME), (c) view of a rotary press unit, and (d) cross-section through press (courtesy of Fournier Industries, Inc.).

Description. The rotary press is a slow-speed, enclosed, modular unit. The sludge or biosolids are fed into the unit at a relatively low pressure into the space between the two parallel filter screens. The sludge or biosolids are typically fed into a cylindrical coated carbon steel containment vessel that has a rectangular cross section. The solids within each module are retained between two parallel rotating stainless steel screens. The flocculated slurry material advances forward within the rotating channel that is formed between the parallel screens, and the filtrate passes out through sides of the screens. The sludge travelling around the channel (between the rotating screens) continues to be dewatered. The frictional force of the slow-moving screen assembly and the adjustable outlet restriction creates back pressure that forces additional filtrate out through the screen. The solids retained between the screens are dewatered, effectively forming an extrusion of relatively dry dewatered cake. Washwater is required intermittently to clean the screens and flush the solids from the unit during shutdown. A cutaway view of the typical rotary press is shown on Fig. 14–7(d).

Design Considerations. The design of the rotary press dewatering system is affected by a number of factors. These include quantity of sludge or biosolids, feed concentration, characteristics of sludge (digested or undigested, primary sludges or secondary sludges or both), safety, allowable noise levels, allowable odor levels, desired operating schedule, level of automation, space availability, reliability and redundancy requirements, washwater quality and availability, filtrate quality and treatment requirements, manufacturers' local service capabilities, and budgetary constraints.

The quantity of sludge or biosolids should be established at the beginning of the design process. The quantities should be developed for both current operation and projected future conditions. The characteristics of the sludges or biosolids that will be dewatered are an important consideration. The digested biosolids and raw secondary sludges are typically the most difficult to dewater effectively. Conversely, the presence of primary sludges tends to aid the dewatering process. The operating schedule at the facility, level of automation, reliability/redundancy requirements, and physical space availability need consideration when selecting the system and number of units. Washwater is used intermittently to flush the rotating screen assemblies during the shutdown sequence. The amount of washwater needed is relatively small, typically 190 L/min (50 gal/min) per channel. The time required for the flushing sequence is approximately 5 min per channel per d. All of the channels are normally flushed simultaneously, although sequential flushing can be used if the washwater supply has a capacity limitation. The units typically are offered with a single-channel, a dual-channel, a four-channel and a six-channel configuration. Special three- and five-channel units can also be provided, but the inlet configuration can create a flow imbalance due to the unequal number of channels on each side of the inlet connection. The screen diameter ranges from 460 to 1220 mm (18 to 48 in.) depending on the selected manufacturer. The effective dewatering area for various rotary press configurations is reported in Table 14–5.

The maximum hydraulic loading limit for a rotary press is approximately 8.5 m/h (3.5 gal/min·ft^2) at a total solids feed concentration of 3 percent. The maximum solids' loading is approximately 244 – 254 kg/h·m^2 (50 – 52 lb/h·ft^2). To optimize cake dryness and minimize polymer usage, rotary presses are normally operated below the maximum hydraulic and solids loading criteria. The typical average operating hydraulic loading rate for a rotary press system is approximately 2.4 m/h (1.0 gal/min·ft^2) at a total solids feed concentration of 4 percent and approximately 3.7 m/h (1.5 gal/min·ft^2) at a total solids feed concentration of 2 percent.

As discussed earlier, the types of sludges and biosolids to be dewatered have a significant impact on the actual allowable hydraulic loading, solids loading, polymer use, and dewatered cake moisture content. The characteristics and composition of sludge and biosolids vary from facility to facility so on-site pilot testing is recommended if strict performance and capacity criteria will be specified for the rotary press equipment.

System Operation and Performance. A typical rotary press system consists of a sludge feed pump, flow metering, polymer feed equipment, conditioning system (either inline or tank designs can be used), the rotary press, a dewatered cake conveyor (if direct discharge to a container or truck is not feasible), compressed air for valve control functions,

[a] Based on feedback from rotary press vendors.

electrical power for the drive components, and control/signal wiring for remote monitoring or operational control. A typical rotary press installation is shown on Fig. 14–7(b).

Rotary press process variables that can be adjusted to optimize performance or minimize operational costs include feed pump speed and flow, polymer concentration, polymer feed pump speed and flow, polymer mixing intensity, screen rotational speed, cake discharge outlet pressure, and washwater flushing frequency and duration. The performance of the unit is affected by each of these variables. In optimizing the performance of a rotary press, it is important to change one variable at a time so that the effect of each variable can be evaluated fully. The typical performance for a rotary press system varies from facility to facility and is affected by the type of solids feed, the process variables listed above, and the physical condition of the equipment and controls. Typical operating performance data for a rotary press system is reported in Table 14–6.

Screw Press

The screw press was adapted from industrial applications in 1990 for dewatering wastewater sludges or digested biosolids. The screw press feed solids are typically conditioned with cationic polymer that is injected into the feed upstream of the inlet to the dewatering unit. A typical process flow diagram for a screw press system is shown on Fig. 14–8(a).

Description. The screw press is a slow-speed, enclosed cylindrical unit. The sludges or biosolids are fed into the unit at a relatively low pressure into a stationary wedge wire screening basket with a rotating screw assembly that transfers the sludges or biosolids through the wedge wire screening basket. The flocculated material advances forward up along the rotating screw assembly. The filtrate passes out through the bottom and sides of the wedge wire screen. The sludges travelling along the screw continue to be dewatered. The frictional force of the slow moving screw assembly and the adjustable outlet restriction

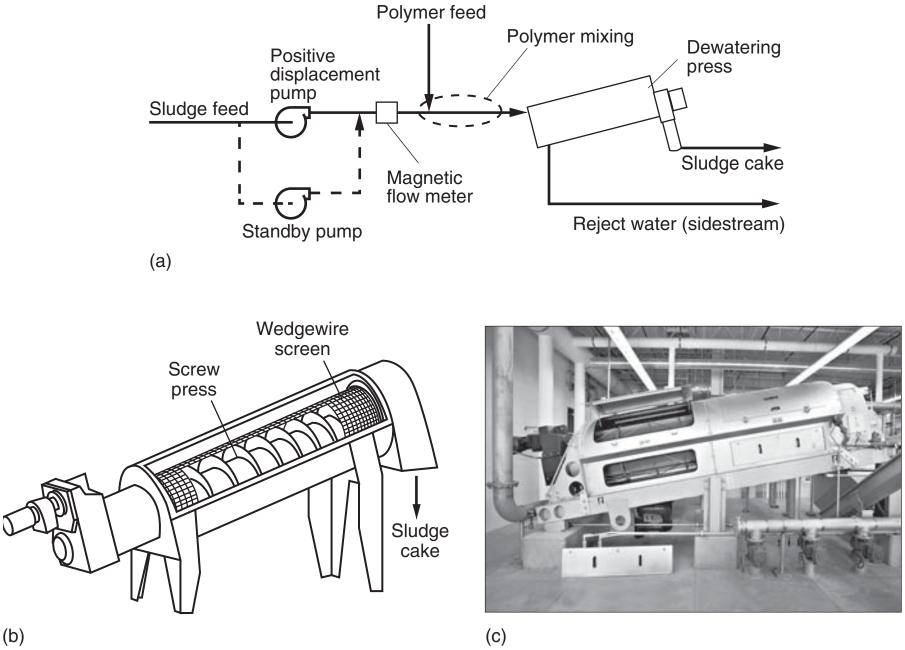

Figure 14–8

Screw press for sludge dewatering: (a) schematic process flow diagram (courtesy of PW Tech, Inc.), (b) cutaway view (adapted from Huber Technology Inc.) and (c) view of inclined screw press.

creates back pressure that forces additional filtrate out through the screen near the outlet end of the unit. The dewatered sludges form an extrusion of relatively dry dewatered cake. Washwater is required intermittently to clean the wedge wire screening assembly and flush the solids from the unit throughout the normal operating cycle. Units are available in either horizontal or inclined configuration depending on the manufacturers' preference. A cutaway view of a typical screw press is illustrated on Fig. 14–8(b). A view of a typical screen press is presented on Fig. 14–8(c).

Design Considerations. The design of the screw press dewatering system will be affected by a number of factors. These include quantity and feed concentration of sludges, volatile solids (VS) content, sludge characteristics (digested or undigested, primary sludges or secondary sludges or both), safety considerations, allowable noise and odor levels, facility operating schedule, extent of automation, building space availability, redundancy and reliability requirements, quality and availability of washwater, required filtrate quality and treatment, local service capabilities of the manufacturer, and financial constraints.

Similar to other types of dewatering systems the quantities of sludges or biosolids need to be established at the beginning of the design process. The quantities should be developed for both current operation, and projected future conditions. The characteristics of the material to be dewatered are an important consideration. Digested biosolids and raw secondary sludges are typically more difficult to effectively dewater than primary sludges. The screw press systems are low speed, totally enclosed units that provide enhanced safety, odor containment, and relatively low noise levels compared with some other types of dewatering systems discussed in this textbook. The schedule of operation, automation requirements, redundancy and reliability considerations, number of units, and building space availability need due consideration. The screw press intermittently utilizes washwater to flush the stationary wedge wire screen assembly regularly throughout the normal operating cycle. The amount of washwater needed is relatively small. Typically a flowrate of 7 to 45 L/min (2 to 12 gal/min) at a pressure between 2.8 to 5.5 bar-gauges (40 to 80 lb/in.^{2}-gauge) is required. The screen is flushed for approximately 15 s every 10 min during its normal operating cycle.

The units typically are offered with a single screw, dual screw, inclined, or horizontal configuration depending on the manufacturer that is selected. Units are available in various sizes and a single unit is capable of processing up to 500 kg/h (1100 lb/h) although the units may be hydraulically limited for thin waste activated sludges (< 1 percent TS). Dual screw units have a flow capacity that is approximately twice the capacity of the single screw configuration units for a given screw diameter and screen length.

As noted, the type of sludges or biosolids to be dewatered has a significant impact on the actual allowable hydraulic loading, solids loading, polymer use, and dewatered cake moisture content. The characteristics and composition of sludges or biosolids vary from facility to facility, so on-site pilot testing of the screw press system is recommended if strict performance and capacity criteria are to be specified for the screw press equipment.

System Operation and Performance. A typical screw press system consists of a sludge feed pump, flow metering, polymer feed equipment, inline solids conditioning system, a dewatered cake conveyor (if direct discharge to a container or truck is not feasible), electrical power for the drive components, and control/signal wiring for remote monitoring or operational control.

Screw press process variables that can be adjusted to optimize performance or minimize operational costs include feed pump speed and flow, polymer concentration, polymer feed pump speed and flow, polymer mixing intensity, screw rotational speed, cake discharge outlet pressure, and washwater flushing frequency and duration. The typical performance of for a screw press system varies from facility to facility and is impacted by the type of feed, the process variables listed above, and the physical condition of the equipment and controls. Typical operating performance data for a screw press system are presented in Table 14–7.

Table 14–7

Filter Presses

In a filter press, dewatering is achieved by forcing the water from the sludge or biosolids under high pressure. Advantages and disadvantages of filter presses are included in Table 14–2. When requiring cake solids contents greater than 35 percent on a routine basis, use of filter press is often dictated as other mechanical dewatering devices cannot achieve this high solids content consistently.

Various types of filter presses have been used to dewater sludges or biosolids. The two types used most commonly are the fixed-volume and variable-volume recessed-plate filter presses.

Fixed-Volume, Recessed-Plate Filter Press. The fixed-volume, recessed-plate filter press consists of a series of rectangular plates, recessed on both sides, that are supported face to face in a vertical position on a frame with a fixed and movable head [see Fig. 14–9(a)]. A filter cloth is hung or fitted over each plate. The plates are held together with sufficient force to seal them to withstand the pressure applied during the filtration process. Hydraulic rams or powered screws are used to hold the plates together.

In operation, chemically conditioned sludge or biosolids is pumped into the space between the plates, and pressure of 700 to 2100 kPa (100 to 300 $\text{lb}_f/\text{in.}^2$) is applied and maintained for 1 to 3 h, forcing the liquid through the filter cloth and plate outlet ports. The plates are then separated and the cake is removed. The filtrate normally is returned to the influent of the treatment plant. The cake thickness varies from about 25 to 38 mm (1 to 1.5 in.), and the moisture content varies from 45 to 70 percent. The filtration cycle time varies from 2 to 5 h and includes the time required to (1) fill the press, (2) maintain the press under pressure, (3) open the press, (4) wash and discharge the cake, and

Figure 14–9

(5) close the press. Depending on the degree of automation incorporated into the machine, operator attention must be devoted to the filter press during feed, discharge, and wash intervals.

Variable-Volume, Recessed-Plate Filter Press. Another type of filter press used for wastewater sludge dewatering is the variable-volume recessed-plate filter press, commonly called the "diaphragm press." This type of filter press is similar to the fixed-volume press except that a rubber diaphragm is placed behind the filter media, as shown on Fig. 14–9(d). The rubber diaphragm expands to achieve the final squeeze pressure, thus reducing the cake volume during the compression step. Generally about 10 to 20 min are required to fill the press and 15 to 30 min of constant pressure are required to dewater the cake to the desired solids content. Variable-volume presses are generally designed for 690 to 860 kN/m^2 (100 to 125 lb$_f$/in.^{2}) for the initial stage of dewatering followed by 1380 to 2070 kN/m^2 (200 to 300 lb$_f$/in.^{2}) for final compression. Variable-volume presses can handle a wide variety of sludges and biosolids with good performance results but require considerable maintenance (WEF, 2010).

Design Considerations. Several operating and maintenance problems have been identified for recessed-plate filter presses ranging from difficulties in the chemical feed and sludge-conditioning system to excessive downtime for equipment maintenance. Features that should be considered in the design of a filter press installation include (1) adequate ventilation in the dewatering room (6 to 12 air changes per hour are recommended depending on the ambient temperature), (2) high-pressure washing systems, (3) an acid wash circulation system to remove calcium scale when lime is used, (4) a grinder ahead of the conditioning tank, (5) cake breakers or shredders following the filter press (particularly if the dewatered sludge is incinerated), and (6) equipment to facilitate removal and maintenance of the plates. Other design criteria are can be found in WEF, (2010).

Combined Diaphragm Press with Vacuum Drying. Two components to the traditional diaphragm filter press are implemented with this combined process shown schematically on Fig. 14–10. First sludge is introduced into the press, and internal filter

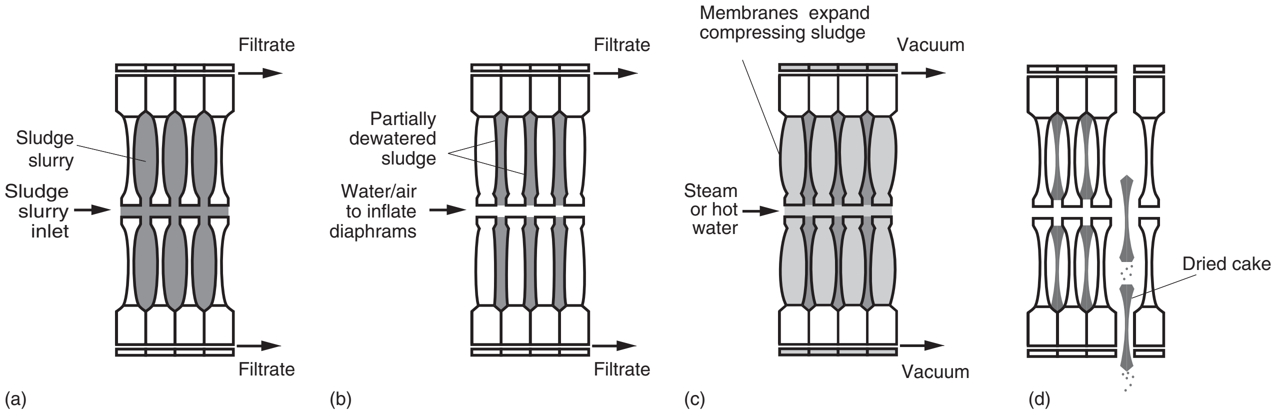

Figure 14–10

Schematic of the operation of variable-volume vacuum assisted recessed-plate filter press: (a) sludge slurry is introduced into the press (b) flexible membrane is expanded with air or water, (c) steam is added along with vacuum to reduce the boiling point of the water and, thus, further dewater the sludge, and (d) at the end of the cycle the filter press is open, and dried sludge is collected in the bin below the press.

plate diaphragms are inflated with air or water to squeeze out free water Next, hot water or steam is introduced to raise the temperature of the sludge while a vacuum is applied to lower the boiling point of water. Vaporized water in sludge is drawn out through the vacuum. At the end of the cycle, the press is opened to drop the dried sludge onto a receiving bin. There are several installations of this technology in North America and Europe (ca. 2013).

Electro-Dewatering

Electric field-assisted dewatering, also called electro-dewatering, is used to dewater municipal sludges and biosolids, industrial residuals, as well as less conventional biomass. The process can be used to dewater raw sludges or digested biosolids. The basic principle of operation, the commercial application of the principle, design considerations, and some performance data are presented and discussed below.

Description. In practice, because the bonding forces and the particle size of the sludge or biosolids, bound water cannot be removed readily by mechanical means. Electro-dewatering involves the application of a direct voltage to sludge or biosolids placed between two electrodes as illustrated on Fig. 14–11. Negatively charged sludge or biosolids move towards or gather at the positive electrode (anode). Positively charged water molecules move towards or gather at the negative electrode (cathode). At the negative electrode water moves through the filter cloth which covers the electrode. The filter cloth on the negative electrode does not clog, a common problem in mechanical filtration, as the sludge or biosolids particles are repelled by the negative electrode (Yoshida, 1993). Pressure is applied to the material to be dewatered to further accelerate the process and to allow the applied DC current to move more uniformly from the anode to the cathode [see Fig. 14–11(a)]. The advanced dewatering capability of electro-dewatering process as compared to other and other dewatering technologies was illustrated previously on Fig. 14–2(b).

Commercial Implementation of the Electro-Dewatering Process. In the most common commercial configurations encountered, a typical electro-dewatering system consists of a feeding module, the electro-dewatering unit, a high pressure wash system, a rectifier, a dewatered cake conveyor (if direct discharge to a container or truck is not feasible), compressed air for valve control functions, electrical power for the drive components and control/signal wiring for remote monitoring or operational control. A typical schematic of an electro-dewatering system is shown on Fig. 14–12(a).

Referring to Fig. 14–12(a), sludges or biosolids are fed in a hopper built as part of a feeding module. At the beginning of each treatment cycle, a conveyor system is actuated and

Figure 14–11

the feeding module extrudes a thin and uniform layer of the material to be dewatered on the filtering belt, to a predetermined thickness. Once the newly formed cake is moved into the treatment area as shown on Fig. 14–12 (a), power-blocks move down on the cake and apply a predetermined pressure. The applied pressure also allows DC current (generated by a rectifier) to flow through the cake and the filtering belt, between the anodes and the cathodes. The DC current is applied at predetermined levels for a controlled period of time until the required cake dryness is achieved, after which the power-blocks are lifted back to their upper position and the treated cake is discharged from the system. The filtering belt is cleaned using a high pressure wash system (filtrated process water or potable water) during its displacement. The high pressure wash system is also used daily to clean the cathodes and the equipment, during programmed automatic wash sequences and before a shutdown sequence. Machine controls and instrumentation ensure management of operating parameters such as pressure, voltage, current, treatment time, belt speed, and automatic wash cycles.

Design Considerations. Important design considerations for the electro-dewatering process are summarized in Table 14–8 and discussed briefly below. Specific design parameters are presented in Table 14–9. The quantity of sludge or biosolids should be established at the beginning of the design process. The quantities should be developed for both current operation and projected, future conditions. The characteristics of the sludge or biosolids that will be dewatered are the most important consideration. Electro-dewatering is particularly suited for processing digested biosolids and/or secondary sludge, typically the most difficult to dewater effectively with conventional mechanical dewatering processes. Electro-dewatering systems, such as shown on Fig. 14–12(b), are totally enclosed for enhanced safety and odor containment. Also the footprint is small and energy usage is relatively low as compared with thermal systems, discussed later in this chapter.

Integrating electro-dewatering into biosolids processing is worthy of consideration, particularly for small-to-mid-sized facilities typically less than 57,000 m^3/d (15 Mgal/d) range (Eschborn, 2011). For any size facility, factors favoring integrating electro-dewatering include high biosolids ultimate disposal costs and a desire to produce a Class A product. It is recommended to contact manufactures at the early stages of design process and obtain initial results from laboratory bench scale equipment. Piloting to evaluate the

Table 14–8

Design considerations for electro-dewatering[a]

Item	Comment
Quantity of sludge and biosolids	The quantity of solids should be established at the beginning of the design process. The quantities should be developed for both current operation and projected, future conditions.
Characteristics of the feed sludge or biosolids	Important feed characteristics include conductivity, pH, particles sizes, concentration, ionic composition and polymer used. Although unit capacity can sometimes be reduced with a wetter feed solids, better treatment response is commonly observed with feeds at 12 to 20 percent TS.
Type of sludge or biosolids	Electro-dewatering is particularly suited for processing digested biosolids and/or secondary sludge which are difficult to dewater effectively by conventional mechanical means.
Sludge or biosolids pretreatment	Conventional mechanical dewatering equipment such as belt filter presses, centrifuges, screw presses or rotary presses are used upstream of the electro-dewatering.
Final dryness desired	Depends on the ultimate use of the dewatered material. Cake solids are typically in the range between 25 and 50 percent TS.
Expected volume reduction	Typically, volume reduction will vary from 50 to 75 percent.
Filtrate characteristics and treatment requirements	The filtrate contains relatively high concentrations of organics (BOD_5 and COD), suspended solids (TSS), ammonia and organic nitrogen (TKN). Although the flow of this filtrate is small, these constituents can have an impact on downstream treatment processes, so they should be characterized and considered during the design of electro-dewatering.
Washwater quality and availability	Filtered process water or potable water is used to avoid clogging the filter. The amount of water needed is relatively small.
Electricity cost	Three to five fold reduction in energy usage compared to thermal drying.
Plant related issues in selection of system and number of units	Safety considerations, allowable odor levels, facility operating schedule, level of automation, space availability, reliability and redundancy requirements, manufacturers local service capabilities, and budgetary constraints.

compatibility of the technology with the sludge or biosolids and to determine time required to achieve the desired cake dewatering along with electricity consumption is highly recommended, once satisfactory laboratory results are obtained.

Process Performance Data. Process variables that can be adjusted to optimize performance or minimize operational costs include cycle time (time of the batch treatment), applied voltage, applied current intensity, applied pressure, thickness of the formed cake (feed), sludge conductivity and ionic composition, polymer type and concentration (applied upstream, at the mechanical dewatering step). Typical operating performance data for linear electro-dewatering, which will vary facility to facility, is presented in Table 14–10. Thermal drying requires around 617–1200 kWh/m^3 of water removed (Gazbar et al., 1994; Mujumdar, 2007) whereas application of linear electro-dewatering often results in a 3 to 5 fold reduction in energy usage. In areas where electricity costs are high, economic evaluation to verify the cost benefit from obtaining the desired cake solids is required.

Sludge Drying Beds

Drying beds used to be the most widely used method of sludge dewatering in the United States. Sludge drying beds are typically used to dewater digested biosolids and settled sludge from plants using the extended aeration activated-sludge treatment process without prethickening. After drying, the dried material is removed and either disposed of in a landfill or used as a soil conditioner. The advantages and disadvantages of drying beds are summarized in Table 14–11. Conventional sand drying beds are the most commonly used sludge drying beds. Other types of drying beds include paved drying beds, wedge-wire drying beds, and vacuum-assisted drying beds. Because paved and wedge-wire drying beds are not used commonly, they are not covered in this textbook. Vacuum-assisted sludge

Table 14–11

Advantages and disadvantages of drying beds

Advantages	**Disadvantages**
1. Low capital and operating cost alternative	1. Requires a large footprint
2. Simple operation with minimal operator attention required	2. Performance highly susceptible to weather conditions
3. High-solids content in the dried product	3. Removing sludge can be labor-intensive high potential for odors
	4. Can attract insects

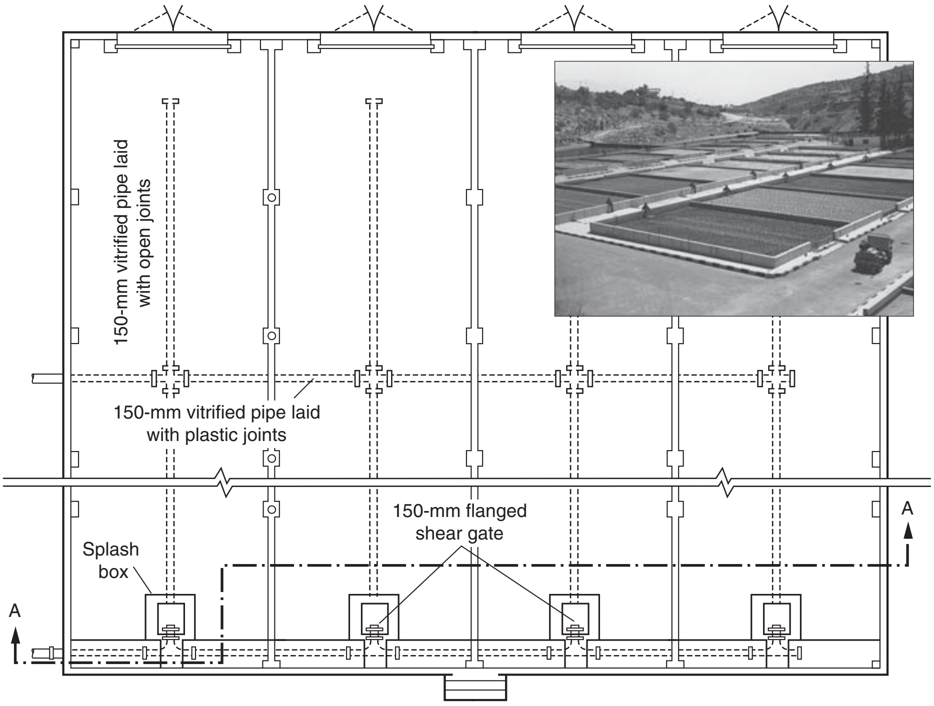
drying beds were used in the past but are no longer commercially available and are not included in this text (WEF, 2012). Because conventional sand drying beds are used most extensively, more detailed discussion is provided for these units.

Conventional Sand Drying Beds. Conventional sand drying beds are generally used for small- and medium-sized communities. For cities with populations over 20,000, consideration should be given to alternative means of sludge dewatering. In larger municipalities, the initial cost, the cost of removing the sludge and replacing sand, and the large area requirements generally preclude the use of sand drying beds.

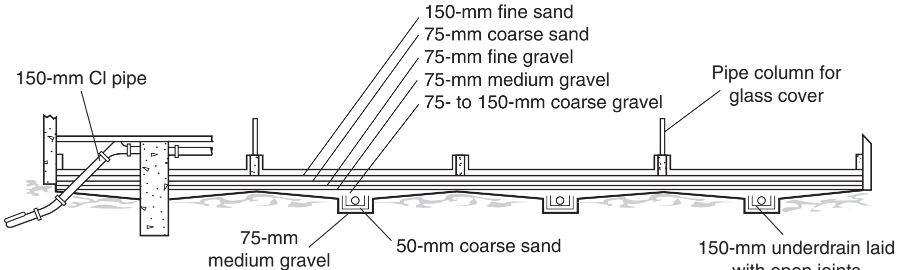
In a typical sand drying bed, sludge is placed on the bed in a 200 to 300 mm (8 to 12 in.) layer and allowed to dry. Sludge dewaters by gravity drainage through the sludge mass and supporting sand and by evaporation from the surface exposed to the air (see Fig. 14–13). Most of the water leaves the sludge by drainage; thus the provision of an adequate underdrainage system is essential. Drying beds are equipped with lateral drainage lines (perforated plastic pipe or vitrified clay pipe laid with open joints), sloped at a minimum of 1 percent and spaced 2.5 to 6 m (8 to 20 ft) apart. The drainage lines

Figure 14–13

Typical conventional sand drying bed: (a) plan and (b) section. Insert – view of sludge drying beds with sludge in various stages of dryness.



(a) Plan



(b) Section A–A

should be adequately supported and covered with coarse gravel or crushed stone. The sand layer should range from 200 to 460 mm (9 to 18 in.) deep with an allowance for some loss from cleaning operations. Deeper sand layers generally retard the draining process. Sand should have a uniformity coefficient of not over 4.0 and an effective size of 0.3 to 0.75 mm.

The drying area is typically partitioned into individual beds 7.5 m wide although the actual width for a particular site should be set to accommodate the sludge removal method. The bed length can vary and beds can be up to 30 to 60 m (100–200 ft) long. The partitions are typically constructed of earthen embankments, wooden planks, concrete planks or reinforced concrete blocks. The outer wall is normally constructed with a 500–900 mm (20–36 in.) freeboard above the sand area and the wall usually extends to the underdrain gravel. Concrete foundation walls are required if the beds are to be covered.

Sludges or biosolids are typically fed to drying beds via an open channel or closed piping. Distribution boxes or valves are required to divert the sludge or biosolids flow into the bed selected. Splash plates are placed in front of the sludge or biosolids outlets to spread the material over the bed and to prevent erosion of the sand. If the feed pipe is pressurized, a 90 elbow should be used to ensure the sludges or biosolids hit the splash plate at all feed flowrates.

Sludges or biosolids can be removed from the drying bed after it has drained and dried sufficiently. Dried material has a coarse, cracked surface and is black or dark brown. Sludge or biosolid removal is accomplished by manual shoveling into wheelbarrows or trucks, or by a scraper, front-end loader, or special mechanical sludge removal equipment. Provisions should be made for driving a truck onto or alongside of the bed to facilitate loading.

Open beds are used where adequate area is available and sufficiently isolated to avoid complaints caused by occasional odors. Open sludge beds should be located at least 100 m (about 300 ft) from dwellings to avoid odor nuisance. Covered beds with greenhouse types of enclosures are used where it is necessary to dewater sludge continuously throughout the year regardless of the weather, and where sufficient isolation does not exist for the installation of open beds.

Drying bed solids loadings are computed on dry solids loading per square foot per year (kilograms of dry solids per square meter per year). Designing drying beds based on a solids loading criteria is typically the preferred approach and loading requirements typically vary from 50 to 125 $kg/m^2 \cdot y$ (10–25 $lb/ft^2 \cdot y$) for open drying beds and 60–200 $kg/m^2 \cdot y$ (12–40 $lb/ft^2 \cdot y$) for closed drying beds (WEF 2010). Typical data for various types of biosolids are shown in Table 14–12. With covered drying beds, more biosolids can be

Table 14–12
Typical area requirements for open sludge drying beds

	Area[a]		Dry sludge loading rate	
Type of biosolids	**ft^2/person**	**m^2/person**	**$lb/ft^2 \cdot y$**	**$kg/m^2 \cdot y$**
Primary digested	1.0–1.5	0.1	25–30	120–150
Primary and trickling filter humus digested	1.25–1.75	0.12–0.16	18–25	90–120
Primary and waste activated digested	1.75–2.5	0.16–0.23	12–20	60–100
Primary and chemically precipitated digested	2.0–2.5	0.19–0.23	20–33	100–160

[a] Corresponding area requirements for covered beds vary from about 70 to 75 percent of those for the open beds.

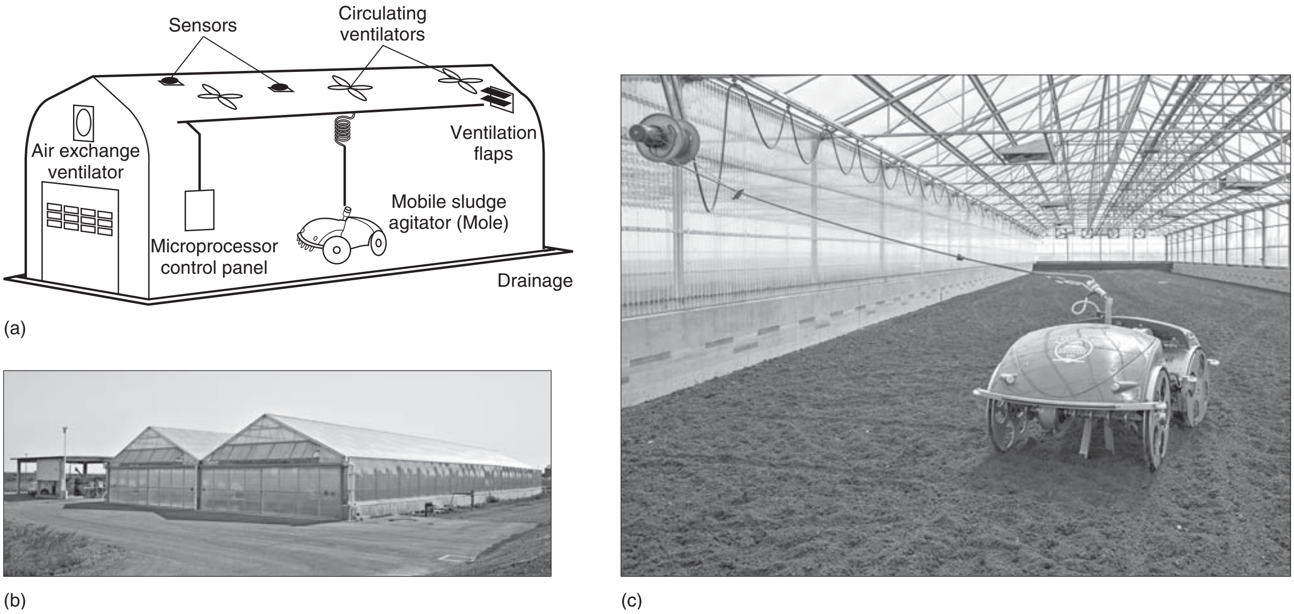


Figure 14–14

applied per year because of the protection from rain and snow. Polymer conditioning is also sometimes used to improve the performance of sludge drying beds.

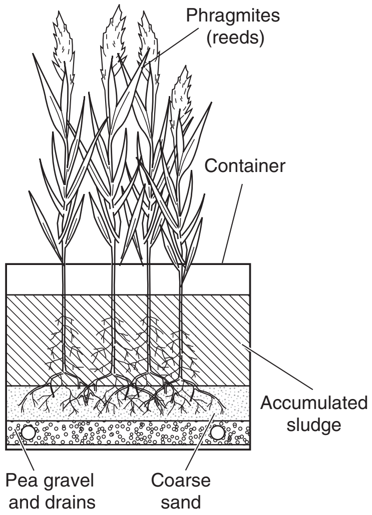
Solar Drying Beds. A method used to enhance the dewatering and drying of liquid, thickened, or dewatered biosolids is solar drying in covered drying beds (see Fig. 14–14). Solar drying systems are typically not used for undigested primary sludge due to concerns of odor and requirements to dry to greater than 90 percent to get Class A biosolids product instead of 75 percent drying for stabilized biosolids. The solar drying system, which is a sophisticated "greenhouse," consists of a rectangular base structure, translucent chamber, sensors to measure atmospheric drying conditions, air louvers, circulation fans, ventilation fans, a mobile electromechanical device that agitates and moves the drying biosolids, and a microprocessor that controls the drying environment [see Figs. 14–14(a) and (b)]. The system's main source of drying energy is solar radiation.

In most solar drying systems, mechanically dewatered biosolids are distributed in a greenhouse either manually or automatically. It is also possible to add liquid sludge directly to the greenhouse; however, the additional greenhouse area required typically outweighs the benefit from eliminating the mechanical dewatering step. Solar drying is best suited for tropical or arid environments however there are installations in both northern and mountainous climates.

During the drying cycle, the microprocessor evaluates the number of climatic variables, such as temperature, humidity and solar radiation, which initiates one or more operations that optimize the conditions inside the greenhouse. The greenhouse contains circulation fans and exhaust fans to provide convective drying and control of climatic conditions inside the greenhouse. The biosolids are periodically turned and aerated with varying devices depending on the manufacturer [see Fig. 14–14(c)]. In addition, low temperature waste heat can be used to

Figure 14–15

Cross section of a reed bed for dewatering and storage of biosolids.



enhance solar drying and reduce area requirements for the greenhouse. Ultimately, it is possible to obtain a dry pelletized material with a solids content as high as 90 percent.

Reed Beds

Reed beds can be used for biosolids dewatering at treatment plants with capacities up to 0.2 m^3/s (5 Mgal/d). A typical reed bed for biosolids dewatering, treatment, and storage is shown on Fig. 14–15. Reed beds are similar in appearance to subsurface flow constructed wetlands, which consist of channels or trenches filled with sand or rock to support emergent vegetation. The difference between reed beds used for biosolids application and subsurface flow wetlands is that the liquid biosolids are applied to the surface of the beds (as compared to subsurface application) and the filtrate flows through the gravel to underdrains.

Typically, reed beds are constructed of washed river-run gravel in the following layers: (1) a 250 mm (10 in.) deep drainage layer composed of 20 mm (0.8 in.) washed gravel, (2) a 250 mm (10 in.) deep layer composed of 4 to 6 mm (0.16 to 0.24 in.) washed gravel, and (3) a 100 to 150 mm (4 to 6 in.) layer of sand (0.4 to 0.6 mm). Sometimes an even coarser bottom layer is used. At least 1 m (3 ft) of freeboard above the sand layer is provided for a 10-y accumulation of sludge. Phragmites (reeds) are planted on 300 mm (12 in.) centers in the gravel layer just below the sand. Other wetland vegetation can be used, although reeds are the most popular. The first sludge application is made after the reeds are well established. Harvesting of the reeds is practiced typically in the winter by cutting the tops back to a level above the sludge blanket. Harvesting is necessary whenever the plant growth becomes too thick and restricts the even flow of biosolids. The harvested material can be composted, burned, or landfilled (Crites and Tchobanoglous, 1998).

The purpose of the plants is to provide a pathway for continuous drainage of water from the sludge layer. As the plants move back and forth due to wind currents, pathways are created for water to drain from the biosolids into the underdrains. The plants also absorb water from the sludge. Oxygen transfer to the plant roots assists in the biological stabilization and mineralization of the sludge. The reed bed system is a form of passive composting. The design loading rates for reed beds range from 30 to 60 $kg/m^2{\cdot}y$ (6 to 12 $lb/ft^2{\cdot}y$). Loading rates as high as 100 $kg/m^2{\cdot}y$ (20 $lb/ft^2{\cdot}y$) have been used, depending on the nature of the sludge and climatic conditions. The liquid sludge is applied intermittently, as in sand drying beds. The typical biosolids depth applied is 75 to 100 mm (3 to 4 in.) every week to 10 d (Crites and Tchobanoglous, 1998; Cooper et al., 1996).

Lagoons

Drying lagoons may be used as a substitute for drying beds for the dewatering of digested biosolids. Lagoons are not suitable for dewatering untreated sludges, limed sludges, or sludges with a high-strength supernatant because of their odor and nuisance potential. The performance of lagoons, like that of drying beds, is affected by climate; precipitation and low temperatures inhibit dewatering. Lagoons are most applicable in areas with high evaporation rates. Dewatering by subsurface drainage and percolation is limited by increasingly stringent environmental and groundwater regulations. If a groundwater aquifer used for a potable water supply underlies the lagoon site, it may be necessary to line the lagoon or otherwise restrict significant percolation.

Unconditioned digested biosolids are discharged to the lagoon in a manner suitable to accomplish an even distribution. Biosolids depths usually range from 0.75 to 1.25 m (2.5 to 4 ft). Evaporation is the principal mechanism for dewatering. Facilities for decanting of supernatant are usually provided, and the liquid is recycled to the treatment facility. Biosolids are removed mechanically, usually at a solids content of 25 to 30 percent. The cycle time for lagoons varies from several months to several years. Typically, biosolids are pumped to the lagoon for 18 months, and then the lagoon is rested for 6 mo. Solids loading criteria range from 36 to 39 $kg/m^3 \cdot y$ (2.2 to 2.4 $lb/ft^3 \cdot y$) of lagoon capacity (U.S. EPA, 1987a). A minimum of two cells is essential, even in very small plants, to ensure availability of storage space during cleaning, maintenance, or emergency conditions.

14–3 HEAT DRYING

Heat drying involves the application of heat to evaporate water and to reduce the moisture content of biosolids below that achievable by conventional dewatering methods. The advantages and disadvantages for heat drying are summarized in Table 14–13.

Heat-Transfer Methods

The classification of dryers is based on the predominant method of transferring heat to wet sludge or biosolids. Heat can be transferred by convection, conduction, radiation, or a combination of two or more methods. Dryers using infrared radiation have been used mostly for demonstration testing and are not covered in detail in this text.

All drying systems follow the three stages of drying which are illustrated in the drying curve shown on Fig. 14–16. The three stages of drying are warm up stage, constant

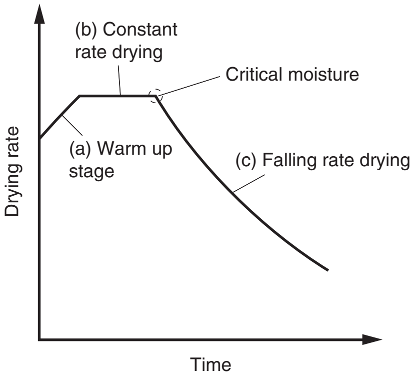
Table 14–13

Advantages and disadvantages of heat drying

Advantages	Disadvantages
1. Proven process	1. Relatively high capital cost
2. Product is readily marketable and suitable for a variety of uses that are consistent with the EPA's national beneficial reuse policy	2. Large fuel requirements
3. Small footprint	3. Payback from the sale of Class A production usually will not offset high operating costs
4. Reduced product transportation costs	4. Potential to create dust
5. Significant pathogen reduction (Class A)	5. Increased fire and explosion risk
6. Improved storage capability	6. Relatively complex system, requires highly trained operating staff
7. Does not require chemical additives	7. Odor potential and potential for odorous and dusty end product
8. Enhances heat value of biosolids	

Figure 14–16

Three stages of drying:
(a) warming up, (b) constant rate, and (c) falling rate.



rate drying stage, and the falling rate drying stage. During the warm up stage, the solids and moisture are heated up to the process temperature by transferring sensible heat. During the constant rate drying period, the moisture evaporated from the surface of the sludge or biosolids is replaced with internal moisture at an equal rate thus the surface remains saturated and the temperature of the sludge or biosolids surface being dried during this period is approximately equal to the wet bulb temperature of the gas present in the dryer. The constant rate period is typically the longest period and most drying occurs during this phase. The falling rate period occurs when most of the free moisture is removed and the rate of drying becomes controlled by diffusion of internal water to the surface of the sludge or biosolids being dried. During this period, the sludge or biosolids surface temperature begins to approach the gas or air temperature. The moisture content at the transition of the constant rate to the falling rate period is known as the critical moisture content.

Convection. In convection (direct drying) systems, wet sludge or biosolids are contacted directly with the heat transfer medium, usually hot gases. Under equilibrium conditions of constant rate drying, mass transfer is proportional to (1) the area of wetted surface exposed, (2) the difference between water content of the drying air and saturation humidity at the wet-bulb temperature of the solid-air interface, and (3) other factors, such as velocity and turbulence of drying air expressed as a mass transfer coefficient. The heat-transfer rate for evaporation is determined by the following equation (WEF, 2010):

$$q_{\text{conv}} = h_c A(T_g - T_s) \tag{14–1}$$

where q_{conv} = convective heat transfer rate, kJ/h (Btu/h)
h_c = convection heat transfer coefficient, kJ/m^2·h·°C (Btu/ft^2·h·°F)
A = area of the heated surface, m^2 (ft^2)
T_g = gas temperature, °C (°F)
T_s = temperature at sludge/gas interface, °C (°F)

The convection heat transfer coefficient can be obtained from dryer manufacturers or from pilot studies; however, many manufacturers consider this proprietary information.

Conduction. In conduction (indirect) drying systems, a solid retaining wall separates the wet sludge from the heat transfer medium, usually steam, thermal oil or another hot fluid. Heat transfer for conduction is determined by the following equation (WEF, 2010):

$$q_{\text{cond}} = h_{\text{cond}} A(T_m - T_s) \tag{14–2}$$

where q_{cond} = conductive heat-transfer rate, kJ/h (Btu/h)
h_{cond} = conductive heat-transfer coefficient, kJ/m^2·h·°C (Btu/ft^2·h·°F)
A = area of wetted surface exposed to gas, m^2 (ft^2)
T_m = temperature of heating medium, °C (°F)
T_s = temperature sludge at drying surface, °C (°F)

The conductive heat-transfer coefficient, a composite term, includes the effects of the heat-transfer surface films of the sludge and the medium. The conduction heat-transfer coefficient can be obtained from dryer manufacturers or from pilot studies.

Process Description

Heat dryers are classified as follows: direct, indirect, combined direct-indirect, and infrared. Direct and indirect dryers are described as they are the types most used commonly for municipal biosolids drying. Coal, oil, gas, infrared radiation, or dried sludge may be used as the means of supplying the energy for heat drying.

Direct Dryers. Direct (convection) dryers that have been used for drying municipal wastewater sludges and biosolids are the flash dryer, rotary dryer, and fluidized-bed dryer. Although as many as 50 municipal flash dryers have been installed in the United States since 1940, only Houston, TX, is still known to use this technology at two of its wastewater treatment plants. Because of safety concerns, high energy requirements, high O&M, and limited interest from vendors to work in the wastewater market, the popularity of this technology has declined, thus flash drying is not discussed in detail in this text (WEF, 2010). Rotary dryers are now very commonly used for wastewater sludges or biosolids. Fluidized-bed drying is a relatively new application in the United States.

Rotary Dryer. Rotary dryers have been used for the drying of raw primary sludge, waste-activated sludge, and digested biosolids from combined primary and WAS (see Fig. 14–17). In general, drying raw primary sludge is not recommended due to material handling concerns, odor and stability of the final product. A rotary dryer consists of a cylindrical steel shell that is rotated on bearings and usually is mounted with its axis at a slight slope from

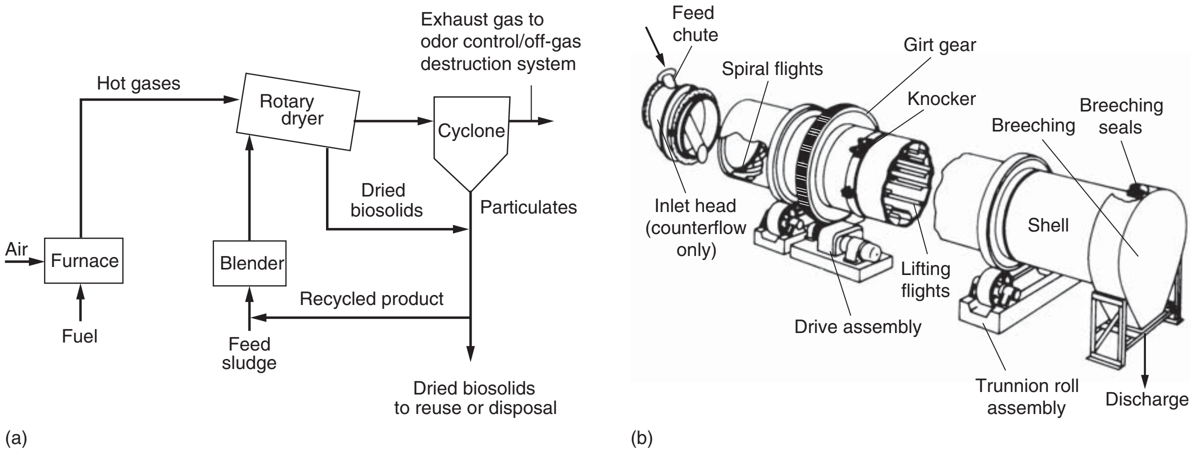


Figure 14–17

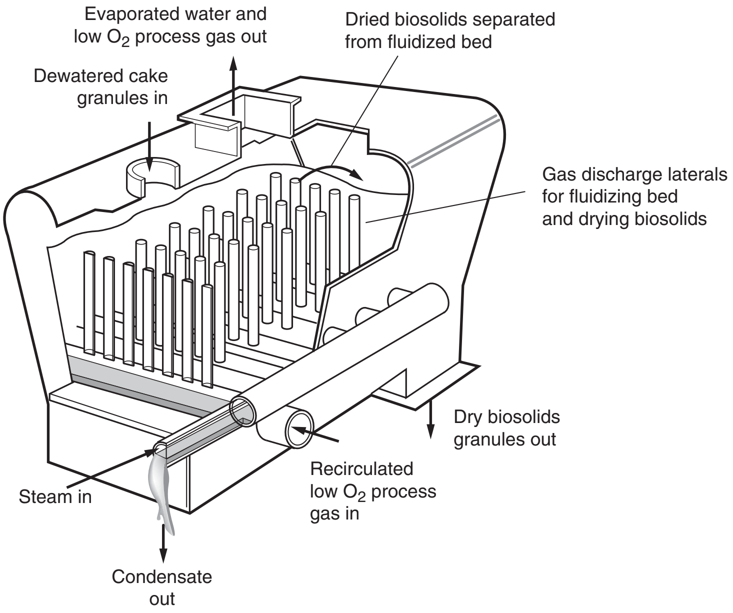
Rotary sludge dryer: (a) typical process flow diagram, and (b) isometric view of rotary dryer.

Figure 14–18

Cross-section through a fluidized-bed reactor. (From Andritz.)



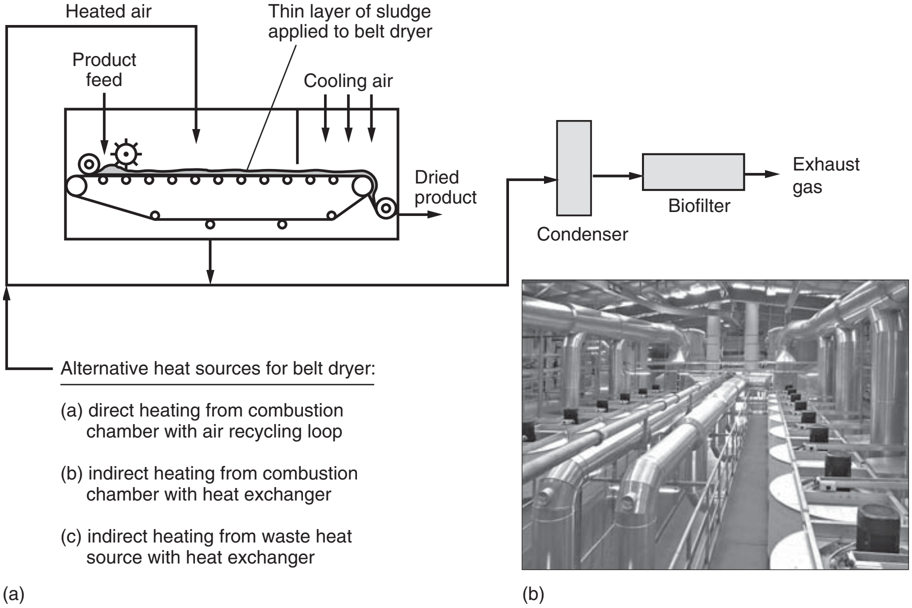
the horizontal [see Figs. 14–17(a) and (b)]. The feed sludge or biosolids is mixed with previously dried material in a blender located ahead of the dryer [see Fig. 14–17(a)]. The blended feed material has a moisture content of approximately 65 percent that improves its ability to move through the dryer without sticking. The mixture and hot gases are conveyed to the discharge end of the dryer. During conveyance, axial flights along the rotating interior wall pick up and cascade the sludge through the dryer. The product, which has a dry solids content of 90 to 95 percent, is screened and the oversize material passes through a crusher and then is transported to a recycle bin. The dried product is amenable to handling, storage, and marketing as a fertilizer or soil conditioner.

Fluidized-Bed Dryer. Fluidized-bed dryers, developed in Europe, were first adapted in the United States in the late 1990's (see Fig. 14–18). There are approximately 30 known installations worldwide with two in North America (WEF, 2012). The dryer has the capability of producing a pellet product, similar to that obtained from rotary drying systems (Holcomb et al., 2000). The method of feeding the dryer varies with different manufacturers. The fluidized-bed dryer consists of a stationary vertical chamber that is divided into three zones; the windbox or gas plenum, the heat exchanger, and the hood. The windbox is where the hot fluidizing gas is distributed through the bed. The heat exchanger is located within the fluidizing zone and heat is provided to the system either by steam or thermal oil. The hood is where the fluidizing gas exits the chamber and the dried biosolids are separated from the gas. The gas from the dryer typically passes through a cyclone before it is reheated and introduced back into the dryer. A portion of the gas, however, is removed from the closed loop and is scrubbed before being treated in an RTO or other odor control device.

The fluidizing gas, typically air, keeps the biosolids in suspension and provides agitation which assists with both heat transfer from the heat exchanger to the biosolids particles and also helps produce a relatively uniform dried biosolids product. A uniform temperature of 85 to 120°C (185 to 230°F) is maintained in the bed through intimate contact between the biosolids granules and the fluidizing air. Since fluid bed dryers operate at relatively low temperatures, they are suitable for low temperature waste heat recovery.

Figure 14–19

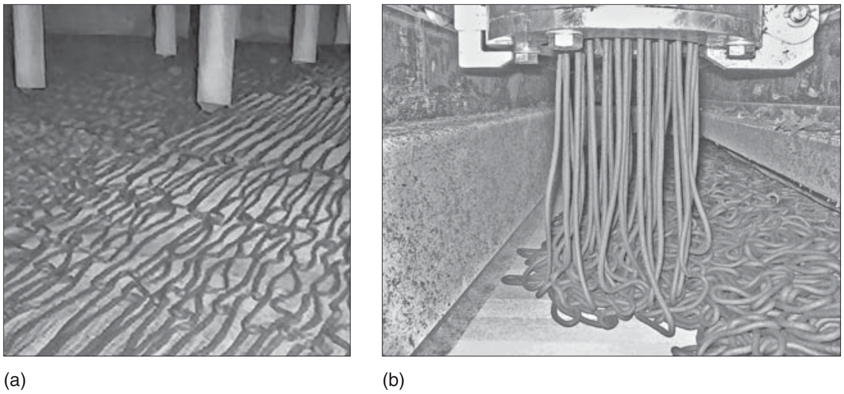
Example of belt dryer: (a) schematic of operation with three different heat sources, and (b) view of enclosed belt dryer (courtesy of SH+E Group U.S.).



Belt Dryers. At the time of writing this text, belt drying is still a relatively new type of sludge or biosolids dryer being implemented in the United States. However, there are up to seven belt dryers either in operation or under construction. Belt dryers are more widely used in Europe. Belt dryers are convection dryers that consist of a conveyor belt where biosolids are distributed in a thin layer (Fig. 14–19). The slowly moving belt transports the sludge or biosolids through the dryer while warm heated gases pass either through the belt and biosolids layer or pass across the biosolids layer to provide convective heat transfer. There are several manufactures currently available each with slightly different configurations and sludge or biosolids distribution methods. Some dryers contain metal mesh belts or perforated plates, while others contain fabric belts similar to what is used on belt filter presses. The dried product can be recycled and back mixed with dewatered cake, similar to rotary drum dryers, ensuring the biosolids being fed to the dryer are past the sticky phase and allowing for better distribution in the dryer. The sludge or biosolids fed to the dryer can also be extruded in ribbons (see Fig. 14–20) with a high drying surface area eliminating the need for back mixing systems. In the case of distributing the biosolids using extrusion method, belt drying cannot typically accept more than 30 percent cake solids.

Figure 14–20

Extruded biosolids for enhanced heat drying: (a) view of extruded biosolids strings (courtesy of Kruger) and (b) view of biosolids ropes being extruded (courtesy of SH+E Group U.S.).



(a) (b)

Belt dryers can be directly fired with flue gases from a hot gas furnace, or they can be indirectly heated with a heat exchanger using thermal oil, steam, or flue gas as the heating source to heat the drying air. Unlike many other types of dryers, belt dryers can also operate at very low temperatures, making this type of dryer very attractive for situations where low temperature waste heat is available. The low drying temperature and minimized agitation in the dryer makes this type of dryer inherently safer than other types of dryers. With the low temperature and high surface area requirements, belt dryers are typically better suited for small- to medium-sized plants as opposed to very large plants where they may become cost prohibitive. A typical covered belt drying installation is shown on Fig. 14–19(b).

Indirect Dryers. Indirect dryers are designed in either a horizontal or vertical configuration. A typical process flow diagram is shown on Fig. 14–21(a). Horizontal dryers employ paddles, hollow flights, or disks mounted on one or more rotating shafts to convey sludge or biosolids through the dryer [see Figs. 14–21(c) and (d)]. A heated medium, usually steam or oil, is circulated through the jacketed shell of the dryer and the hollow core of the rotating assembly. Dewatered sludge or biosolids are fed perpendicular to the dryer shaft and pass horizontally in a helical pattern through the dryer. The dryer performs the dual function of heat transfer and sludge or biosolids conveying. Drying occurs as the sludge or biosolids particles are broken up through agitation and come into contact with the heated metal surfaces in the dryer. The granular particles are both hot and abrasive.

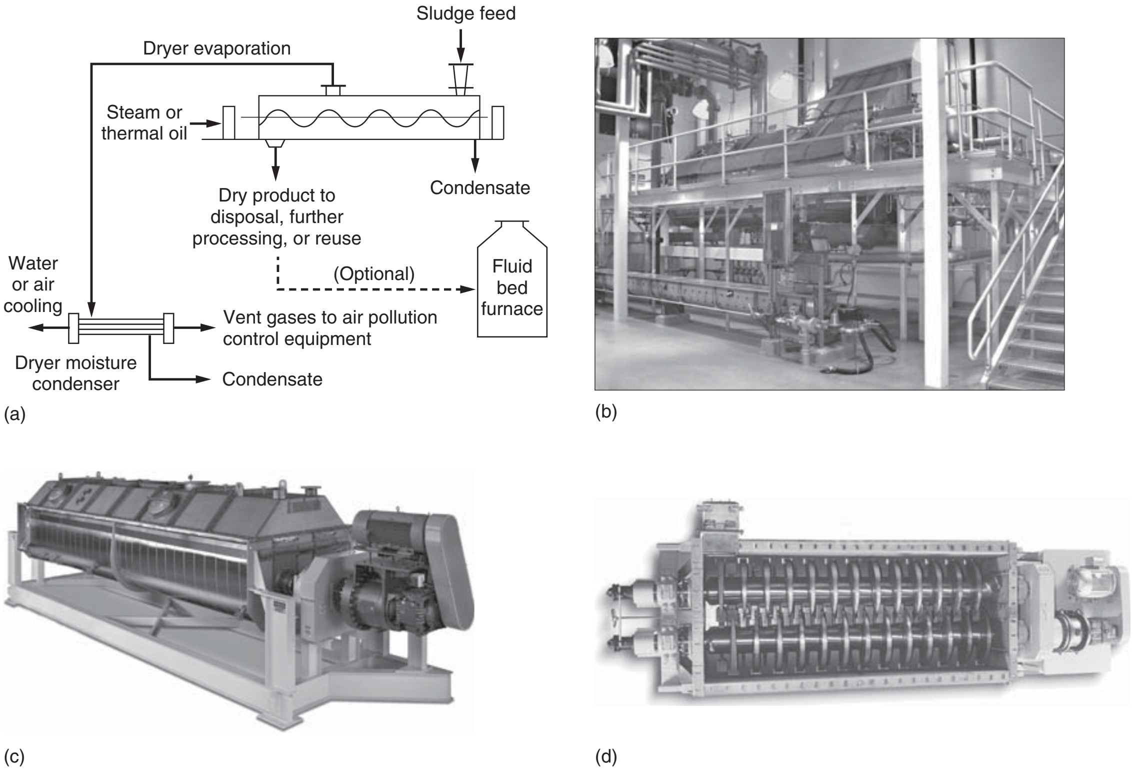


Figure 14–21

Indirect sludge dryer: (a) schematic process flow diagram, (b) view of typical dryer installation, (c) view of dryer without support facilities, and (d) view of interior paddle flights. [Figures (b), (c), and (d) courtesy of Komline-Sanderson.]

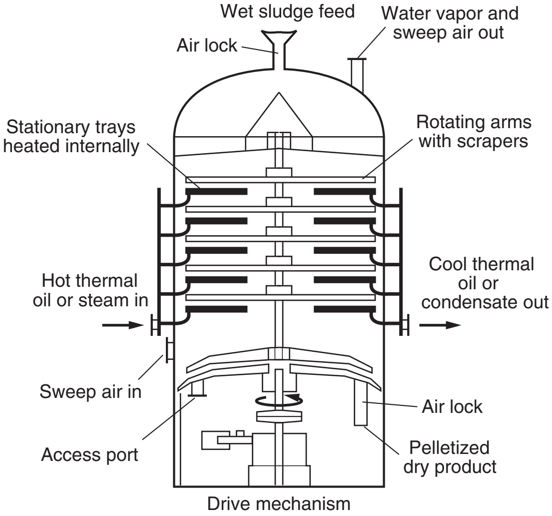

Figure 14–22

Cross section through a vertical indirect dryer (From Pelletech).

Moving parts, as in most dryers, will become abraded, and corrosion will accelerate the deterioration of the metal. The design of the agitator has to allow for efficient heat transfer, mixing of the sludge mass, and minimum fouling of the agitator. A weir at the discharge end ensures complete submergence of the heat-transfer surface in the biosolids being dried. The water vapor derived from the drying operation may be drawn off under a slightly negative pressure by an induced-draft fan located in the off-gas duct.

In vertical indirect dryers (see Fig. 14–22), sludge or biosolids contacts a metal surface heated by a medium, such as steam or oil, and the heat is conductively transferred to the sludge. The biosolids or sludge does not come in contact with the heating medium. Dewatered product (approximately 20 percent solids) mixed with recycled product is fed through the top inlet of a multistage dryer. Rotating arms move the sludge from the heated stationary tray to another in a rotating zigzag motion until it exits at the bottom as a dried, pelletized product. The rotating arms are equipped with adjustable scrapers that move and tumble the sludge in thin layers (20 to 30 mm) over the heated stationary trays. Dried product exits the dryer and is conveyed by a bucket elevator to a separation hopper. A portion of the properly sized pellets are cooled and conveyed to storage. Oversized particles are crushed and mixed with fines and a portion of the properly sized pellets and backmixed with the dewatered cake being fed to the dryer. Because of the backmixing process, this type of dryer produces a relatively uniform product similar to rotary drum dryers.

In indirect dryers, sludge or biosolids is dried to a specific level of dryness and discharged to a product conveyor for transfer to storage. Solids concentrations in the dryer product can range from 65 to over 95 percent depending on the ultimate use of the product.

Product Characteristics and Use

Dried biosolids are mainly used in a similar manner to commercial fertilizers, depending on the nutrient content of the material. Some of the dried material is well established as fertilizer and sold for profit to the producer. For example, OCEANGRO™, which is a dried pellet product from Ocean County Utilities Authority in New Jersey, is sold in bulk or in bags as a fertilizer to the agricultural community. The OCEANGRO™ guaranteed analysis is summarized in Table 14–14. The characteristics of the finished biosolids product depend on the type of sludge, the type of preprocessing, and the physical configuration of the drying surfaces. Raw primary sludge produces more of a fibrous, dusty, and odorous

Table 14–14
OCEANGROW™ guaranteed analysis

Ingredients	Unit	Value
Total Nitrogen (N)	%	5.0
Water Soluble Nitrogen	%	0.50
Water Insoluble Nitrogen[a]	%	4.50
Available Phosphate (P_2O_5)	%	5.00
Calcium (Ca)	%	2.50
Total Magnesium (Mg)	%	0.33
Combined Sulfur (S)	%	1.00
Total Copper (Cu)	%	0.04
Total Iron (Fe)	%	2.50
Total Zinc (Zn)	%	0.05
Standard Guide Number		150
Product Size Range	mm	1.5 to 2.5
Uniformity Index	%	60

[a] This product contains 4.50 percent slow release nitrogen.

material that is difficult to manage and pelletize. Digested sludge can be pelletized, depending on the type of dryer or downstream conditioning process, to produce an amorphous particle that can be easily handled and transported. Dryers with backmixing typically produce more uniform pellets but other downstream processes such as screening, conditioning agents or pelletizing can be added to dryers without backmixing if a more uniform product is required for marketing purposes. The best size range for marketing is approximately from 2 to 4 mm, but can vary depending on the specific market (WEF, 2012). To maximize marketing potential, screening for sizes smaller and larger than the selected size range will be required. The fines and oversized particles can be returned to blend with the incoming sludge, hence increasing the solids content entering the dryer but not changing the amount of moisture that must be evaporated.

Biosolids dried products can be used as an energy source depending on the characteristics of the sludge or biosolids that were dried. In recent years, dried biosolids have been used as a coal substitute for fuel in cement kilns. The use of dried product as an energy source is expected to increase, due to high energy costs and because the energy recovered from dried biosolids is considered renewable energy.

Product Transport and Storage

Although the granular product from heat drying is reasonably durable, long mechanical conveyors, such as screw conveyors, drag conveyors, and pneumatic conveyors that create an abrasive action could cause crumbling and dust formation. These types of conveyors, however, are commonly used at many sites. If product friability is a concern, open or folded belt conveyors may be preferred.

Upon exiting the dryer, the hot biosolids should be cooled to below 50°C (120°F) before placing in silos or storage vessels. The combination of initial heat plus heat that could be introduced by biological activity in the silo can cause smoldering or an open flame. This condition can occur where the drying operation is expected to pass through frequent start-and-stop cycles and drying may not be complete. In general, the product entering storage should be from 92 to 98 percent dry solids.

Fire and Explosion Hazards

With the fine particles and high levels of dryness in heat-dried sludge, hazards due to fire and explosion may exist in the dryer or when dried sludge is conveyed or stored. An organic dust suspended in air can rapidly combust if exposed to an ignition source. The heat of combustion can rapidly increase the volume and/or pressure of hot combustion products. If the pressure exceeds the rupture strength of the containing vessel, an explosion occurs. The phenomenon is called "deflageration," and deflageration explosions are the most serious concern when handling dried biosolids (Haug et al., 1993). Dried biosolids can also reheat if rewetted due to biological activity. In addition, the sludge being dried could contain a high level of fiber or grease content which could cause problems inside the dryer. Design considerations that are recommended for safety purposes and to prevent thermal events are given in Table 14–15.

Air Pollution and Odor Control

Two important control measures associated with heat drying of sludge are dust collection and odor control. All dryers produce some sort of offgas which results from the process gas and evaporated water that is continuously removed from the drying process. The offgas can contain

Table 14–15

Prevention measures to avoid dust hazards in heat drying[a]

Item	Prevention measure
Venting system (for processing, conveyance, and storage components)	Provide explosion relief vents. Size explosion vents for "worst case" explosion in an air atmosphere.
Temperature control	Use controls to prevent high temperatures which could cause unsafe conditions Temperature control can also be used to prevent the material from being over dried which could cause excess dust formation.
Water deluge	Include a water deluge or sprinkler system that reacts based on high temperature conditions. Water deluge can also be set to react to the presence of carbon monoxide or carbon dioxide which could indicate smoldering.
Nitrogen padding	Provide a nitrogen inerting atmosphere for all dried biosolids conveyance and processing facilities. Maintain oxygen levels below 5 percent by volume to reduce potential for self-heating and ignition of hot biosolids.
Electrical equipment	Design in accordance with appropriate National Fire Protection Association criteria. If dust is present, all equipment must be dust tight and electronic cabinets nitrogen purged. Motor control centers that contain sparking devices, such as starters and relays, must be located outside classified areas.
Ducts and vessels	Electrically bond and ground all conductive elements of the system that contact dried biosolids.
Maintenance	Keep areas clean to prevent accumulation of dust. Any vessel containing powder must have powder removed before opening or the powder must be cooled to ambient temperatures before safe entry clearance is given.
Product cooling	Ensure product is cooled to below 50°C (120°F) before being transported to product storage.
Miscellaneous	Eliminate or move outside all heat sources from classified areas. Equip electric motors located in a Class II, Division 2 area with Class F insulation to reduce "skin" temperatures.

[a] Adapted from Haug, et al. (1993) and WEF (2012).

high levels of odors due to volatilization and heat reactions. The method for dealing with dryer offgas varies depending on the dryer type, manufacturer and local site requirements.

Most dryers include wet scrubbers that have relatively high efficiencies and will condense the water evaporated from the sludge as well as remove some of the organic matter in the vent gas. Most wet scrubbers will also include mist eliminators to minimize carryover of water droplets. Some dryers also include cyclone separators, either on the process air circulation loop or upstream of the wet scrubber, to remove particles entrained in the air. The cyclones used typically have efficiencies of 75 to 80 percent and are suitable for vent gas temperatures up to 340 or 370°C (650 or 700°F). The final scrubbed off gas must then go through some sort of odor control treatment. The use of a thermal oxidizer is one common method used on many types of dryers to eliminate odors. Thermal oxidizers typically operate at temperatures greater than 815°C (1500°F) with a residence times of 0.75 to 1 s (WEF, 2012). The dryer offgas can also be sent to an incinerator (if one is onsite), or it can be mixed with combustion air for the dryer system's burner (if the dryer is indirectly fired). Other options that have been used for off-gas odor control include chemical scrubbers, biofilters, and directing the off-gas to diffusers in the aeration basin of the activated sludge process.

14–4 ADVANCED THERMAL OXIDATION

Incineration, referred to in this chapter as advanced thermal oxidation (ATO) of sludge and biosolids, involves the total conversion of organic solids to oxidized end products, primarily carbon dioxide, water, and ash. The major advantages and disadvantages of incineration are summarized in Table 14–16. ATO is used most commonly by medium to large sized plants with limited disposal or reuse options.

Sludges processed by ATO are usually first dewatered. It is normally unnecessary to stabilize sludge before incineration. In fact, such practice may be detrimental because stabilization, specifically aerobic and anaerobic digestion, decreases the volatile content of the sludge and consequently increases the requirement for an auxiliary fuel. When ATO is practiced for biosolids, it is desirable that the dewatered biosolids concentration be between 30 to 35 percent,

Table 14–16

Advantages and disadvantages of incineration

Advantages	Disadvantages
1. Maximum volume reduction and end product stability thereby lessening disposal requirements	1. High capital and operating cost
2. Maximum destruction of pathogens and toxic compounds	2. Complex system that requires highly trained operating staff
3. Relatively small process footprint	3. Possible adverse environmental effects from air emission and ash
4. Greatest control over final biosolids disposition	4. Disposal of residuals which may be classified as hazardous wastes if they exceed prescribed maximum pollutant concentrations
5. Well suited for larger plants with larger disposal requirements	5. Relatively lengthy implementation timeframe due to planning and public consultation requirements
6. Energy recovery potential	6. Air permitting can be tedious and difficult
7. Well proven process	7. May not be feasible for a nonattainment area

to reduce the use of an auxiliary fuel and achieve autogenous oxidation. In Europe, ATO has been used with dewatered biosolids from thermally hydrolyzed sludges as discussed in Chap. 13. Sludges may be thermally oxidized separately or in combination with municipal solid wastes. The ATO processes considered in the following discussion include multiple-hearth incineration, fluidized-bed incineration, and coincineration with municipal solid waste. Before discussing these processes, some fundamental aspects of complete combustion are introduced.

Fundamental Aspects of Complete Combustion

Combustion is the rapid exothermic oxidation of combustible elements in fuel. ATO is complete combustion. The predominant elements in the carbohydrates, fats, and proteins composing the volatile matter of sludge are carbon, oxygen, hydrogen, sulfur, and nitrogen (C-O-H-S-N). Other major components include moisture and ash. The approximate percentages of these may be determined in the laboratory by a technique known as ultimate analysis (ASTM, 2009) and proximate analysis (ASTM, 2009). Heating (or calorific) value may be obtained using ASTM (2011).

Oxygen requirements for complete combustion of a material may be determined by knowing its constituents, assuming that carbon and hydrogen are oxidized to the ultimate end products CO_2 and H_2O. The formula becomes

$$C_aO_bH_cN_d + (a + 0.25c - 0.5b)O_2 \rightarrow aCO_2 + 0.5cH_2O + 0.5dN_2 \tag{14–3}$$

The theoretical quantity of air required will be 4.35 times the calculated quantity of oxygen because air is composed of 23 percent oxygen on a mass basis. To ensure complete combustion, sufficient excess air is required. Too little excess air may lead to poor emissions performance and may also limit the throughput of the process. Too much excess air may lead to high auxiliary fuel usage and unnecessarily large equipment sizing. In some jurisdictions, air pollution regulations may require a minimum flue gas oxygen concentration. The design range of excess air required depends on the ATO process configuration, the system design, and the characteristics of the biosolids. For some units operating with very dry, high heating value biosolids, air is also used to quench, control, and spread the heat released in the process to maintain below an upper temperature limit. In this case, the air required for cooling may far exceed the theoretical quantity of air.

A materials balance must be made to include the above compounds and the inorganic substances in the sludge, such as the inert material (ash), moisture, and the other constituents of the air (primarily the approximately 77 percent N_2 in the air that is supplied along with O_2 reaction in Eq. (14–3). The specific heat of each of these substances and of the products of combustion must be taken into account in determining the heat required for the incineration process.

Heat requirements will include the sensible heat Q_s in the ash, plus the sensible heat required to raise the temperature of the flue gases to 760°C (1400°F) or whatever temperature of operation is selected for complete oxidation, elimination of odors, and assurance of suitable environmental performance less the heat recovered in preheaters or recuperators. Heat loses to the ambient space around the ATO process is also a heat requirement. Latent heat must also be furnished to evaporate all of the moisture in the sludge. The total heat required may be expressed as

$$Q = \sum Q_S + Q_E + Q_L = \sum C_P W_S (T_2 - T_1) + W_W \lambda + Q_L \tag{14–4}$$

where Q = total heat, kJ (Btu)
Q_S = sensible heat in the ash, kJ (Btu)
Q_E = latent heat, kJ (Btu)
Q_L = heat loss

C_p = specific heat for each category of substance in ash and flue gases, kJ/kg°C (Btu/lb°F)
W_s = mass of each substance, kg (lb)
W_w = mass of water, kg (lb)
T_1, T_2 = initial and final temperatures
λ = latent heat of evaporation, kJ/kg (Btu/lb)

Reduction of moisture content of the sludge is the principal way to lower heat requirements, and the moisture content may determine whether additional fuel will be needed to support combustion. It is desirable both from a cost perspective and from an environmental sustainability perspective not to have to add additional fuel to the process. Therefore, it is desirable that the heat required to drive the process should come from the exothermic oxidation of the biosolids' volatile components, which is called "autogenous combustion."

The heating value of a sludge may be estimated by using Eq. (2–66) presented previously in Chap. 2 and repeated here for convenience:

$$\text{HHV (MJ/kg)} = 34.91\ \text{C} + 117.83\ \text{H} - 10.34\ \text{O} - 1.51\ \text{N} + 10.05\ \text{S} - 2.11\text{A} \qquad (2\text{–}66)$$

where, HHV = higher heating value, MJ/kg (Btu/lb = MJ/kg × 0.00043)
C = carbon, percent by weight expressed as a decimal (dry basis)
H = hydrogen, percent by weight expressed as a decimal (dry basis)
O = oxygen, percent by weight expressed as a decimal (dry basis)
N = nitrogen, percent by weight expressed as a decimal (dry basis)
S = sulfur, percent by weight expressed as a decimal (dry basis)
A = ash, percent by weight expressed as a decimal (dry basis)

The comparable expression proposed by the U.S. EPA (1979) and WEF (2010) is

$$\text{HHV (MJ/kg)} = 33.83\ \text{C} + 144.70\ (\text{H} - \text{O}/8) + 9.42\ \text{S} \qquad (14\text{–}5)$$

The fuel value of sludge ranges widely depending on the type of sludge and the volatile solids content. The fuel value of untreated primary sludge is the highest, especially if it contains appreciable amounts of grease and skimmings. Where kitchen food grinders are used, the volatile and thermal content of the sludge will also be high. Digested biosolids have significantly lower heating values than raw sludge. Typical heating values for various types of sludge and biosolids are reported in Table 14–17. The heating value for sludge is equivalent to that of some of the lower grades of coal. Computation of the heating value of biosolids is illustrated in Example 14–2.

Table 14–17

Typical heating values for various types of sludge and biosolids[a]

	Btu/lb of total solids[b]		kJ/kg of total solid[b]	
Type of sludge or biosolids	**Range**	**Typical**	**Range**	**Typical**
Raw primary	10,000–12,500	11,000	23,000–29,000	25,000
Activated	8500–10,000	9000	20,000–23,000	21,000
Anaerobically digested primary	4000–6000	5000	9000–14,000	12,000
Raw chemically precipitated primary	6000–8000	7000	14,000–18,000	16,000
Biological filter	7000–10,000	8500	16,000–23,000	20,000

[a] Adapted, in part, from WEF (1988).

[b] Lower value applies to plants with long solids retention time.

EXAMPLE 14–2 **Energy Content of Biosolids** A wastewater treatment plant is considering an ATO for handling of their biosolids. The plant currently dewaters waste activated sludge on belt filter presses prior to lime addition for Class B land application. A sample of dewatered sludge, before lime addition, was sent out for an ultimate analysis and the results are shown below.

Parameter	As received basis	Dry basis
Carbon	6.84	41.33
Hydrogen	0.94	5.66
Oxygen	3.71	22.41
Nitrogen	0.92	5.57
Sulfur	0.14	0.86
Ash	4.00	24.17
Moisture	83.45	0.00
HHV (MJ/kg)	2.96	17.88

Compare the lab results of the HHV on a dry basis to the theoretical HHV's calculated from Eq (2–66) and Eq (14–5).

Solution

1. Determine the energy content of the biosolids using Eq. (2–66).

$$\text{HHV (MJ/kg)} = 34.91\text{ C} + 117.83\text{ H} - 10.34\text{ O} - 1.51\text{ N} + 10.05\text{ S} - 2.11\text{ A}$$

$$\text{HHV (MJ/kg)} = 34.91\,(41.33/100) + 117.83\,(5.66/100) - 10.34\,(22.41/100) - 1.51\,(5.57/100) + 10.05\,(0.86/100) - 2.11\,(24.17/100)$$

$$\text{HHV} = 18.27\text{ MJ/kg}$$

$$\text{Percent difference (measured vs. calculated)} = \left(\frac{17.88 - 18.27}{17.88}\right)100 = -2.18\%$$

2. Determine the energy content of the biosolids using Eq. (14–5).

$$\text{HHV (MJ/kg)} = 33.83\text{ C} + 144.70\,(\text{H} - \text{O}/8) + 9.42\text{ S}$$

$$\text{HHV (MJ/kg)} = 33.83\,(41.33/100) + 144.70\,(5.66/100 - (22.41/100)/8) + 9.42\,(0.86/100)$$

$$\text{HHV} = 18.20\text{ MJ/kg}$$

$$\text{Percent difference (measured vs. calculated)} = \left(\frac{17.88 - 18.20}{17.88}\right)100 = -1.79\ \%$$

Comment The computed results from both Eq. (2–66) and Eq. (14–5) are very close to each other. There is also good agreement, within 3 percent, between the predicted and measured values. For theoretical calculations Eq. (2–66) is favored because it was derived from an analysis of hundreds of organic feed stocks and includes nitrogen and ash, whereas Eq. (14–5) is a modification of the well-known Dulong formula for coal. To design an ATO system, a detailed heat balance must be prepared. Such a balance must include the energy required to evaporate water in the sludge and heat losses from the process equipment, ductwork, stack, and ash as well as any heat recovery (such as combustion air preheating). Heat is obtained from the combustion of volatile matter in the sludge and from the burning of auxiliary fuels. If the process is autogenous, the auxiliary fuel is needed only for warming up the ATO or adjusting from a process upset should the desired temperature be too low or operation become unstable. Regardless of the feed biosolids characteristics, the design should include provisions for auxiliary heat for startup and for assuring complete oxidation at the desired temperature under all conditions. Fuels such as oil, natural gas, or excess digester gas are typically used for supplemental heating purposes.

To design an ATO system, a detailed heat balance must be prepared. Such a balance must include heat losses through the walls and pertinent equipment of the incinerator, as well as losses in the stack gases and ash. Approximately 4.0 to 5 MJ (4000 to 5500 Btu) are required to evaporate each kg (2.2 lb) of water in the sludge. Heat is obtained from the combustion of the volatile matter in the sludge and from the burning of auxiliary fuels. If the process is autogenous, auxiliary fuel is needed only for warming up the incinerator or adjusting from a process upset should the desired temperature be too low or operation become unstable. Regardless of the feed biosolids characteristics, the design should include provisions for auxiliary heat for startup and for assuring complete oxidation at the desired temperature under all conditions. Fuels such as oil, natural gas, or excess digester gas are suitable.

Multiple-Hearth Incineration

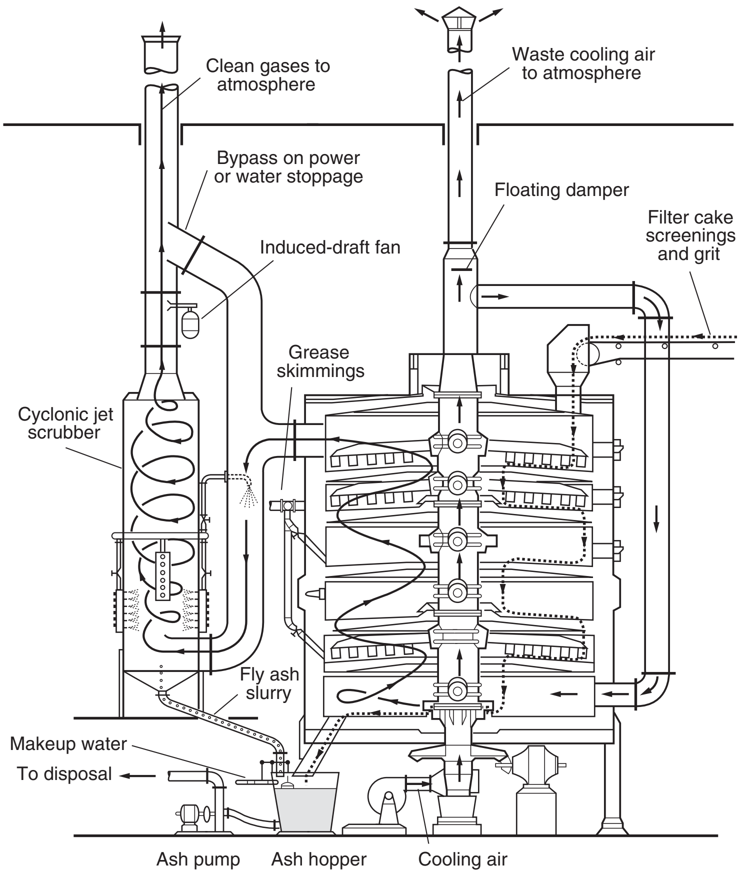
Multiple-hearth incineration is used to convert dewatered sludge cake to an inert ash. Because the process is complex and requires specially trained operators, multiple-hearth furnaces are normally used only in large plants. Multiple-hearth incinerators have been used at smaller facilities where land for the disposal of sludge is limited and at chemical treatment plants for the recalcining of lime sludges. As of 2011, about 70 percent of ATO installations in the United States utilized multiple-hearth units. These units are all fairly old, all having been installed in the mid and late twentieth century.

Process Description. As shown on Fig. 14–23 , a multiple-hearth incinerator is set up as a counter flow process with a series of hearths (typically 7–11) where the sludge introduced into the unit is successively, dried, combusted, cooled, and discharged. Air and flue gases are the heat exchange fluids in the vessel and generally travel counter-current to the biosolids. The sludge cake is fed onto the top hearth and is slowly raked to the center by a series of teeth mounted on a set of rake (or “rabble”) arms. The teeth direct the solids in a spiral pattern toward the center with each consecutive arm pushing a ridge of biosolids in toward the center and in the direction of rotation. The teeth also act to agitate the exposed surfaces of the biosolids and to mix the solids in an attempt to provide even exposure to the heat and air. From the center, sludge cake drops to the second hearth, where the rabble arms and teeth move it to the periphery. The sludge cake then drops to the third hearth and is again raked to the center. The hottest temperatures are typically on the middle hearths, where the sludge begins combustion after having evaporated enough water to raise the solids to a high enough temperature to sustain combustion. Preheated air is introduced to the lowest hearth and gains heat as it travels pass the sludge where the fixed carbon continues to burn off and the remaining ashes cool prior to discharge from the unit. The air is further heated by the sludge as the air rises past the middle hearths where combustion occurs and generates flue gases. The flue gases then cool as it gives up its heat to dry the incoming sludge on the top hearths.

Because air and flue gases are used as the primary heat exchange fluid in this counter flow system, proper air and flue gas flow, sufficient convection, and mixing is required to

Figure 14–23

Corss section through a typical multiple-hearth incinerator.



operate the system properly. The rabble tooth pattern is also important to provide even distribution, and frequent overturning of the biosolids on the hearths. Auxiliary fuel may be added at many different points on the unit. Typically, there are 3 to 4 burners around the circumference of a hearth and every second hearth is fitted with burners. By choosing the location and firing rate for these burners, the temperature and location of the combustion zone within the furnace can be changed to suit the material being combusted. The highest moisture content of the flue gas is found on the top hearths where sludge with the highest moisture content is heated and some water is vaporized. Cooling air is initially blown into the central column and hollow rabble arms to keep them from overheating. A large portion of this air, after passing out of the central column at the top, is recirculated to the lowest hearth as preheated combustion air.

Operational Controls. Operators may set feed rate, excess air, air injection location, burner location, burner firing rate, rake speed, etc. Given the large number of interrelated and codependent process variables for a multiple hearth furnace, consistent operation is sometimes challenging. These furnaces generally operate at relatively high levels of excess air (up to 100 percent) to avoid localized air/oxygen deficits and to provide sufficient buffer to ensure consistent, quality combustion.

Feed sludge must contain more than 15 percent solids because of limitations on the maximum evaporating capacity of the furnace. Auxiliary fuel is required usually when the feed sludge contains between 15 and 30 percent solids. Feed sludge containing more than

50 percent solids may create temperatures in excess of the refractory and metallurgical limits of standard furnaces. Average loading rates of wet cake are approximately 40 kg/m^2•h (8 lb/ft^2•h) of effective hearth area but may range from 25 to 75 kg/m^2•h (5 to 15 lb/ft^2•h).

Process Variables. Variations in the basic form exist with some furnaces having varying numbers of hearths, an array of systems to introduce auxiliary air for combustion, cooling, or mixing, upper hearths with little or no exposure to the biosolids (typically termed a "zero hearth" or an "on-hearth afterburner"), a wide degree of burner configurations, and flue gas recirculation to promote enhanced combustion controls.

In addition to dewatering, multiple hearth incinerators have a large amount of required ancillary processes. On the unit itself there are at least 2 or more fans for burner air and center shaft cooling air, additional fans are required for auxiliary combustion air and flue gas recirculation, a large number of burners (typically between 9 and 36 per unit) each with a gas and combustion air supply train, and the center shaft drive and gear reducer. In addition, there are ash handling systems and some type of wet or dry scrubber to meet air pollution requirements. Other ancillaries include an induced draft fan, bypass stack, any additional air pollution controls, and possibly energy recovery.

Air Pollution Control. In the most basic units, the air pollution controls are wet scrubbers. In these units, scrubber water comes in contact with and removes most of the particulate matter in the exhaust gases. The recycle BOD and COD is nil, and the total suspended solids content is a function of the particulates captured in the scrubber. Under proper operating conditions, particulate discharges to the air from wet scrubbers are less than 0.65 kg/10^3 kg (1.3 lb/ton) of dry sludge input. With recent (2011) upgrades to the regulations in the United States, many of the existing multiple hearth incinerators will require upgrades to the air pollution controls. Additional details on air pollution controls are discussed later in this chapter.

Ash Handling. Ash handling may be either wet or dry. In the wet system, the ash falls into an ash hopper located beneath the furnace, where it is slurried with water from the exhaust gas scrubber. After agitation, the ash slurry is pumped to a lagoon or is dewatered mechanically. The effluent water from the ash lagoon or ash dewatering process can either be sent back into the wastewater treatment process or discharged back into the plant effluent and sent to the outfall. In the dry system, the ash is conveyed mechanically to a storage hopper for discharge into a truck for eventual disposal. The ash is usually conditioned with water. Ash density is about 5.6 kg/m^3 (0.35 lb/ft^3) dry and 880 kg/m^3 (55 lb/ft^3) wet.

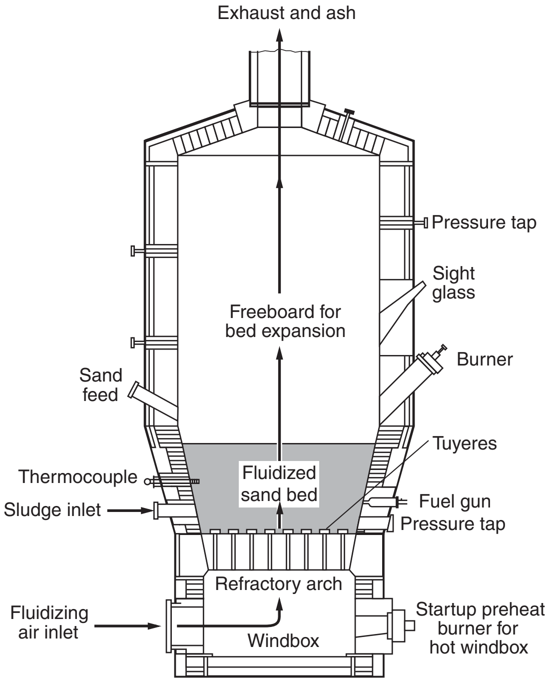
Fluidized-Bed Incineration

The fluidized-bed incinerator used commonly for sludge incineration is a vertical, cylindrically shaped, refractory-lined steel shell that contains a sand bed (media) and fluidizing air orifices to produce and sustain combustion (see Fig. 14–24). As of 2011, about 30 percent of ATO installations in the United States utilized fluidized-bed technology. These units tend to be much newer than the multiple-hearth installations that they are typically replacing. As of 2012, all of the new full-scale units currently being installed are fluidized-bed incinerators.

Process Description. The fluidized-bed incinerator ranges in size from 2.7 to 9.1 m (9 to 30 ft) in diameter. The incinerator is generally composed of three areas. These are (from bottom to top): (1) the windbox, (2) the sand bed, and (3) the freeboard. The windbox acts as an air plenum for distributing the fluidizing air, and may also have one or more burners for startup. Above the windbox is the sand bed. When quiescent, the

Figure 14–24

Cross section through a typical fluidized-bed incinerator.



sand bed is approximately 0.8 m (2.5 ft) thick and rests on a brick dome, refractory-lined grid, or a steel plate that keeps the sand bed separated from the windbox. The sand bed support area contains orifices, called "tuyeres," through which the fluidizing air is injected into the incinerator at a pressure of 20 to 35 kN/m^2 (3 to 5 lb$_f$/in.^{2}) by fluidizing air blowers. At low velocities, combustion gas "bubbles" appear within the fluidized bed. The main bed of suspended particles remains at a certain elevation in the combustion chamber and "boils" in place. Units that function in this manner are called "bubbling-bed" incinerators. The mass of suspended solids and gas, when active and at operating temperatures, expands to about double the at-rest volume. Sludge is mixed quickly within the fluidized-bed by the turbulent action of the bed. If required and auxiliary fuel injection ports are available, auxiliary fuel, such as oil, natural gas, or digester gas can be injected directly into the bed.

The minimum temperature needed in the sand bed prior to injection of sludge is approximately 700°C (1300°F). The temperature of the sand bed is controlled between 760 and 820°C (1400 and 1500°F). Evaporation of the water and combustion of the sludge solids takes place rapidly due to the high turbulence. The freeboard area, located above the bed, provides for residence time for the completion of combustion of the gaseous constituents. The flue gas (products of combustion) and ash leave the gas outlet through the top of the incinerator. No ash exits from the bed at the bottom of the incinerator as it is entrained with the flue gases.

Most fluid bed units that have been designed for autogenous operation should not require any auxiliary fuel after startup. The large thermal mass within the unit (i.e., the sand bed and refractory dome) helps to dampen fluctuations in heat input and also tends to retain the temperature in the unit if required to shut down for a limited duration. The large thermal mass tends to provide a stable, slow acting process that is robust, reliable, and controllable by most operators.

The fluidized-bed, though reliable, is complex and requires the use of trained personnel. Because fluidized-bed incinerators are complex, they are normally used in medium to large plants, but may be used in plants with lower flow ranges where land for the disposal of sludge is limited.

The main process vessel is very simple and contains no moving parts, which is a significant difference from the multiple-hearth incinerator design. The ancillary equipment required includes a fluidizing air blower, a burner combustion air blower, auxiliary fuel train, a sand system, an air pollution control system, and an ash handling system (which is typically combined with the air pollution control system).

Scrubber Water. Most of the ash (over 99 percent) is captured in the scrubber water, and the total suspended solids content is approximately 20 to 30 percent of the dry solids feed (inline with the ash content of feed sludge). Plant effluent is typically used as scrubber water at a rate of approximately 25 to 40 L/kg (3 to 5 gal/lb) of dry solids feed to the fluidized-bed. The ash slurry flows from the scrubber are normally directed to an ash lagoon or are mechanically dewatered to separate the ash from water. The effluent from the ash lagoon or ash dewatering process can either be sent back to the head of the wastewater treatment process or combined with the plant effluent at the outfall. The concentrations of BOD and COD are low, typically below 50 mg/L. Additional details on air pollution control are noted later in this chapter. Particulates, criteria air contaminants, and other air emissions are typically much less than a similarly sized multiple-hearth incinerator.

Process Modifications. Many new fluid bed units now incorporate at least one downstream air-to-air heat exchanger. The heat exchanger is used to transfer the heat from the exiting flue gases to the preheat the fluidizing air before it is introduced into the unit below the tuyeres. In this manner, heat is preserved within the fluid bed unit, despite the high volumetric flowrate of air through the bed. These units are called "hot windbox" fluid beds and are able to operate autogenously on biosolids with higher moisture contents. Some new units also incorporate energy recovery systems (separate from the fluidizing air preheat heat exchanger), which is discussed below.

A modification of the fluidized-bed incineration technology is the "circulating-bed" incinerator. In the circulating-bed unit, the reactor gas passes through the combustion chamber at much higher velocities, ranging from 3 to 8 m/s (10 to 25 ft/s). At these velocities, the bubbles in the fluidized bed disappear and streamers of solids and gas prevail. The entire mass of entrained particles flow up the reactor shaft to a particle separator, are deposited in storage momentarily, and are recirculated back to the primary combustion zone in the bottom of the reactor. Ash is removed continuously from the bottom of the bed. On turndown, the circulating bed becomes a bubbling bed.

Energy Recovery from Thermal Oxidation

Energy recovery from thermal oxidation processes is now an important component of the overall ATO process. The design of hot wind box fluidized-bed units incorporate at least one fluidizing air preheat heat exchanger as part of the main process to allow for highly efficient operation. Additional heat exchangers may be utilized to reheat the flue gases further downstream depending on the requirements of the air pollution control system. The reheating of the flue gases prior to stack tip discharge may also be desired for enhanced atmospheric dispersion or for aesthetic/plume suppression reasons. The heat recovery heat exchangers can also be used generate hot water, steam, or heated thermal oil for waste heat recovery or electricity production.

The quantity, quality, and form of the energy extracted from the ATO process depend on the heat and solids content of the dewatered sludge fed to the process. Undigested sludge with solids content greater than 25 percent offers good potential for energy recovery. One example

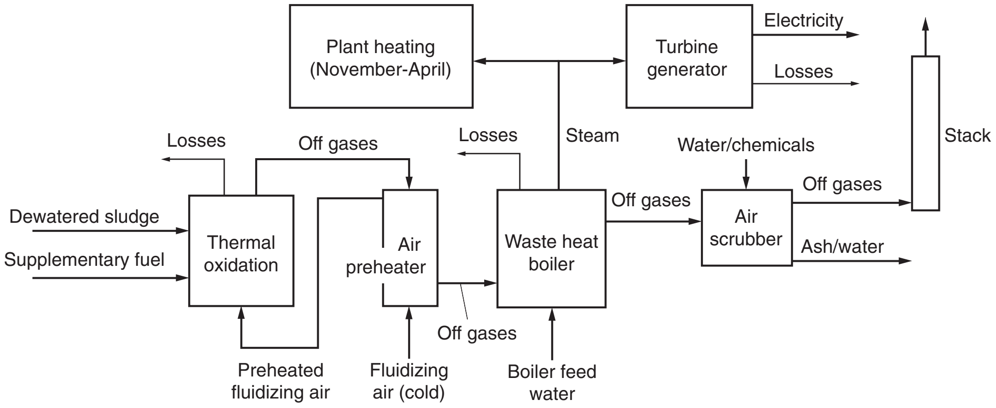


Figure 14–25

An example of an energy recovery process diagram.

of energy recovery is shown on Fig. 14–25. The hot off gases from thermal oxidation process is first introduced to an air preheater, then fed to a waste heat boiler that produces steam, which is fed to a steam turbine generator producing electricity. Depending on the electricity and fuel costs, the steam can be used to heat the buildings in the winter months instead of the turbine generator. Other uses for the steam extracted from the ATO process include process heating for digesters, heating FOG systems, or dewatering and drying processes.

Because generating and operating high pressure steam facilities require specialized boiler and pressure vessel operators, this application is not used widely. In this case, the hot off gases generated from the thermal oxidation process can be used to heat thermal oil or hot water that is used to generate electricity using the organic Rankin cycle. Other sources of waste heat (typically lower grade heat sources) which have been utilized at biosolids ATO facilities include capturing and recuperating heat lost from the exterior of the incinerator vessel via an air to glycol heat reclaim circuit, recovering heat from the scrubber water prior to the ash lagoon or ash dewatering with a water to water heat exchanger, and recovering heat from the residual temperature of the flue gas.

Coincineration with Municipal Solid Waste

Coincineration is the process of incinerating wastewater sludges with municipal solid wastes. Coincinerator types can vary but many consist of reciprocating grates that are designed for more of a solid fuel than the multiple heath and fluidized-bed incinerators discussed in the previous section. The major objective of coincineration is to reduce the combined costs of incinerating sludge and solid wastes. Coincineration is not practiced widely. The process has the advantages of producing the heat energy necessary to evaporate water from sludges, supporting combustion of solid wastes and sludge, and providing an excess of heat for steam generation, if desired, without the use of auxiliary fossil fuels. In properly designed systems, the hot gases from the process can be used to remove moisture from sludges to a content of 10 to 15 percent. Direct feeding of sludge cake containing 70 to 80 percent moisture over solid wastes on traveling or reciprocating grates has been found to be ineffective. For systems operating without heat recovery, a disposal ratio of 1 kg (2.2 lb) of dry wastewater sludge to 4.6 kg (11 lb) of solid wastes is fired in normal operation. In the case of the water-walled boiler with heat recovery, the ratio is approximately 1 kg of dry (industrial plant) sludge to 7 kg (17 lb) of solid wastes. Based on past experience in municipal solid-waste disposal, the application of coincineration will likely continue to proceed very slowly, despite the advantages to the community in combining the two waste-disposal functions.

Air-Pollution Control

Incineration methods for wastewater sludge have the potential to be significant contributors to air pollution. Air contaminants associated with incineration can be divided into two categories: (1) odors and (2) combustion emissions.

Odors from Incineration. Odors are particularly offensive to the human senses, and special attention is required to minimize nuisance odor emissions. Odors historically associated with multiple-hearth incinerators resulted from units with rudimentary air pollution controls and low incinerator exhaust exit temperatures. Today, many units are required to run at higher exhaust temperatures to meet stringent air emission requirements, and by doing so, nuisance odors from the incineration processes themselves are nonexistent. Odors may occur from the ancillary processes for both multiple-hearth and fluid bed incinerators. Dewatering, cake storage, and conveyance all emit odors that require proper capture, treatment, and discharge. Incinerators can generally use the foul air as combustion air in the ATO process resulting in cost effective odor elimination.

Emissions from Incineration. Combustion emissions vary depending upon the type of thermal reduction technology employed and the nature of the sludge and auxiliary fuel used in the combustion process. Combustion emissions of particular concern are the criteria air pollutants (i.e., particulate matter, carbon monoxide, oxides of nitrogen, and sulfur dioxide), acid gases (mainly hydrogen chloride), and hazardous air pollutants (mercury, cadmium, lead, dioxins and furans). Under Part 503 regulations in the United States, heavy metals (arsenic, beryllium, chromium, and nickel), and total hydrocarbons (or carbon monoxide) are also a concern for regulators. Regulations promulgated by the U.S. EPA in 2011 concerning incinerator emissions are discussed in Sec. 13–2 and are generally more strict than the rules in the European Union.

Generally, emission controls fall into three main categories. These are (1) source control, (2) combustion control, and (3) air pollution control equipment. For certain pollutants, namely the heavy metals, source control is one of the most cost effective methods of reducing air pollution from the incinerator stack.

Source Control. Source control programs and collection systems use bylaw enforcement, and directed control programs (such as dental amalgam separators for mercury reduction) are effective at reducing loadings into the downstream collection system, which eventually ends up in the biosolids.

Combustion Control. Nitrogen oxides, carbon monoxide, total hydrocarbons, certain volatile organic compounds, dioxin, and furans are all air pollutants that are formed during the ATO process and combustion controls are effective at reducing levels of these contaminants in the flue gases. Most of these pollutants will be decreased to acceptable levels with elevated temperatures in the incinerator exhaust (generally greater than 750°C) and sufficient residence time (greater than 1 s). However, increased levels of nitrogen oxides may form with highly elevated temperatures, so a careful balance must be maintained in the specific details of the incinerator design and operation.

Air Pollution Control. For both multiple-hearth and fluid bed incinerators, the typical (historically most common, as least in North America) type of air pollution control equipment has been discussed previously. However, advances in the level of air pollution control equipment are being driven by stricter legislation. In general because fluid bed ATO units produce cleaner emissions than multiple-hearths, the industry is moving towards fluid bed technology for new systems. Air pollution control equipment is used as the final step to reduce the remaining pollutant levels in the flue gases. Although the majority of systems in North America have historically been wet scrubbers, there are also "dry" systems which are more common in Europe and Asia and more closely resemble the equipment utilized on solid waste incinerators. For primarily fluid bed incinerators, ammonia or urea injection may be used for selective non-catalytic reduction of nitrogen oxides. This treatment is done early while the flue gases are hot as they exit from the incinerator.

Advanced wet systems are now being used which contain multiple throat venturi scrubbers for particulate and heavy metal removal, caustic wet scrubbing for residual acid gas and sulfur dioxide removal, wet electrostatic precipitation for enhanced fine particulate and metal removal and polishing. A packed bed of sulfur impregnated media is sometimes used for the removal of mercury. Unfortunately, the mercury removal process requires a significant quantity of water, which can result in large quantities of wastewater. The generation of wastewater is usually not a problem for biosolids incinerators, as they are most commonly co-located with a wastewater treatment plant. Wet ash handling is used similar to the traditional wet venturi scrubber system.

Dry systems typically employ some method of flue gas cooling (whether this is part of a waste heat recovery boiler or a quench tower) to temper the gases before proceeding to the downstream equipment. Powdered activated carbon is injecting into the flue gas stream for heavy metal removal, and dioxin and furan control. Lime may also be injected for sulfur dioxide and acid gas control. A bag house, employing filter bags, is used to filter the flue gases. For this type of system, the ash is dry and is sent to silos for truck loading and disposal.

Hybrid systems may be employed which incorporate components of wet and dry air pollution control trains depending on the requirements of the level of pollution control, the site constraints, and the availability of water.

14–5 COMPOSTING

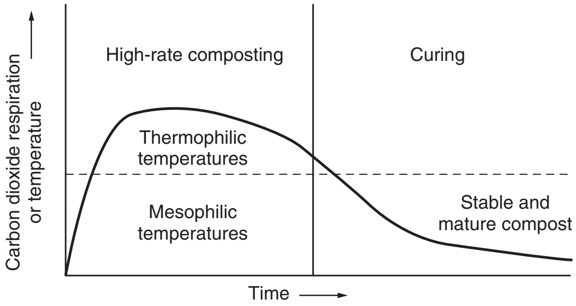
Composting is a process in which organic material undergoes biological degradation to a stable end product. Sludge that has been composted properly is a nuisance-free, humus-like material. Approximately 20 to 30 percent of the volatile solids are converted to carbon dioxide and water. As the organic material in the sludge decomposes, the compost heats to temperatures in the pasteurization range of 50 to 70°C (120 to 160°F), and enteric pathogenic organisms are destroyed. Properly composted biosolids may be used as soil conditioners in agricultural or horticultural applications, subject to any limitations based on the constituents in the composed biosolids (WEF, 2010). Composting is a cost-effective and environmentally sound alternate for the stabilization of wastewater sludges. Composting can be practiced for dewatered sludges or dewatered digested biosolids. However, composting biosolids is preferred, due to the odor issues during the composting process itself and the quality of the compost product.

Although composting may be accomplished under anaerobic or aerobic conditions, essentially all municipal wastewater biosolids composting applications are under mostly aerobic conditions (composting is never completely aerobic). Aerobic composting accelerates material decomposition and results in the higher rise in temperature necessary for pathogen destruction. Aerobic composting also minimizes the potential for nuisance odors.

The anticipated daily production of biosolids from a wastewater-treatment facility will have a pronounced effect on the alternate composting systems available for use, as will the availability of land for the construction of the composting facility. Other factors affecting

Figure 14–26

Stages during composting as related to carbon dioxide respiration and temperature (Epstein, 1997.).



the type of composting system are the nature of the biosolids produced; stabilization, if any, of the biosolids prior to composting; the type of dewatering equipment and chemicals used. Biosolids that are stabilized by aerobic or anaerobic digestion prior to composting may result in reducing the size of the composting facilities by up to 40 percent.

Process Microbiology

The composting process involves the complex destruction of organic material coupled with the production of humic acid to produce a stabilized end product. The microorganisms involved fall into three major categories: bacteria, actinomycetes, and fungi. Although the interrelationship of these microbial populations is not fully understood, bacterial activity appears to be responsible for the decomposition of proteins, lipids, and fats at thermophilic temperatures, as well as for much of the heat energy produced. Fungi and actinomycetes are also present at varying levels during the mesophilic and thermophilic stages of composting and appear to be responsible for the destruction of complex organics and the cellulose supplied in the form of amendments or bulking agents.

Composting Process Stages

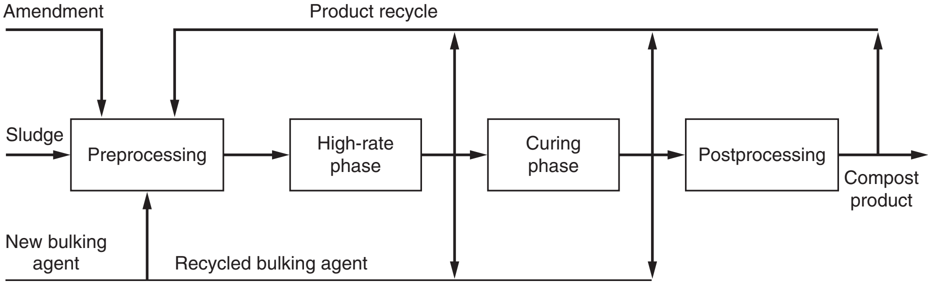
During the composting process, three separate stages of activity and associated temperatures are observed: mesophilic, thermophilic, and curing (cooling) (see Fig. 14–26). In the initial mesophilic stage, the temperature in the compost pile increases from ambient to approximately 40°C (104°F) with the appearance of fungi and acid-producing bacteria. As the temperature in the composting mass increases to the thermophilic range of 40 to 70°C (104 to 160°F), these microorganisms are replaced by thermophilic bacteria, actinomycetes, and thermophilic fungi. It is in the thermophilic temperature range that the maximum degradation and stabilization of organic material occur. The curing stage is characterized by a reduction in microbial activity, and replacement of the thermophilic organisms with mesophilic bacteria and fungi. During the curing stage, further evaporative release of water from the composted material will occur, as well as stabilization of pH and completion of humic acid formation.

Composting Process Steps

Most composting operations consist of the following basic steps (see Fig. 14–27): (1) preprocessing, the mixing of dewatered sludge with an amendment and/or a bulking agent; (2) high-rate decomposition, aerating the compost pile either by the addition of air, by mechanical turning, or by both; (3) recovery of the bulking agent (at the end of either the high-rate decomposition or curing phase, if practical); (4) further curing and storage, which allows further stabilization and cooling of the compost; (5) postprocessing,

Figure 14–27

Generalized process diagram for composting showing inputs of sludge (feed substrate), amendments, and bulking agents (Haug, 1993.).



screening for the removal of nonbiogradable material such as metals and plastics or grinding for size reduction, and (6) final disposition. A portion of the final product is sometimes recycled to the preprocessing step to aid in conditioning the compost mixture.

Feed Stock Amendments. An amendment is an organic material added to the feed substrate primarily to, reduce moisture content, and increase the air voids for proper aeration. Amendments can also be used to increase the quantity of degradable organics in the mixture. Commonly used amendments are sawdust, straw, recycled compost, and rice hulls. A bulking agent is an organic or inorganic material that is used to provide structural support and to increase the porosity of the mixture for effective aeration. Wood chips are the most commonly used bulking agents and can be recovered and reused. The characteristics of bulking agents used most commonly are reported in Table 14–18. An amendment

Table 14–18

Characteristics of compost bulking agents used in the aerobic composting of sludge from wastewater treatment[a]

Bulking agent	Comments
Wood chips	May have to be purchased High recovery rate by screening Provides supplemental carbon source
Chipped brush	Possibly available as a waste material Low recovery rate by screening Provides supplemental carbon source Longer curing time of compost
Leaves and yard waste	Must be shredded Wide range of moisture content Readily available source of carbon Relatively low porosity Nonrecoverable
Shredded tires	Often mixed with other bulking agents Supplemental carbon is not available Nearly 100 percent recoverable May contain metals
Ground waste lumber	Possibly available as a waste material Often a poor source of supplemental carbon

[a] Adapted in part from WEF (2010).

can also provide supplemental carbon to the mix and it is typically recommended to maintain a carbon to nitrogen ratio of 25:1 to 35:1. Insufficient carbon can lead to nitrogen loss as ammonia which can cause odor issues and reduce the nutrient content of the resulting compost (WEF, 2010).

High-Rate Decomposition. The high-rate decomposition stage of composting has been more engineered and controlled due to the need to reduce odors, supply high aeration rates, and maintain process control. The curing stage is often less engineered, less controlled, and given only small consideration in some designs, however, the curing stage is an integral part of the system design and operation, and both stages need to be designed and operated properly to produce a mature compost product.

Recovery of the Bulking Agent. If practicable, the bulking agent should be recovered at the end of either the high-rate decomposition or curing phase. The most common method for recovery of bulking agent is screening with mesh size based on the physical size of the bulking agent.

Postprocessing. Postprocessing is often used to prepare the finished compost for marketing. Preparation includes conveying the finished compost from the active composting area to the curing, screening, and preparation areas. Trommel screens and belt shredders are used frequently; shredding can precede or follow curing. In some cases, double screening is preferable, especially for the horticultural market to meet product quality requirements. Particle size of the finished product for general use ranges typically from 6 to 25 mm (1/4 to 1 in.).

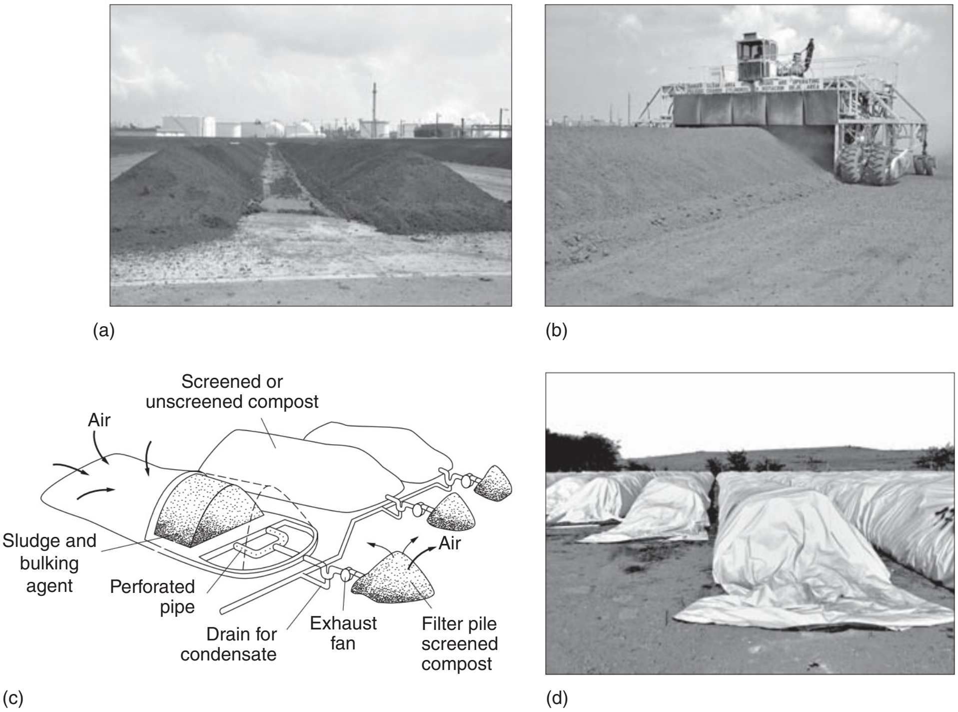
Composting Methods

The two principal methods of composting now in use in the United States may be classified as agitated or static. In the agitated method the material to be composted is agitated periodically to introduce oxygen, to control the temperature, and to mix the material to obtain a uniform product. In the static method, the material to be composted remains static and air is blown through the composting material. The most common agitated and static methods of composting are known as the windrow and static pile methods, respectively. Proprietary composting systems in which the composting operation is carried out in a reactor of some type are known as in-vessel composting systems.

Windrow. In a windrow system, a mixture of dewatered sludge and bulking agent is placed in windrows, which are typically from 1 to 2 m (3 to 6 ft) high and 2 to 4.5 m (6 to 14 ft) at the base [see Fig. 14–28(a)]. The windrows are turned and mixed periodically during the composting period using specialized equipment [see Fig. 14–28(b)]. Supplemental mechanical aeration is used in some applications. The composting period is about 21 to 28 d. Under typical operating conditions, the windrows are turned a minimum of five times while the temperature is maintained at or above 55°C. In windrow composting, aerobic conditions are difficult to maintain throughout the cross-sectional area of the windrow. Thus, the microbial activity within the pile may be aerobic, facultative, anaerobic, or various combinations thereof, depending on when and how often the pile is turned. Turning of the windrows is often accompanied by the release of

Figure 14–28

Composting systems: (a) view of compost windrows, (b) view of equipment for turning and grading windrows, (c) schematic of aerated static pile compost process, and (d) view of force-aerated static pile in compost bags for odor control.



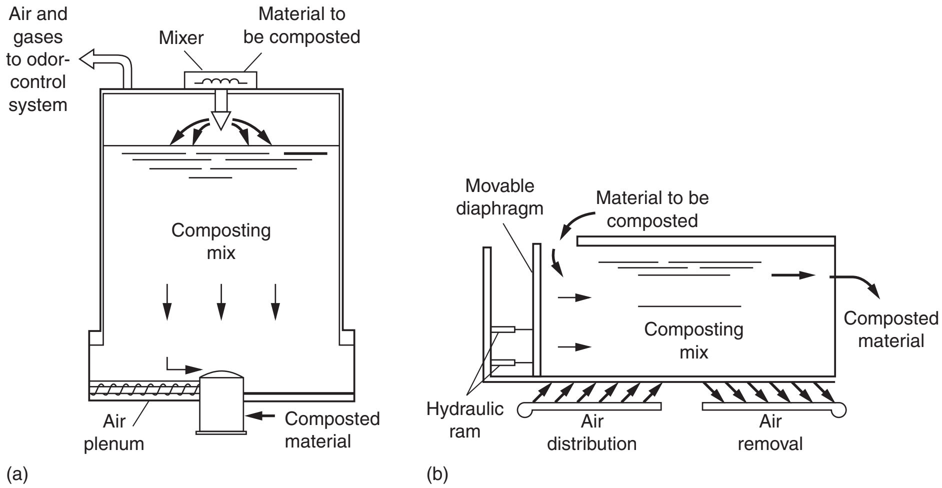
offensive odors. The release of odors occurs typically when anaerobic conditions develop within the windrow. Some windrow operations are covered or enclosed, similar to aerated static piles.

Aerated Static Pile. The aerated static pile system consists of a grid of aeration or exhaust piping over which a mixture of dewatered sludge and bulking agent is placed [see Fig. 14–28(c)]. An alternative version of the static pile composting method is carried out in an enclosed plastic bag with forced aeration [see Fig. 14–28(d)]. In a typical static pile system, the bulking agent consists of wood chips, which are mixed with the dewatered sludge by a pug-mill type or rotating-drum mixer or by movable equipment such as a front-end loader. Material is composted for 21 to 28 d and is typically followed by a curing period of 30 d or longer. Typical pile heights are generally about 2 to 2.5 m (6 to 8 ft). A layer of screened compost is often placed on top of the pile for insulation. Disposable corrugated plastic drainage pipe is commonly used for air supply and each individual pile is recommended to have an individual blower for more effective aeration control. Screening of the cured compost usually is done to reduce the quantity of the end product requiring ultimate disposal and to recover the bulking agent. For improved process and odor control, many facilities cover or enclose all or significant portions of the system.

In-Vessel Composting Systems. In-vessel composting is accomplished inside an enclosed container or vessel. Mechanical systems are designed to minimize odors and process time by controlling environmental conditions such as air flow, temperature, and oxygen concentration. The advantages of in-vessel composting systems are better process and odor control, faster throughput, lower labor costs, and smaller area requirements.

Figure 14–29

Plug flow in-vessel composting reactors: (a) unmixed vertical plug flow reactor and (b) unmixed tunnel (horizontal plug flow) reactor.



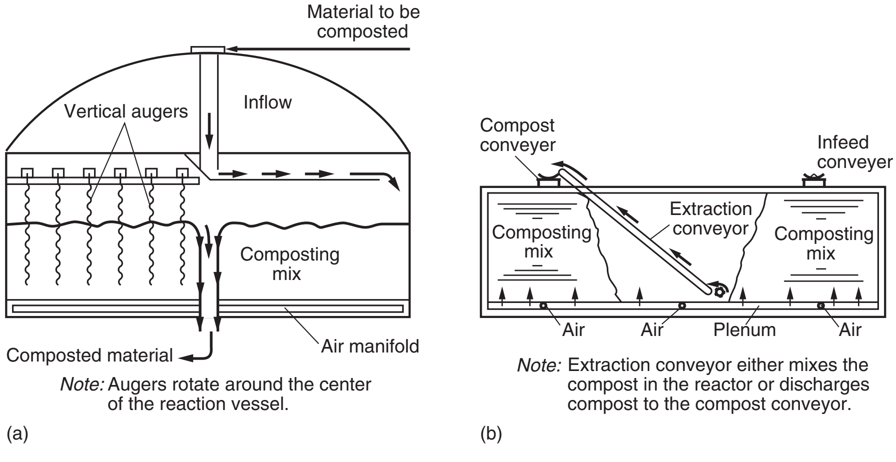
In-vessel composting systems can be divided into two major categories: plug flow and dynamic (agitated bed). In plug-flow systems, the relationship between particles in the composting mass stays the same throughout the process, and the system operates on the basis of a first-in, first-out principle. In a dynamic system, the composting material is mechanically mixed during the processing. In-vessel systems can be further categorized based on the geometric shape of the vessels or containers used. Examples of plug-flow reactors are shown on Fig. 14–29 and examples of dynamic-type systems are illustrated on Fig. 14–30.

Design Considerations

A number of factors, each of which must be evaluated to meet the specific requirements, must be considered in the design of a composting system (see Table 14–19). A design approach using a materials balance is particularly useful because the amount of each component (sludge or biosolids, bulking agent, and amendment) used during each phase of the process is determined. In a materials balance, the following parameters must be measured or calculated for each component: (1) total volume, (2) total wet weight, (3) total solids content (dry weight), (4) volatile solids content (dry weight), (5) water content

Figure 14–30

Dynamic (mixed) in-vessel composting units: (a) vertical reactor and (b) horizontal reactor.



Note: Augers rotate around the center of the reaction vessel.

Note: Extraction conveyor either mixes the compost in the reactor or discharges compost to the compost conveyor.

Table 14–19

Design considerations for aerobic sludge composting processes[a]

Item	Comment
Type of sludge	Both sludge and biosolids can be composted successfully. Sludge has a greater potential for odors, particularly for windrow systems. Sludge, as compared to biosolids, has more energy available, will degrade more readily, and has a higher oxygen demand.
Amendments and bulking agents	Amendment and bulking agent characteristics, such as moisture content, particle size, and available carbon, affect the process and quality of product. Bulking agents should be readily available.
Carbon-nitrogen ratio	The initial C:N ratio should be in the range of 25:1 to 35:1 by weight. At lower ratios, ammonia is given off. Carbon should be checked to ensure it is readily biodegradable.
Volatile solids	The volatile solids of the composting mix should be greater than 30 percent of the total solids content. Dewatered sludge will usually require an amendment or bulking agent to adjust the solids content.
Air requirements	Air with at least 50 percent of the oxygen remaining should reach all parts of the composting material for optimum results, especially in mechanical systems.
Moisture content	Moisture content of the composting mixture should be not greater than 40 percent for static pile, windrow, and in-vessel composting.
pH control	The pH of the composting mixture should generally be in the range of 6 to 9. To achieve optimum aerobic decomposition, pH should remain at 7 to 7.5 range.
Temperature	For best results, temperature should be maintained between 50 and 55°C for the first few days and between 55 and 60°C for the remainder of the active composting period. If the temperature is allowed to increase beyond 65°C for a significant period of time, biological activity will be reduced.
Control of pathogens	If properly conducted, it is possible to kill all pathogens, weeds, and seed during the composting process. To achieve this level of control, the temperature must be maintained at levels required by the EPA 503 regulations for Class A (see Table 13–11).
Mixing and turning	To prevent drying, caking, and air channeling, material in the process of being composted should be mixed or turned on a regular schedule or as required. Frequency of mixing or turning will depend on the type of composting operation.
Heavy metals and trace organics	Heavy metals and trace organics in the sludge and finished compost should be monitored to ensure that the concentrations do not exceed the applicable regulations for end use of the product.
Site constraints	Factors to be considered in selecting a site include available area, access, proximity to treatment plant and other land uses, climatic conditions, and availability of buffer zone.

[a] Adapted in part from Tchobanoglous, et al. (1993).

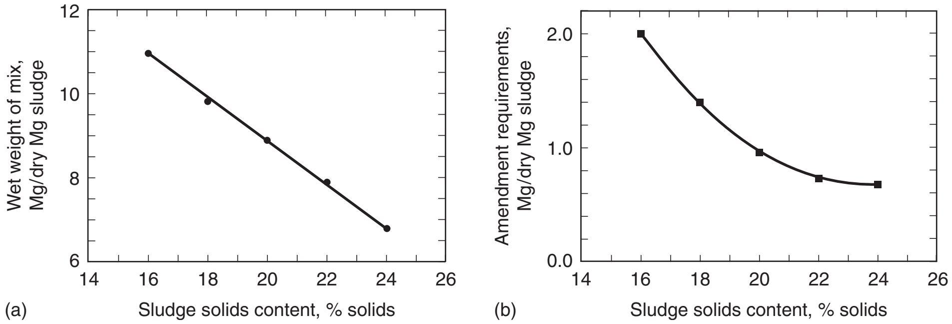
(weight), (6) bulk density (wet weight/unit volume), (7) percent water content, and (8) percent volatile solids of the compost mix.

An important output of the materials balance is to determine the composition of the compost mix. The compost mix should be about 40 percent dry solids to ensure adequate composting in windrow and static-pile composting. In-vessel systems require similar solids requirements, but slightly lower values may be used, depending on the aeration system. Starting the compost process with solids higher than 40 percent soon results in a “dry mix.” A dry mix is dusty, and sufficient biological activity and temperature levels are difficult to maintain. The addition of water will likely be required for the duration of the process; thus, provisions for a water supply should be made.

The effect of moisture content in the dewatered sludge on the compost mix is illustrated on Fig. 14–31. The moisture content of the sludge affects the wet weight of the mixture and the amount of amendment that has to be used. Using Fig. 14–31 (a), for

Figure 14–31

Effect of sludge solids content on compost mix and amendment quantities: (a) mix quantities versus sludge solids content, (b) amendment requirements versus sludge solids content. (U.S. EPA, 1989.)



example, if the sludge cake contains 24 percent solids, the wet weight of the mix is about 6.7 Mg (tonne) per dry Mg of sludge. If the sludge solids content decreases to 16 percent, the wet weight increases to about 11 Mg per dry Mg of sludge. The additional moisture content would require larger materials-handling systems and larger reactors. The amendment requirements, as indicated on Fig. 14–31(b), would triple over the same range of sludge solids. In compost-system design, the type of sludge-dewatering system and the consistency of resulting product have to be evaluated carefully.

Co-composting with Municipal Solid Wastes

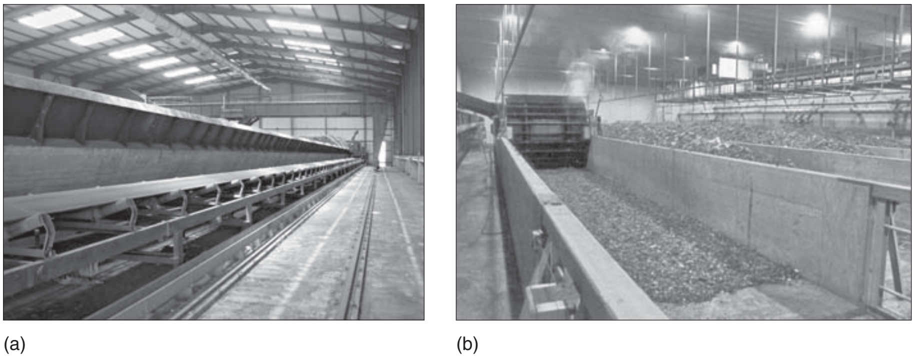
Co-composting of sludge and municipal solid wastes is a possible alternative where integrated waste-disposal facilities are considered. Mixing the sludge with the organic fraction of municipal solid waste or source separated yard wastes is beneficial because (1) sludge dewatering may not be required, and (2) the overall metals content of the composted material will be less than that of the composted sludge alone. Liquid treatment plant sludges typically have a solids content ranging from 3 to 8 percent. A 2-to-1 mixture of compostable municipal solid or yard wastes to sludge is recommended as a minimum. Both static and agitated compost systems have been tried (Tchobanoglous et al., 1993). Two examples of composting facilities in reactors with mechanical mixing, located within a building for odor control, are shown on Fig. 14–32.

Public Health and Environmental Issues

The principal public health and environmental issues concerning compost operations relate to exposure to pathogens and bioaerosols. Exposure to pathogens can occur during the composting process or through the use of the product if the composting process is not executed properly and the resulting product is not disinfected. The potential modes of infection for workers are (1) inhalation of aerosols containing airborne microorganisms,

Figure 14–32

Examples of compost reactors with mechanical mixing. The reactors are in enclosed buildings for odor control.



(a) (b)

(2) dermal contact, or (3) oral through inadvertent contact of dust or contaminated food or through hand-to-mouth contact such as cigarette smoking. Ingestion of contaminated product or contamination by the product to cigarettes or food is the greatest potential source of pathogen invasion by workers or users (Epstein, 1997).

Compost bioaerosols are organisms or biological agents that can be dispersed through the air and affect human health. Bioaerosols can contain living organisms including bacteria, fungi, actinomycetes, arthropods, protozoa and microbial products such as endotoxin and microbial enzymes. During composting, bioaerosols are not only present in waste materials but also can be generated during the process. The level and type of bioaerosols are a function of feedstock. The two bioaerosols of greatest interest to worker health and the environment surrounding composting facilities are *Aspergillus fumigatus* and endotoxin.

A. fumigatus, a common fungus, is of concern to both worker health and populations surrounding composting facilities, as it can cause lung disease. Endotoxin, part of the cell wall of gram-negative bacteria that is released to the environment during the composting process, is of primary concern to workers in composting, recycling, and other solid-waste processing facilities. There is little evidence that exposure to airborne endotoxin causes toxic conditions. Most of the data, however, concerning worker illness is associated with composting municipal solid waste, principally in Europe. Proper ventilation, dust control, and use of dust masks reduce worker exposure to bioaerosols (Epstein, 1997).

14–6 SLUDGE AND BIOSOLIDS CONVEYANCE AND STORAGE

The sludges from primary and biological treatment processes are concentrated and stabilized by mechanical, biological, and thermal means and are reduced in volume in preparation for final disposal. Because the methods of conveyance and final disposal often determine the type of stabilization required and the amount of volume reduction that is needed, they are considered briefly in the following discussion.

Conveyance Methods

Biosolids may be transported long distances by (1) pipeline, (2) truck, (3) barge, (4) rail, or any combination of these four modes. Truck transportation, however, is the most common method used currently [see Fig. 14–33(a)]. To minimize the danger of spills, odors, and dissemination of pathogens to the air, liquid biosolids should be transported in closed vessels, such as tank trucks, railroad tank cars, or covered tank barges. Stabilized, dewatered biosolids can be transferred in open vessels, such as dump trucks, or in railroad gondolas. If biosolids are hauled long distances, the vessels should be covered. The method of transportation chosen and its costs are dependent on a number of factors,

Figure 14–33

Views of sludge transport vehicle and storage facilities: (a) typical side dump sludge transport vehicle, and (b) large bins used for the temporary storage for lime-stabilized sludge. Overhead bucket is used to distribute sludge in bins and to transport to trucks.

(a) (b)

including (1) the nature, consistency, and quantity of biosolids to be transported; (2) the distance from origin to destination; (3) the availability and proximity of the transit modes to both origin and destination; (4) the degree of flexibility required in the transportation method chosen; and (5) the estimated useful life of the ultimate disposal facility.

Each transportation method contributes a minor air pollutant load, either directly or indirectly. A certain amount of air pollution is produced from the facility that generates electricity necessary for sludge pumping. The engines that move trucks, barges, and railroad cars also produce some air pollutants. On a mass (tonnage) basis, the transportation mode that contributes the lowest pollutant load is piping. Next, in sequence, are barging and unit train rail transportation. The highest pollutant load is from trucking. Other factors of environmental concern include traffic, noise, and construction disturbance.

Storage

It is often necessary to store biosolids that have been digested anaerobically before they are disposed of or used beneficially. Although sludge can be stored for short periods of time in clarifiers, biological systems, digesters or holding tanks, the available storage capacity may not be sufficient for long term storage. Storage of liquid biosolids can be accomplished in storage basins and lagoons, and storage of dewatered biosolids can be done on storage pads. An example of large temporary sludge storage bins for lime-stabilized biosolids is shown on Fig.14–33 (b). Drying beds, discussed previously, can also be used for storage.

Storage Basins and Lagoons. Biosolids stored in basins become more concentrated and are further stabilized by continued anaerobic biological activity. Long-term storage is effective in pathogen destruction. Depth of the biosolids storage basins may vary from 3 to 5 m (10 to 16 ft). Solids loading rates vary from about 0.1 to 0.25 kg VSS/m^2·d (20 to 50 lb VSS/10^3 ft^2·d) of surface area. If the basins are not loaded too heavily ($\leq$ 0.1 kg VSS/m^2·d), it is possible to maintain an aerobic surface layer through the growth of algae and by atmospheric reaeration. Alternatively, surface aerators can be used to maintain aerobic conditions in the upper layers. The number of basins to be used should be sufficient to allow each basin to be out of service for a period of about 6 months. Stabilized and thickened biosolids can be removed from the basins using a mud pump mounted on a floating platform or by mobile crane using a drag line. Biosolids concentrations as high as 35 percent solids have been achieved in the bottom layers of these basins.

Long-term storage of sludge and biosolids in lagoons is simple and economical if the treatment plant is in a remote location. A lagoon is an earthen basin into which untreated sludge, or digested biosolids are deposited. In lagoons with untreated sludge, the organic matter is stabilized by anaerobic and aerobic decomposition, which may give rise to objectionable odors. The stabilized biosolids settle to the bottom of the lagoon and accumulate, and excess liquid from the lagoon, if there is any, is returned to the plant for treatment. Lagoons should be located away from highways and dwellings to minimize possible nuisance conditions and should be fenced to keep out unauthorized persons. Lagoons should be relatively shallow, 1.25 to 1.5 m (4 to 5 ft), if they are to be cleaned by scraping. If the lagoon is used only for digested biosolids, the nuisances mentioned should not be a problem. If subsurface drainage and percolation are potential problems, the lagoon should be lined. Solids may be stored indefinitely in a lagoon and may be removed periodically after draining and drying.

Storage Pads. Where dewatered biosolids have to be stored prior to land application, sufficient storage area should be provided based on the number of consecutive days that biosolids hauling could occur without applying biosolids to land. Allowances also have to be made for paved access and for area to maneuver the biosolids hauling trucks, loaders, and application vehicles. The storage pads should be constructed of concrete and designed to withstand the truck loadings and biosolids piles. Provisions for leachate and stormwater collection and disposal also have to be included in the design of sludge storage pads.

14–7 SOLIDS MASS BALANCES

Sludge and biosolids processing facilities, such as thickening, digestion, and dewatering, produce waste streams that must be recycled to the treatment process or to treatment facilities designed specifically for the purpose. The recycled flows impose an incremental solids, hydraulic, organic, and nutrient load on the wastewater-treatment facilities that must be considered in the plant design. When the flows are recycled to the treatment process, they should be directed to the head of the plant and blended with the plant flow following preliminary treatment. Equalization facilities can be provided for the recycled flows so that their reintroduction into the plant flow will not cause a shock loading on the subsequent treatment processes. To predict the incremental loads imposed by the recycled flows, it is necessary to perform a materials mass balance for the treatment system.

Preparation of Solids Mass Balances

Typically, a materials mass balance is computed on the basis of average flow, average BOD and total suspended solids concentrations. To size certain facilities properly, such as sludge storage tanks and plant piping, it is also important to perform a materials mass balance for the maximum expected concentration of BOD and TSS in the untreated wastewater. However, the maximum concentrations will not usually result in a proportional increase in the recycled BOD and TSS. The principal reason is that the storage capacity in the wastewater and sludge-handling facilities tends to dampen peak solids loads. For example, for a maximum TSS load equal to twice the average value, the resulting peak solids loading to a dewatering unit may be only 1.5 times the average loading. Further, it has been shown that periods of maximum hydraulic loading typically do not correlate with periods of maximum BOD and TSS. Therefore, coincident maximum hydraulic loadings should not be used in the preparation of a materials mass balance for maximum organic loadings (see Chap. 5). The preparation of a mass balance is illustrated in Example 14–3.

Performance Data for Solids Processing Facilities

To prepare a materials mass balance, it is necessary to have information on the operational performance and efficiency of the various unit operations and processes that are used for the processing of waste sludge and biosolids. Representative data on the solids capture and expected solids concentrations for the most commonly used operations are reported in Tables 14–20 and 14–21. These data were derived from an analysis of the records from a number of installations throughout the United States. The wide variation that can occur in the reported values is apparent; thus, the values in Tables 14–20 and 14–21 should be used only if no other information is available. Wherever possible, local conditions and data should be used in performing the mass balance.

Impact of Return Flows and Loads

In addition to performance data for expected solids capture and constituent concentrations for the various process components, data for the expected concentrations of BOD and TSS in the return flows must also be included in preparing of mass balances. If the quantities

Table 14–20

Typical solids concentration and capture values for various sludge and biosolids processing methods

	Solids concentration, %		Solids capture %	
Operation	**Range**	**Typical**	**Range**	**Typical**
Gravity thickeners:

and characteristics of recycled flows and loads are not accounted for properly, the facilities that receive them may be underdesigned significantly. The major impacts of return flows and measures that can mitigate these impacts are summarized in Table 14–22. Impact of returned flows on the overall treatment process is discussed in detail in Chap. 15.

Table 14–22

Major impacts and potential mitigation measures for return flows from sludge and biosolids-processing facilities[a]

Source of return flow	Impact	Process impacted	Mitigation measure
Sludge thickening	Effluent degradation by colloidal SS	Sedimentation	Add flocculent aid ahead of sedimentation tank
			Separately thicken primary and biological sludges
			Optimize gravity thickener dilution water
	Floating sludge	Sedimentation	Minimize gravity thickener detention time
			Remove sludge continuously and uniformly
	Odor release and septicity	Recycle point	Reduce gravity thickener detention time
			Return flows ahead of aerated grit chamber
			Provide odor containment, ventilation, and treatment (scrubber or biofilter)
		Biological	Return odorous flows to aeration tank
			Remove sludge continuously and uniformly
			Provide separate return flow treatment (with other recycle streams)
	Solids buildup	Sedimentation	Increase dewatering unit operation time
		Biological	Remove sludge continuously and uniformly
			Include recycle loads in mass balance analysis
Sludge dewatering	Effluent degradation by colloidal suspended solids	Sedimentation	Optimize dewatering units solids capture by improved sludge conditioning
			Add flocculent aid ahead of sedimentation tank
			Return centrate/filtrate to thickener
			Provide separate return flow treatment (with other recycle streams)
	Solids buildup	Sedimentation	Increase dewatering unit operation time

(*continued*)

Table 14–22 (*Continued*)

Source of return flow	Impact	Process impacted	Mitigation measure
		Biological	Remove sludge continuously and uniformly Reduce trickling-filter recycle rate Include recycle loads in mass balance analysis
Sludge stabilization	Effluent degradation by excessive BOD load	Biological	Optimize supernatant/decant removal, i.e., remove smaller amounts over a longer period of time, or reschedule removal to off-peak periods Provide separate return flow treatment Increase RBC speed Increase MLVSS in activated-sludge system (decrease F:M ratio) Increase dissolved oxygen level in activated-sludge process
	Effluent degradation by nutrients	Biological	Regulate digester supernatant/decant removal Thicken sludge before stabilization Provide separate return flow treatment
Washwater from depth filters	Hydraulic surges	Sedimentation	Provide backwash storage for flow equalization Schedule filter backwashing for off-peak periods

[a] Adapted, in part, from U.S. EPA (1987b).

EXAMPLE 14–3 **Preparation of a Solids Mass Balance for a Secondary Treatment Facility** Prepare a solids balance for the treatment flow diagram shown in the following figure, using an iterative computational procedure.

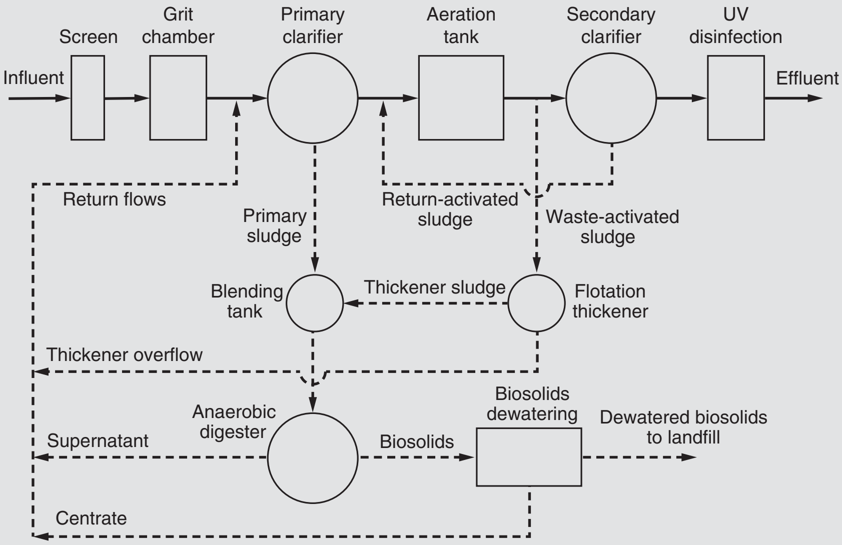
1. Definition of terms

   BOD_C = biochemical oxygen demand expressed as a concentration, g/m^3
   BOD_M = biochemical oxygen demand expressed as a mass, kg/d
   TSS_C = total suspended solids expressed as a concentration, g/m^3
   TSS_M = total suspended solids expressed as a mass, kg/d

   Assume for the purpose of this example that the following data apply:
2. Wastewater flowrates
   a. Average dry weather flowrate = 21,600 m^3/d
   b. Peak dry weather flowrate = 2.5(21,600 m^3/d) = 53,900 m^3/d
3. Influent characteristics
   a. $BOD_C = 375\ g/m^3$
   b. $TSS_C = 400\ g/m^3$ (assume VSS_c/TSS_c ratio in influent = 67%)
   c. TSS_C after grit removal = 360 g/m^3 (assume volatile fraction of the grit = 10%)
4. Sludge and biosolids characteristics
   a. Concentration of primary sludge = 6%
   b. Concentration of thickened waste-activated sludge = 4% (assume solids capture in the flotation thickeners = 90%)
   c. Total suspended solids in digested sludge = 5%
   d. For the purposes of this example, assume that the specific gravity of the solids from the primary sedimentation tank and the flotation thickener is equal to 1.0

   e. Fraction of the biological solids that are biodegradable = 65%
   f. The value of BOD$_C$ can be obtained by multiplying the value of UBOD by a factor of 0.68 (corresponds to a k value of 0.23 d^{-1} in the BOD equation, see Chap. 2)

5. Effluent characteristics
   a. BOD$_C$ = 20 g/m^3
   b. TSS$_C$ = 22 g/m^3
6. Primary clarifier
   a. Assumes performance of 33% BOD removal and 70% TSS removal
   b. Assume VSS$_C$/TSS$_C$ ratio in primary effluent going to the secondary treatment process = 85%
7. Secondary treatment
   a. Assume the mixed-liquor VSS$_C$/ TSS$_C$ ratio is 0.8
   b. Aeration tank volume, V_r = 4700 m^3
   c. Y = 0.5 kg/kg
   d. b = 0.06 d^{-1}
   e. SRT = 10 d
8. Sludge digestion
   a. Assume SRT = 20 d
   b. Assume VSR = 50%
   c. Assume digester gas production = 1.12 m^3/kg VSS destroyed
   d. Assume BOD$_C$ in digester supernatant = 1000 g/m^3
   e. Assume TSS$_C$ in digested sludge = 5%
9. Sludge dewatering
   a. Assume sludge cake = 22% solids
   b. Specific gravity of sludge = 1.06
   c. Solids capture = 93%
   d. Centrate BOD$_C$ = 2000 mg/L



Solution

1. Convert the given constituent quantities to daily mass values.
   a. BOD$_M$ in influent:

$$\begin{aligned} BOD_M &= (21{,}600\ m^3/d)(375\ g/m^3)/(10^3\ g/1\ kg)\\ &= 8100\ kg/d \end{aligned}$$

b. TSS_M in influent:

$$TSS_M = (21{,}600 \text{ m}^3/\text{d})(400 \text{ g/m}^3)/(10^3 \text{ g/1 kg}) = 8640 \text{ kg/d}$$

c. TSS_M after grit removal (influent to primary settling tanks):

$$TSS_M = (21{,}600 \text{ m}^3/\text{d})(360 \text{ g/m}^3)/(10^3 \text{ g/1 kg}) = 7776 \text{ kg/d}$$

2. Estimate the concentration of soluble BOD_C in the effluent using the following relationship:

   Effluent BOD_C = influent soluble BOD_C escaping treatment + BOD_C of effluent TSS_C

   a. Determine the BOD_C of the effluent TSS_C.
      - i. Biodegradable portion of effluent TSS_C is $0.65\ (22 \text{ g/m}^3) = 14.3 \text{ g/m}^3$
      - ii. UBOD of the biodegradable effluent TSS_C is $[0.65(22 \text{ g/m}^3)](1.42 \text{ g/g}) = 20.3 \text{ g/m}^3$
      - iii. BOD_C of effluent suspended solids $= 20.3 \text{ g/m}^3\ (0.68) = 13.8 \text{ g/m}^3$

   b. Solve for the influent soluble BOD_C escaping treatment.

      $20 \text{ g/m}^3 = S + 13.8 \text{ g/m}^3$

      $S = 6.2 \text{ g/m}^3$

3. Prepare the first iteration of the solids balance. (In the first iteration, the effluent wastewater total suspended solids and the biological solids generated in the process are distributed among the unit operations and processes that make up the treatment system.)

   a. Primary setting
      - i. Operating parameters:

        BOD_C removed = 33%

        TSS_C removed = 70% (see also Fig. 5–51)
      - ii. BOD_M removed $= 0.33(8100 \text{ kg/d}) = 2700 \text{ kg/d}$
      - iii. BOD_M to secondary $= (8100 - 2700) \text{ kg/d} = 5400 \text{ kg/d}$
      - iv. TSS_M removed $= 0.7(7776 \text{ kg/d}) = 5443 \text{ kg/d}$
      - v. TSS_M to secondary $= (7776 - 5443) \text{ kg/d} = 2333 \text{ kg/d}$

   b. Determine the volatile fraction of primary sludge.
      - i. Operating parameters:

        Volatile fraction of TSS_C in influent = 67%

        Volatile fraction of grit =10%

        Volatile fraction of incoming TSS_C discharged to the secondary process = 85%
      - ii. Volatile suspended solids (VSS_M) in influent prior to grit removal $= 0.67\ (8640 \text{ kg/d}) = 5789 \text{ kg/d}$
      - iii. VSS_M removed in grit chamber $= 0.10(8640 - 7776) \text{ kg/d} = 86 \text{ kg/d}$
      - iv. VSS_M in secondary influent, kg/d $= 0.85(2333 \text{ kg/d}) = 1983 \text{ kg/d}$
      - v. VSS_M in primary sludge, kg/d $= (5789 - 86 - 1983) \text{ kg/d} = 3710 \text{ kg/d}$
      - vi. Volatile fraction in primary sludge $= [(3710 \text{ kg/d})/(5443 \text{ kg/d})](100) = 68.2\%$

   c. Secondary process
      - i. Determine the secondary process operating parameters

$$\text{Mixed liquor } VSS_C = \frac{(Q)(Y)(S_o - S)\text{SRT}}{[1 + b(\text{SRT})]\ (V_r)}$$

$$= \frac{(21{,}600\ \text{m}^3/\text{d})(0.5)[(250 - 6.2)\ \text{g/m}^3](10\text{d})}{[1 + (0.06\,\text{d}^{-1})(10\,\text{d})](4700\ \text{m}^3)}$$

$$= 3500\ \text{g/m}^3$$

$$\text{Mixed Liquor TSS}_C = \frac{\text{VSS}_c}{0.8} = \frac{(3500\ \text{g/m}^3)}{0.8} = 4375\ \text{g/m}^3$$

$$Y_{\text{obs}} = \frac{Y}{1 + b(\text{SRT})} = \frac{0.5}{1 + 0.06 \times 10} = 0.3125$$

ii. Determine the effluent mass quantities.

$\text{BOD}_M = (21{,}600\ \text{m}^3/\text{d})(20\ \text{g/m}^3)/(10^3\ \text{g/1 kg}) = 432\ \text{kg/d}$
$\text{TSS}_M = (21{,}600\ \text{m}^3/\text{d})(22\ \text{g/m}^3)/(10^3\ \text{g/1 kg}) = 475\ \text{kg/d}$

iii. Estimate the mass of volatile solids produced in the activated-sludge process that must be wasted. [The required value is computed using Eq. (8–14)].

$$P_{x,VSS} = Y_{\text{obs}}Q(S_o - S)/(10^3\ \text{g/1 kg})$$

$$= \frac{0.3125(21{,}600\ \text{m}^3/\text{d})[(250 - 6.2)\ \text{g/m}^3]}{(10^3\ \text{g/1 kg})} = 1646\ \text{kg/d}$$

Note: The actual flowrate will be the primary influent less the flowrate of the primary underflow. However, the primary underflow is normally small and can be neglected. If the underflow is significant, the actual flowrate should be used to determine the volatile solids production.

iv. Estimate the TSS_M that must be wasted assuming the volatile fraction represents 0.80 of the total solids.

$\text{TSS}_M = 1646/0.80 = 2057\ \text{kg/d}$

Note: If it is assumed that the fixed solids portion of the influent suspended solids equals 0.15, the mass of fixed solids in the input from the primary settling facilities is equal to 0.15 × 2333 = 350 kg/d. This value can then be compared with the fixed solids determined in the above computations, which is equal to 2057 − 1646 = 411 kg/d. The ratio of these values is 1.18[(411 kg/d)/(350 kg/d)]. Values that have been observed for this ratio vary from about 1.0 to 1.3; a value of 1.15 is considered to be the most representative.

v. Estimate the waste quantities discharged to the thickener. (It is assumed in this example that wasting is from the biological reactor.)

$\text{TSS}_M = (2057 - 475)\ \text{kg/d} = 1582\ \text{kg/d}$

$$\text{Flowrate} = \frac{(1582\ \text{kg/d})(10^3\ \text{g/1 kg})}{(4375\ \text{g/m}^3)} = 362\ \text{m}^3/\text{d}$$

The assumed concentration value of MLSS of 4375 g/m^3 in the aeration tank will increase when the recycled BOD_C and TSS_C are taken into consideration in the second and subsequent iterations of the mass balance.

d. Flotation thickeners

i. Operating parameters:
Concentration of thickened sludge = 4%
Assumed solids recovery = 90%
Assumed specific gravity of feed and thickened sludge = 1.0

ii. Determine the flowrate of the thickened sludge.

$$\text{Flowrate} = \frac{(1582\ \text{kg/d})(0.9)}{(10^3\ \text{kg/m}^3)(0.04)} = 35.6\ \text{m}^3/\text{d}$$

iii. Determine the flowrate recycled to the plant influent.

$$\text{Recycled flowrate} = (362 - 35.6)\ \text{m}^3/\text{d} = 326.4\ \text{m}^3/\text{d}$$

iv. Determine the TSS_M to the digester.

$$TSS_M = (1582\ \text{kg/d})(0.9) = 1424\ \text{kg/d}$$

v. Determine the TSS_M recycled to the plant influent.

$$TSS_M = (1582 - 1424)\ \text{kg/d} = 158\ \text{kg/d}$$

vi. Determine the BOD_C of the TSS_C in the recycled flow.

$$TSS_C \text{ in recycled flow} = \frac{(158\ \text{kg/d})(10^3\ \text{g/1 kg})}{326\ \text{m}^3/\text{d}} = 485\ \text{g/m}^3$$

$$\begin{aligned} BOD_C \text{ of the } TSS_C &= (485\ \text{g/m}^3)(0.65)(1.42)(0.68) \\ &= 304.6\ \text{g/m}^3 \end{aligned}$$

$$BOD_M = (304.6\ \text{g/m}^3)(326\ \text{m}^3/\text{d})(1\ \text{kg}/10^3\ \text{g}) = 99\ \text{kg/d}$$

e. Sludge digestion

i. Operating parameters:

SRT = 20 d
VSS destruction during digestion = 50%
Gas production = 1.12 m^3/kg of VSS destroyed
BOD_C in digester supernatant = 1000 g/m^3 (0.1%)
TSS_C in digester supernatant = 5000 g/m^3 (0.5%)
TSS_C in digested sludge = 5%

ii. Determine the total solids fed to the digester and the corresponding flowrate.

TSS_M = solids from primary settling plus waste solids from thickener
TSS_M = 5443 kg/d + 1424 kg/d = 6867 kg/d

$$\begin{aligned} \text{Total flowrate} &= \frac{(5443\ \text{kg/d})}{0.06(10^3\ \text{kg/m}^3)} + \frac{(1424\ \text{kg/d})}{0.04(10^3\ \text{kg/m}^3)} \\ &= (90.7 + 35.6)\ \text{m}^3/\text{d} = 126.3\ \text{m}^3/\text{d} \end{aligned}$$

iii. Determine the VSS_M fed to the digester.

$$\begin{aligned} VSS_M &= 0.682(5443\ \text{kg/d}) + 0.80(1424\ \text{kg/d}) \\ &= (3712 + 1139)\ \text{kg/d} = 4851\ \text{kg/d} \end{aligned}$$

$$\begin{aligned} \text{Percent } VSS_M \text{ in mixture fed to digester} &= \frac{(4851\ \text{kg/d})}{(6867\ \text{kg/d})}(100) \\ &= 70.6\% \end{aligned}$$

iv. Determine the VSSM destroyed.

$$VSS_M = 0.5(4851\ \text{kg/d}) = 2426\ \text{kg/d}$$

v. Determine the mass flowrate to the digester.

Primary sludge at 6% solids:

$$\text{Mass flow} = \frac{(5443\ \text{kg/d})}{0.06} = 90{,}717\ \text{kg/d}$$

Thickened waste-activated sludge at 4% solids:

$$\text{Mass flowrate} = \frac{(1424\ \text{kg/d})}{0.04} = 35{,}600\ \text{kg/d}$$

$$\text{Total mass flowrate} = (90{,}717 + 35{,}600)\ \text{kg/d} = 126{,}317\ \text{kg/d}$$

Note: The total mass flow can also be computed by multiplying the total flowrate to the digester by the density of the combined primary sludge and the thickened biosolids, if known.

vi. Determine the mass quantities of gas and sludge after digestion. Assume that the total mass of fixed solids does not change during digestion and that 50% of the volatile solids is destroyed.

$$\text{Fixed solids} = \text{TSS}_M - \text{VSS}_M = (6867 - 4851)\ \text{kg/d} = 2016\ \text{kg/d}$$
$$\text{TSS}_M \text{ in digested sludge} = 2016\ \text{kg/d} + 0.5(4851\ \text{kg/d}) = 4441\ \text{kg/d}$$

Gas production assuming that the density of digester gas is equal to 0.86 times that of air (1.204 kg/m^3, see Appendix B):

$$\text{Gas} = (1.12\ \text{m}^3/\text{kg})(0.5)(4851\ \text{kg/d})(0.86)(1.204\ \text{kg/m}^3) = 2813\ \text{kg/d}$$

Mass balance of digester output:

Mass input = 126,317 kg/d
Less gas = − 2813 kg/d
Mass output = 123,504 kg/d (solids and liquid)

vii. Determine the flowrate distribution between the supernatant at 5000 mg/L and digested sludge at 5% solids. Let TSS_{SP} = kg/d of supernatant suspended solids.

$$\frac{\text{TSS}_{SP}}{0.005} = \frac{4441 - \text{TSS}_{SP}}{0.05} = 123{,}504\ \text{kg/d}$$

$$\text{TSS}_{SP} + 444.1 - (0.1)\text{TSS}_{SP} = 617.5\ \text{kg/d}$$

$$(0.9)\text{TSS}_{SP} = 173\ \text{kg/d}$$

$$\text{TSS}_{SP} = 192\ \text{kg/d}$$

$$\text{Digested solids} = (4441 - 192)\ \text{kg/d} = 4249\ \text{kg/d}$$

$$\text{Supernatant flowrate} = \frac{(192\ \text{kg/d})}{0.005(10^3\ \text{kg/m}^3)} = 38.4\ \text{m}^3/\text{d}$$

$$\text{Digested sludge flowrate} = \frac{(4929\ \text{kg/d})}{0.05(10^3\ \text{kg/m}^3)} = 85\ \text{m}^3/\text{d}$$

viii. Establish the characteristics of the recycled flow.

Flowrate = 38.4 m^3/d
$\text{BOD}_C = (38.4\ \text{m}^3/\text{d})(1000\ \text{g/m}^3)/(10^3\ \text{g/1 kg}) = 38\ \text{kg/d}$
$\text{TSS}_M = (38.4\ \text{m}^3/\text{d})(5000\ \text{g/m}^3)/(10^3\ \text{g/1 kg}) = 192\ \text{kg/d}$

f. Sludge dewatering. (Note: In the analysis that follows, the weight of the polymer or other sludge-conditioning chemicals that may be added was not considered. In some cases, their contribution can be significant and must be considered.)

i. Operating parameters for centrifuge:

Sludge cake = 22% solids
Specific gravity of sludge = 1.06
Solids capture = 93%
Centrate BOD_C = 2000 mg/L

ii. Determine the sludge-cake characteristics.

$$\text{Solids} = (4249 \text{ kg/d})(0.93) = 3952 \text{ kg/d}$$

$$\text{Volume} = \frac{(3952 \text{ kg/d})}{1.06\,(0.22)(0.22)(10^3 \text{ kg/m}^3)} = 16.9 \text{ m}^3/\text{d}$$

iii. Determine the centrate characteristics.

$$\text{Flowrate} = (85 - 16.9) \text{ m}^3/\text{d} = 68.1 \text{ m}^3/\text{d}$$

$$\begin{aligned}\text{BOD}_M \text{ (at 2000 g/m}^3) &= (2000 \text{ g/m}^3)(68.1 \text{ m}^3/\text{d})(10^3 \text{ g/1 kg}) \\ &= 136 \text{ kg/d}\end{aligned}$$

$$\text{TSS}_M = (4249 \text{ kg/d})(0.07) = 297 \text{ kg/d}$$

g. Prepare a summary table of the recycle flows and waste characteristics for the first iteration.

Operation	Flowrate, m^3/d	BOD_M, kg/d	TSS_M, kg/d
Flotation thickener	326.0	99	158
Digester supernatant	38.4	38	192
Centrate	68.1	136	297
Totals	432.5	273	647[a]

[a] The volatile fraction of the returned suspended solids will typically vary from 50 to 75 percent. A value of 60 percent will be used for the computation in the second iteration.

4. Prepare the second iteration of the solids balance.

a. Primary settling

i. Operating parameters = same as those in the first iteration

ii. TSS_M and BOD_M entering the primary tanks

$$\begin{aligned}\text{TSS}_M &= \text{influent TSS}_M + \text{recycled TSS}_M \\ &= 7776 \text{ kg/d} + 647 \text{ kg/d} = 8423 \text{ kg/d}\end{aligned}$$

$$\begin{aligned}\text{Total BOD}_M &= \text{influent BOD}_M + \text{recycled BOD}_M \\ &= 8100 \text{ kg/d} + 273 \text{ kg/d} = 8373 \text{ kg/d}\end{aligned}$$

iii. BOD_M removed = 0.33(8373 kg/d) = 2763 kg/d

iv. BOD_M to secondary = (8,373 − 2763) kg/d = 5610 kg/d

v. TSS_M removed = 0.7(8423 kg/d) = 5896 kg/d

vi. TSS_M to secondary = (8423 − 5896) kg/d = 2527 kg/d

b. Determine the volatile fraction of the primary sludge and effluent suspended solids.

i. Operating parameters:

Incoming wastewater = same as those for the first iteration
Volatile fraction of solids in recycle returned to headworks = 60%

ii. Although the computations are not shown, the computed change in the volatile fractions determined in the first iteration is slight and, therefore, the values determined previously are used for the second iteration. If the volatile fraction of the return is less than about 50%, the volatile fractions should be recomputed.

c. Secondary process

i. Operating parameters = same as those for the first iteration and as follows:

Aeration tank volume = 4700 m^3
SRT = 10 d
$Y = 0.50$ kg/kg
$b = 0.06\ d^{-1}$

ii. Determine the BOD_C in the influent to the aeration tank.

Flowrate to aeration tank = influent flowrate + recycled flowrate

$$= (21{,}600 + 432.5)\ \text{m}^3/\text{d} = 22{,}033\ \text{m}^3/\text{d}$$

$$\text{BOD}_C = \frac{(5610\ \text{kg/d})(10^3\ \text{g/1 kg})}{(22{,}032.5\ \text{m}^3/\text{d})} = 255\ \text{g/m}^3$$

iii. Determine the new concentration of mixed liquor VSS.

$$X_{\text{VSS}} = \frac{(Q)(Y)(S_o - S)\text{SRT}}{[1 + b(\text{SRT})](V_r)}$$

$$X_{\text{VSS}} = \frac{(22{,}035\ \text{m}^3/\text{d})(0.5)(255 - 6.2)(10\ \text{d})}{[1 + (0.06\ \text{d}^{-1})(10\ \text{d})](4700\ \text{m}^3/\text{d})} = 3648\ \text{g/m}^3$$

iv. Determine the mixed liquor suspended solids.

$$X_{\text{SS}} = \frac{X_{\text{VSS}}}{0.8}$$

$$X_{\text{SS}} = 3648/0.8 = 4560\ \text{g/m}^3$$

v. Determine the cell growth.

$$P_{x,\text{VSS}} = Y_{\text{OBS}}\, Q\, (S_o - S)/(10^3\ \text{g/1 kg})$$

$$= \frac{0.3125\ (22{,}032.5\ \text{m}^3/\text{d})[(255 - 6.2\ \text{g/m}^3)]}{(10^3\ \text{g/1 kg})} = 1714\ \text{kg/d}$$

$$P_{x,\text{TSS}} = 1714/0.8 = 2143\ \text{kg/d}$$

vi. Determine the waste quantities discharged to the thickener.

Effluent TSS_M = 432 kg/d (specified in the first iteration)

Total TSS_M to be wanted to the thicker = (2143 – 432) kg/d

= 1711 kg/d

$$\text{Flowrate} = \frac{(1711\ \text{kg/d})(10^3\ \text{g/1 kg})}{(4560\ \text{g/m}^3)} = 375\ \text{m}^3/\text{d}$$

d. Flotation thickeners

i. Operating parameters:

Concentration of thickened sludge = 4%
Assumed solids recovery = 90%
Assumed specific gravity of feed and thickened sludge = 1.0

ii. Determine the flowrate of the thickened sludge.

$$\text{Flowrate} = \frac{(1711\ \text{kg/d})(0.9)}{(10^3\ \text{kg/m}^3)(0.04)} = 38.5\ \text{m}^3/\text{d}$$

iii. Determine the flowrate recycled to the plant influent.

Recycled flowrate = $(375 - 38.5)\ \text{m}^3/\text{d} = 336.5\ \text{m}^3/\text{d}$

iv. Determine the TSS_M to the digester.

$TSS_M = (1711\ \text{kg/d})(0.9) = 1540\ \text{kg/d}$

v. Determine the TSS_M recycled to the plant influent.

$TSS_M = (1711 - 1540)\ \text{kg/d} = 171\ \text{kg/d}$

vi. Determine the BOD_C of the TSS_C in the recycled flow.

$$\text{TSS}_C \text{ in recycled flow} = \frac{(171 \text{ kg/d})(10^3 \text{ g/1 kg})}{(336.5 \text{ m}^3/\text{d})} = 508 \text{ g/m}^3$$

$$\text{BOD}_C \text{ of TSS}_C = (508 \text{ g/m}^3)(0.65)(1.42)(0.68) = 319 \text{ g/m}^3$$
$$\text{BOD}_M = (319 \text{ g/m}^3)(336.5 \text{ m}^3/\text{d})(10^3 \text{ g/1 kg})^{-1} = 107 \text{ kg/d}$$

e. Sludge digestion

i. Operating parameters = same as those in the first iteration

ii. Determine the total solids fed to the digester and the corresponding flowrate.
$\text{TSS}_M = \text{TSS}_\text{M}$ from primary settling plus waste TSSM from thickener
$\text{TSS}_M = 5443 \text{ kg/d} + 1540 \text{ kg/d} = 6983 \text{ kg/d}$

$$\text{Total flowrate} = \frac{(5443 \text{ kg/d})}{0.06(10^3 \text{ kg/m}^3)} + \frac{(1540 \text{ kg/d})}{0.04(10^3 \text{ kg/m}^3)}$$
$$= (90.7 + 38.5) \text{ m}^3/\text{d} = 129.2 \text{ m}^3/\text{d}$$

iii. Determine the total VSSM fed to the digester.

$$\text{VSS}_M = 0.682(5443 \text{ kg/d}) + 0.80(1540 \text{ kg/d})$$
$$= (3712 + 1232) \text{ kg/d} = 4944 \text{ kg/d}$$

$$\text{Percent VSS in mixture fed to digester} = \frac{(4944 \text{ kg/d})}{(6983 \text{ kg/d})}(100)$$
$$= 71.3\%$$

iv. Determine the VSS destroyed.

$$\text{VSS destroyed} = 0.5(4944 \text{ kg/d}) = 2472 \text{ kg/d}$$

v. Determine the mass flowrate to the digester.

Primary sludge at 6% solids:

$$\text{Mass flowrate} = \frac{(5443 \text{ kg/d})}{0.06} = 90{,}717 \text{ kg/d}$$

Thickened waste-activated sludge at 4% solids:

$$\text{Mass flowrate} = \frac{(1540 \text{ kg/d})}{0.04} = 38{,}500 \text{ kg/d}$$

$$\text{Total mass flowrate} = (90{,}717 + 38{,}500) \text{ kg/d} = 129{,}217 \text{ kg/d}$$

vi. Determine the mass quantities of gas and sludge after digestion. Assume that the total mass of fixed solids does not change during digestion and that 50% of the volatile solids is destroyed.

$$\text{Fixed solids} = \text{TSS}_M - \text{VSS}_M = (6983 - 4944) \text{ kg/d} = 2039 \text{ kg/d}$$
$$\text{TSS in digested sludge} = 2039 \text{ kg/d} + 0.5(4944) \text{ kg/d} = 4511 \text{ kg/d}$$

Gas production assuming that the density of digester gas is equal to 0.86 times that of air (1.204 kg/m^3):

$$\text{Gas} = (1.12 \text{ m}^3/\text{kg})(0.5)(4944 \text{ kg/d})(0.86)(1.204 \text{ kg/m}^3) = 2867 \text{ kg/d}$$

Mass balance of digester output:

Mass input = 129,217 kg/d
Less gas = −2867 kg/d
Mass output = 126,350 kg/d (solids and liquid)

vii. Determine the flowrate distribution between the supernatant at 5000 mg/L and digested sludge at 5 percent solids. Let TSS_{sp} = kg/d of supernatant suspended solids.

$$\frac{\mathrm{TSS}_{sp}}{0.005} = \frac{4441 - \mathrm{TSS}_{sp}}{0.05} = 126{,}350 \text{ kg/d}$$

$$\mathrm{TSS}_{sp} + 451.1 - (0.1)\mathrm{TSS}_{sp} = 631.8 \text{ kg/d}$$

$$(0.9)\mathrm{TSS}_{Sp} = 180.7 \text{ kg/d}$$
$$\mathrm{TSS}_{sp} = 201 \text{ kg/d}$$

$$\text{Digested } \mathrm{TSS}_M = (4511 - 201) \text{ kg/d} = 4310 \text{ kg/d}$$

$$\text{Supernatant flowrate} = \frac{(201 \text{ kg/d})}{0.005(10^3 \text{ kg/m}^3)} = 40.2 \text{ m}^3\text{/d}$$

$$\text{Digested sludge flowrate} = \frac{(4310 \text{ kg/d})}{0.05(10^3 \text{ kg/m}^3)} = 86.2 \text{ m}^3\text{/d}$$

viii. Establish the characteristics of the recycled flow.

Flowrate = 40.2 m^3/d
$\mathrm{BOD}_M = (40.2 \text{ m}^3\text{/d})(1000 \text{ g/m}^3)/(10^3 \text{ g/1 kg}) = 40 \text{ kg/d}$
$\mathrm{TBB}_M = (40.2 \text{ m}^3\text{/d})(5000 \text{ g/m}^3)/(10^3 \text{ g/1 kg}) = 201 \text{ kg/d}$

f. Sludge dewatering

i. Operating parameters for centrifuge = same as those in the first iteration
ii. Determine the sludge-cake characteristics.

$$\mathrm{TSS}_M = (4310 \text{ kg/d})(0.93) = 4008 \text{ kg/d}$$

$$\text{Volume} = \frac{(4008 \text{ kg/d})}{1.06(0.22)(10^3 \text{kg/m}^3)} = 17.2 \text{ m}^3\text{/d}$$

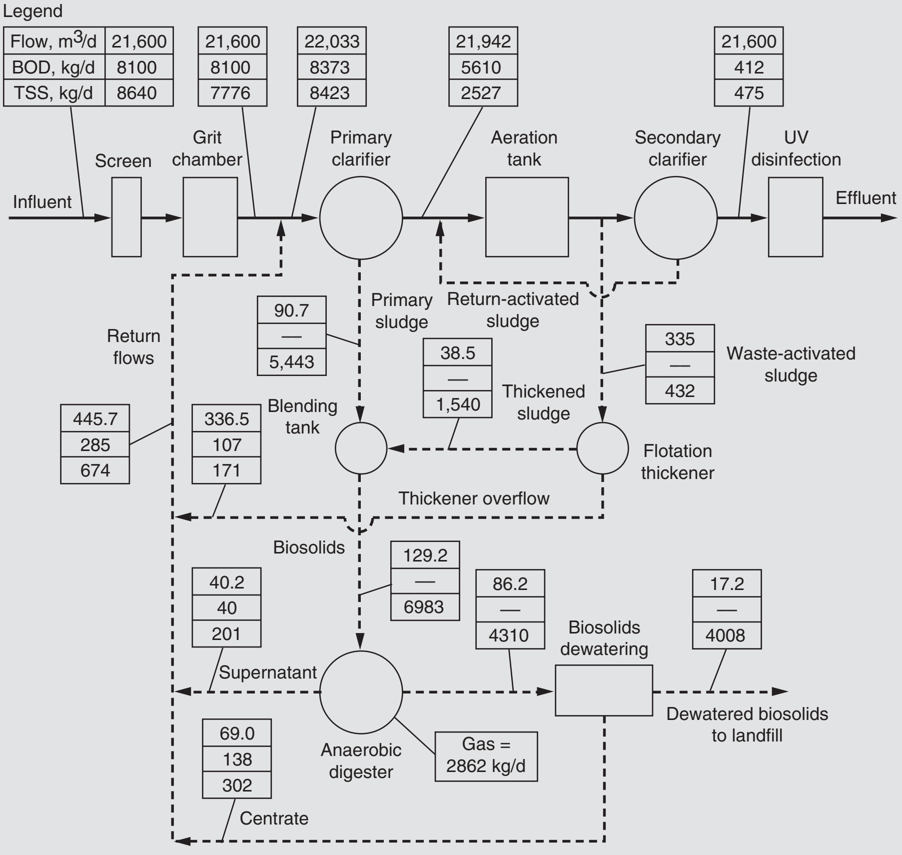
iii. Determine the centrate characteristics.

Flow = $(86.2 - 17.2) \text{ m}^3\text{/d} = 69 \text{ m}^3\text{/d}$
BOD_M (at 2000 g/m^3) = $(2000 \text{ g/m}^3)(69 \text{ g/m}^3)/(10^3 \text{ g/1 kg}) = 138 \text{ kg/d}$
$\mathrm{TSS}_M = (4310 \text{ kg/d})(0.07) = 302 \text{ kg/d}$

g. Prepare a summary table of the recycle flows and waste characteristics for the second iteration.

				Incremental change from previous iteration		
Operation/process	Flow, m^3/d	BOD_M, kg/d	TSS_M, kg/d	Flowrate, m^3/d	BOD_M, kg/d	TSS_M, kg/d
Flotation thickener	326.0	99	158	10.5	8	13
Digester supernatant	38.4	38	192	1.8	2	9
Centrate	68.1	136	297	0.9	2	5
Totals	432.5	273	647[a]	13.2	12	27

5. Because the incremental change in the return quantities is less than 5 percent, the values summarized in the above table are acceptable for design. Given that the above computations would be done on a spreadsheet program, additional iterations could be made to obtain an incremental change of less than 1 percent. The flow, TSSM, and BODM values for the various processes from the second iteration are presented in following figure.



Solids balance for second iteration

Comment In this example, an iterative approach was used to illustrate the computational steps in preparing a solids mass balance. Sludge and biosolids solids balances can be prepared using a specially designed spreadsheet or a proprietary solids balance software program. In general, if the iterative computational procedure is used, similar to the method used in this example, it should be carried out until the incremental change in all of the return quantities from the previous iteration is equal to or less than 5 percent.

14–8 RESOURCE RECOVERY FROM SLUDGES AND BIOSOLIDS

Sludges and biosolids can serve as a source of nutrients that can be used as a fertilizer, as a feedstock for the production of energy, and in the fabrication of value-added products. As discussed in Sec. 13–2 in Chap. 13, biosolids that have been stabilized properly according to EPA Part 503 Regulations can be used for a variety of beneficial uses.

Significant fractions of nutrients in biosolids become solubilized when biosolids are stabilized by anaerobic digestion and return flow from the dewatering process (often called centrate, filtrate or sidestream) contains high concentrations of nutrients. Nutrients in the sidestream can be returned to the main liquid treatment trains or recovered through sidestream treatment. Recovery and use of nutrients in solids is discussed in this section, and recovery of nutrients in the liquid stream is discussed in Chap. 15. The recovery of energy from biosolids and sludge is considered in the following section and in Chap. 17.

Recovery of Nutrients

Among the most valuable nutrients contained in sludges and biosolids are organic nitrogen and phosphorous. The recovery of phosphorous and ammonia is usually from the liquid stream of the dewatering process, as discussed in detail in Chap.15. Following dewatering, Class A or B biosolids can be used beneficially in agriculture land application or non-agriculture land application. The principal beneficial uses of biosolids include (1) agricultural land application, (2) non-agricultural land application, (3) energy recovery and generation, and (4) commercial use. Agricultural and non-agricultural land application are examined below. Energy recovery and generation are discussed in Sec. 14–9.

Agricultural Land Application

Biosolids contain a range of valuable nutrients such as nitrogen, phosphorus, iron, calcium, magnesium and various other macro and micro nutrients which are essential for plant growth. Many nutrients found in biosolids are also essential components in the healthy diet of animals. Biosolids are usually applied to agricultural land at rates designed to supply crops with adequate nitrogen (see Sec. 14–9 for details regarding biosolids land application). Recycling biosolids to agricultural land enables farmers to improve the economics of crop production in lieu of the use of expensive chemical fertilizers and reduces greenhouse gas emission generated from producing chemical fertilizer and carbon sequestration. Class B or A biosolids from processes such as anaerobic digestion and lime stabilization discussed in Chap. 13 are applied to land for crop production as cake; as compost material (see Sec. 14–5); or as a granular material in pellets form produced from drying processes (see Sec. 14–3).

Non-Agricultural Land Applications

Non-agricultural uses of biosolids include reclaiming mining sites, land reclamation, landscaping, and forest crops. Biosolids have been used widely for repairing land damaged by mining such as surface mined areas, abandoned mine lands, and coal refuse piles. Combining mine soils with biosolids, increases the organic matter, the cation exchange capacity, and soil nutrient levels. In mine damaged lands, biosolids application controls pH, metal content, and fertilization of the soils. Reclaiming and improving disturbed and marginal soils is another beneficial use of biosolids. Several biosolids characteristics make this use very successful. The organic matter in biosolids improves the soil physical properties through improving soil granulation and increasing soil water holding capacity. Biosolids increase soil cation exchange capacity, supply plant nutrients, and buffer soil. Land application to forest land is also practiced. However, this use has been difficult to achieve due to difficulties in spreading biosolids evenly through heavily forested areas. Finally, the use of biosolids for horticulture and landscaping, such as golf courses, is similar to agricultural land application but not used as a fertilizer. Biosolids compost is most popular product for landscaping uses as compost is primarily a soil conditioner and not a fertilizer.

14–9 ENERGY RECOVERY FROM SLUDGE AND BIOSOLIDS

Sludges and biosolids are considered renewable energy resources as they contain organic material that has a fuel value that can be harnessed. Under a properly engineered and controlled environment, energy recovery and generation from biosolids is considered at the top of the hierarchy of beneficial use due to the increased cost of energy and the need to obtain green energy credit by municipal utilities. Sludges from wastewater can be processed to generate energy by (WERF, 2008b):

1. Producing methane through anaerobic digester
2. Thermally oxidize sludge
3. Producing syngas through gasification process and/or pyrolysis
4. Producing oil and liquid fuel

Each of these options along with the appropriate method for energy recovery is considered briefly below. Additional details on energy recovery are presented in Chap. 17.

Energy Recovery through Anaerobic Digestion

Production of methane rich gas by anaerobic digestion is one pathway used to recover energy from biosolids. Gas production, collection and use methods are discussed in Sec. 13–9. Combined heat and power (CHP) recovery from the biogas generated from anaerobic digestion of sludge is illustrated on Fig. 14–34. As shown on Fig. 14–34 , the waste heat can be used as an energy source to further dry and stabilize the cake solids. Drying processes are discussed in Sec. 14–3. The dried material can also be used beneficially in agricultural or non-agricultural land application. Another beneficial use of the dried material can be hauling to cement kilns to supplement coal as a fuel. The value of the dried material is usually compared to the market value of coal on a heat content basis. Energy can be further recovered from the dried material on site to provide energy needed for drying as discussed below.

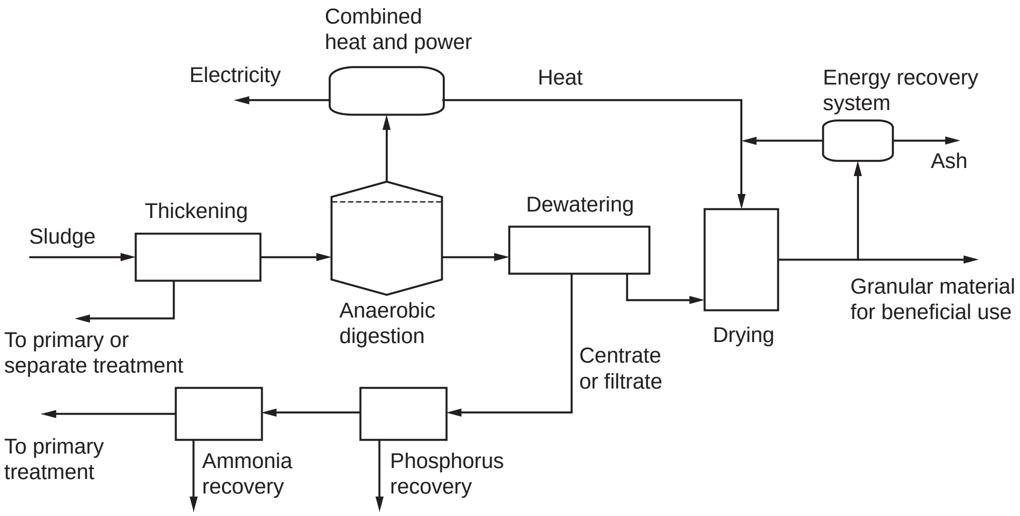


Figure 14–34

Schematic process flow diagram for the recovery of energy with anaerobic digestion. (The simultaneous recovery of nutrients is considered in Chap. 15.)

Table 14–23

Characteristics of different thermal processing technologies

Parameter	Combustion	Gasification	Pyrolysis
Temperature, °C (°F)	900–1100 (1650–2000)	590–980 (1100–1800)	200–590 (390–1100)
O_2 supplied	>Stoichiometric (excess air)	<Stoichiometric (limited air)	None
By-products	Flue gas (CO_2, H_2O) and ash	Syngas (CO, H_2) and ash	Pyrolysis gas, oils, tars and char

Energy Recovery by Thermal Oxidation

The three basic thermal processes are combustion or advanced thermal oxidation, gasification, and pyrolysis. All thermal processing of dried biosolids is followed by energy recovery methods. The difference between the three thermal processing technologies, in terms of operating temperature and oxygen requirements, and the main byproducts from each are summarized in Table 14–23. Thermal oxidation of sludge or biosolids is more common in the areas where ultimate disposal of sludge and biosolids is costly due to limited disposal sites. Sludges or biosolids to be incinerated, as described in Sec. 14–4, are typically dewatered to 15 to 30 percent dry solids. Further drying and combustion occurs simultaneously in the combustion reactor. The combustion process produces hot flue gas where the energy can be recovered for combustion air preheating and other energy needs or electrical production as shown previously on Fig. 14–25. The ash produced from the advanced thermal oxidation is an inert material that can be used in commercial applications such as cement making, asphalt, etc. Technologies to recover valuable material from the ash such as phosphorous are under development and once commercially developed may gain wide interest due to the potential market value of such resources. Excess heat from thermal oxidation of dewatered sludge has been used recently to generate steam for electricity generation.

Energy Recovery from Dried Material through Gasification and Pyrolysis

Gasification is an established process for converting organic materials to a fuel gas called synthetic gas or syngas, and has been practiced since the 1800s to generate fuel gas from coal and other biomass. Syngas is composed mainly of CO, CO_2, H_2, and CH_4 and has a low heating value of 4500–5500 kJ/m^3 (120–150 BTU/ft^3), which is approximately 25 percent of the heat value of biogas generated from anaerobic digestion. While gasification is still in the early phases of development for processing biosolids, there has been increased interest in applying this technology to sludges and biosolids. Sludges or biosolids have a higher ash content as compared to traditional organic materials used as a fuel source in gasification processes, which makes ash handling more difficult. Further details of gasification and energy recovery is considered in Chap. 17.

Pyrolysis is also an established technology used in the chemical industry to produce charcoal, activated carbon and methanol. Similar to gasification, pyrolysis at high temperatures generates a combustible gas, pyrolysis gas, with a low heating value but also can be used to generate char and oil. Pyrolysis is actually the first step that occurs in both gasification and combustion reactions. Pyrolysis of sludges and biosolids is still considered innovative technology and not widely practiced for municipal applications.

To effectively harness energy through a gasification or pyrolysis technology, most commercially available systems require dried biosolids with greater than 75 percent solids in granular form. Pelletization is not required; however, a certain degree of uniformity in the dried granular material along with low dust content is required. The required dryness depends on the technology. The energy required for drying is typically supplied by the thermal technology. Energy can also be recovered from waste heat, such as a combined heat and power (CHP) system, if available onsite.

Production of Oil and Liquid Fuel

Converting sludge to liquid and oil fuel is another use of sludge as energy source. However, the commercial application of such technologies is hindered by the high capital cost and requirement for large amount of sludge feed to lower the capital and operating costs.

14–10 APPLICATION OF BIOSOLIDS TO LAND

Land application of biosolids is defined as the spreading of biosolids on or just below the soil surface. Biosolids may be applied to (1) agricultural land, (2) forest land, (3) disturbed land, and (4) dedicated land disposal sites. In all four cases, the land application is designed with the objective of providing further biosolids treatment. Sunlight, soil microorganisms, and desiccation combine to further inactivate any residual pathogens and many toxic organic substances. Trace metals are trapped in the soil matrix and nutrients are taken up by plants and converted to useful biomass. In some cases, a geomembrane liner is installed below a dedicated land disposal area.

To qualify for application to agricultural and nonagricultural land, biosolids or material derived from biosolids must meet at least the pollutant ceiling concentrations, Class B requirements for pathogens, and vector attraction requirements. Bulk biosolids applied to lawns and home gardens and biosolids that are sold or given away in bags or containers must meet the Class A criteria and one of several available vector-attraction reduction processes.

Benefits of Land Application

The application of biosolids to land for agricultural purposes is beneficial because organic matter improves soil structure, tilth, water holding capacity, water infiltration, and soil aeration. Macronutrients (nitrogen, phosphorus, potassium) and micronutrients (iron, manganese, copper, chromium, selenium, and zinc) aid plant growth. Organic matter also contributes to the cation-exchange capacity (CEC) of the soil, which allows the soil to retain potassium, calcium, and magnesium. The presence of organic matter improves the biological diversity in soil and improves the availability of nutrients to the plants (Wegner, 1992). Nutrients in the biosolids also serve as a partial replacement for expensive chemical fertilizers.

Land application can also be of great value in silviculture and site reclamation. Forest utilization has been practiced extensively in the northwest, and biosolids application has been recognized as being beneficial to forest growth (WEF, 2010). Reclamation of disturbed land such as superfund sites has also been successful (Henry and Brown, 1997).

U.S. EPA Regulations for Beneficial Use and Disposal of Biosolids

As discussed in Sec. 13–2, the U.S. EPA published regulations for biosolids (sewage sludge is the term used in the regulations) use and disposal under the code of Federal Regulations (CFR), 40 CFR Part 503. For land application, the regulations provide numerical limits on 10 metals, management practice guidance, and requirements for monitoring, record keeping, and reporting. The regulations are summarized in Table 14–24 and discussed in the following paragraphs.

Table 14–24

U.S. EPA sludge regulations for land application

Classification	Class A: no restrictions[a] Class B: site restrictions
Management practices	See Table 14–25
Pathogen reduction alternatives	See Table 13–9
Vector attraction reduction	See Table 13–10
Site restrictions for Class B biosolids	See Table 14–26
Metal limits and loading rates	See Table 14–30

[a] Other than bag labeling (like a fertilizer).

Table 14–25

Land application management practices under U.S. EPA Part 503 rule[a]

For bulk biosolids[b]

- Bulk biosolids cannot be applied to flooded, frozen, or snow-covered agricultural land, forests, public contact sites, or reclamation sites in such a way that the biosolids enters a wetland or other waters of the United States (as defined in 40 CFR Part 122.2), except as provided in a permit issued pursuant to Section 402 (NPDES permit) or Section 404 (Dredge and Fill Permit) of the Clean Water Act, as amended.
- Bulk biosolids cannot be applied to agricultural land, forests, or reclamation sites that are 10 m or less from U.S. waters, unless otherwise specified by the permitting authority.
- If applied to agricultural lands, forests, or public contact sites, bulk biosolids must be applied at a rate that is equal to or less than the agronomic rate for the site. Biosolids applied to reclamation sites may exceed the agronomic rate if allowed by the permitting authority.
- Bulk biosolids must not harm or contribute to the harm of a threatened or endangered species or result in the destruction or adverse modification of the species' critical habitat when applied to the land. Threatened or endangered species and their critical habitats are listed in Section 4 of the Endangered Species Act. Critical habitat is defined as any place where a threatened or endangered species lives and grows during any stage of its life cycle. Any direct or indirect action (or the result of any direct or indirect action) in a critical habitat that diminishes the likelihood of survival and recovery of a listed species is considered destruction or adverse modification of a critical habitat.

For biosolids sold or given away in a bag or other container for application to the land[a]

- A label must be affixed to the bag or other container, or an information sheet must be provided to the person who receives this type of biosolids in another container. At a minimum, the label or information sheet must contain the following information:
  - The name and address of the person who prepared the biosolids for sale or give-away in a bag or other container.
  - A statement that prohibits application of the biosolids to the land except in accordance with the instructions on the label or information sheet.
  - An AWSAR (annual whole sludge application rate) for the biosolids that does not cause the annual pollutant loading rate limits to be exceeded.

[a] from U.S. EPA (1995).

[b] These management practices do not apply if the biosolids is of "exceptional quality."

Management Practices

Management practices that must be followed when biosolids are applied on land are specified in the Part 503 rule (see Table 14–25). The practices vary depending on whether the material that is applied is hauled in bulk or in individual bags.

Pathogen-Reduction Alternatives. As discussed in Chap. 13 and in Sec. 13–2, the Part 503 pathogen-reduction requirements for biosolids are divided into Class A and Class B categories (see Table 13–9). The goal of the Class A requirements is to reduce the pathogens in the biosolids (including Salmonella sp. bacteria, enteric viruses, and viable helminth ova) to below detectable levels. When this goal is achieved, Class A biosolids can be land applied without any pathogen-related restrictions on the site (U.S. EPA, 1995). The goal of the Class B requirements is to ensure that pathogens have been reduced to levels that are unlikely to pose a threat to public health and the environment under specific use conditions. Site restrictions on land application of Class B biosolids minimize the potential for human and animal contact with the biosolids until environmental factors have reduced pathogens to below detectable levels.

Vector Attraction Reduction. There are 10 potential vector attraction reduction measures that can be combined with pathogen-reduction alternatives for an acceptable land-application project using Class B biosolids (see Table 13–10). The list in Table 13–10 also includes some stabilization processes that reduce pathogens.

Site Restrictions for Class B Biosolids. Site restrictions, listed in Table 14–26, depend on the crops to be used and the contact control for animals and the public. Food crops and turf grass are given the longest time restrictions because of the potential for public exposure (U.S. EPA, 1995).

Table 14–26

Site restrictions for Class B biosolids[a]

Restrictions for the harvesting of crops and turf

- Food crops with harvested parts that touch the biosolids/soil mixture and are totally above ground shall not be harvested for 14 mo after application of biosolids.
- Food crops with harvested parts below the land surface where biosolids remains on the land surface for 4 mo or longer prior to incorporation into the soil shall not be harvested for 20 mo after biosolids application.
- Food crops with harvested parts below the land surface where biosolids remains on the land surface for less than 4 mo prior to incorporation shall not be harvested for 38 mo after biosolids application.
- Food crops, feed crops, and fiber crops, whose edible parts do not touch the surface of the soil, shall not be harvested for 30 d after biosolids application.
- Turf grown on land where biosolids is applied shall not be harvested for 1 y after application of the biosolids when the harvested turf is placed on either land with a high potential for public exposure or a lawn, unless otherwise specified by the permitting authority.

Restriction for the grazing of animals

- Animals shall not graze on land for 30 d after application of biosolids to the land.

Restrictions for public contact

- Access to land with a high potential for public exposure, such as a park or ball field, is restricted for 1 y after biosolids application. Examples of restricted access include posting with no trespassing signs or fencing.
- Access to land with a low potential for public exposure (e.g., private farmland) is restricted for 30 d after biosolids application. An example of restricted access is remoteness.

[a] From U.S. EPA (1995).

Exceptional Quality Biosolids. The category of "exceptional quality" biosolids has been defined as those biosolids that meet metal standards, Class A pathogen reduction standards, and vector reduction standards as defined in the Part 503 regulations.

Site Evaluation and Selection

A critical step in land application of biosolids is finding a suitable site. The characteristics of the site will determine the actual design and will influence the overall effectiveness of the land-application concept. The sites considered potentially suitable will depend on the land-application option or options being considered, such as application to agricultural lands, forest lands, etc. The site-selection process should include an initial screening on the basis of the factors and criteria described in the following discussion. For screening purposes, it is necessary to have at least a rough estimate of land-area requirements for each feasible option.

Ideal sites for land application of biosolids have deep silty loam to sandy loam soils, groundwater deeper than 3 m (10 ft), slopes at 0 to 3 percent; no wells, wetlands, or streams; and few neighbors. Site characteristics of importance are topography, soil characteristics, soil depth to groundwater, and accessibility and proximity to critical areas.

Topography. Topography is important as it affects the potential for erosion and runoff. Suitability of site topographies also depends on the type of biosolids and the method of application. As shown in Table 14–27, liquid biosolids can be spread, sprayed, or injected onto sites with rolling terrain up to 15 percent in slope. Dewatered sludge is usually spread on agricultural land that requires a tractor and spreader. Forested sites can accommodate slopes up to 30 percent if adequate setbacks from streams are provided.

Soil Characteristics. In general, desirable soil characteristics include (1) loamy soil, (2) slow to moderate permeability, (3) soil depth of 0.6 m (2 ft) or more, (4) alkaline or neutral soil pH (pH > 6.5), and (5) well drained to moderately well drained soil. Practically any soil can be adapted to a well-designed and well-operated system.

Soil Depth to Groundwater. A basic philosophy inherent in federal and state regulations is to design biosolids application systems that are based on sound agronomic principles, so that biosolids pose no greater threat to groundwater than current agricultural practices. Because the groundwater fluctuates on a seasonal basis in many soils, difficulties are encountered in establishing an acceptable minimum depth to groundwater. The quality of the underlying groundwater and the biosolids application option have to be considered carefully, especially where groundwater nondegradation restrictions apply.

Table 14–27

Typical slope limitations for land application of biosolids

Slope,%	Comment
0–3	Ideal; no concern for runoff or erosion of liquid or dewatered biosolids
3–6	Acceptable; slight risk of erosion; surface application of liquid or dewatered biosolids is acceptable
6–12	Injection of liquid biosolids required for general cases, except in closed drainage basin and/or when extensive runoff control is provided; surface application of dewatered biosolids is generally acceptable
12–15	No application of liquid biosolids should be made without extensive runoff control; surface application of dewatered biosolids is acceptable, but immediate incorporation into the soil is recommended
Over 15	Slopes greater than 15 percent are suitable only for sites with good permeability where the length of slope is short and where the area with steep slope is a minor part of the total application area

Generally, the greater the depth to the water table, the more desirable a site is for biosolids application. At least 1 m (3 ft) to groundwater is preferred for land-application sites. Seasonal water-table fluctuations to within 0.5 m (1.5 ft) of the surface can be tolerated. If the shallow groundwater is excluded as a drinking-water aquifer, the groundwater depth can be as shallow as 0.5 m before problems with trafficability of the soil arise. The presence of faults, solution channels, and other similar connections between soil and groundwater is undesirable unless the depth of overlying soil is adequate. When a specific site or sites are being considered for biosolids application, a detailed field investigation may be necessary to obtain the required groundwater information.

Accessibility and Proximity to Critical Areas. Buffer zones or setbacks are needed to separate the active application area from sensitive areas such as residences, wells, roads, surface waters, and property boundaries. Local and state regulations often include minimum distances for setbacks depending on the method of application; example minimum setback distances used in California are listed in Table 14–28.

Design Loading Rates

Design loading rates for land application of biosolids can be limited by pollutants (heavy metals) or by nitrogen. The long-term loadings of heavy metals are based on U.S. EPA 503 regulations. The annual loading rate is usually limited by the nitrogen loading rate.

Nitrogen Loading Rates. Nitrogen loading rates are set typically to match the available nitrogen provided by commercial fertilizers (Chang et al., 1995). Because municipal biosolids represent a slow-release organic fertilizer, a combination of ammonia and organic nitrogen must be made according to Eq. (14–6).

$$L_N = [(\mathrm{NO_3}) + K_V(\mathrm{NH_4}) + f_n(N_o)]F \qquad (14\text{–}6)$$

where L_N = plant available nitrogen in the application year, g N/kg (lb N/ton)

$\mathrm{NO_3}$ = percent nitrate nitrogen in biosolids, decimal

Table 14–28

Typical setback distances for land application sites[a]

Setback from:	Minimum distance ft	m
Property Boundaries	10	3
Domestic water supply wells	500	150
Nondomestic water supply wells	100	30
Public roads and onsite occupied residences	50	15
Surface waters (wetlands, creeks, ponds, lakes, underground aqueducts, and marshes)	100	30
Primary agricultural drainageways	33	10
Occupied nonagricultural buildings and offsite residences	500	150
Domestic water supply reservoir	400	120
Primary tributary to a domestic water supply	200	60
Domestic surface water supply intake	2500	750

[a] CSWRCB (2000).

K_v = volatilization factor for ammonia loss
= 0.5 for surface-applied liquid sludge
= 0.75 for surface-applied dewatered sludge
= 1.0 for injected liquid or dewatered sludge
NH_4 = percent ammonia nitrogen in sludge, decimal
f_n = mineralization factor for organic nitrogen
= 0.5 for warm climates and digested sludge
= 0.4 for cool climates and digested sludge
= 0.3 for cold climates or composted sludge
N_o = percent organic nitrogen in sludge, decimal
F = conversion factor, 1000 g/kg of dry solids (2000 lb/ton)

To use Eq. (14–6) requires knowledge of the method of application, the nitrogen content of the biosolids (nitrate, ammonia, and organic), the type of stabilization, and the type of climate. The use of the mineralization factors simplifies the previously used method of calculating the amount of organic nitrogen mineralized each year and adding up the total for an annual equivalent. The use of Eq. (14–6) is also appropriate if biosolids are applied to a single site once every 2 to 3 y.

The loading rate based on nitrogen loadings is then calculated from Eq. (14–7).

$$L_{SN} = \frac{U}{N_P F} \tag{14–7}$$

where L_{SN} = biosolids loading rate based on N, kg/ha·y (ton/ac·y)
U = crop uptake of nitrogen, kg/ha (lb/ac) (see Table 14–29)
N_p = plant available nitrogen in sludge, g/kg (lb/ton)
F = conversion factor, 10^{-3} kg/g (1 lb/lb)

Loading Rates Based on Pollutant Loading. The pollutants of concern are those listed in Table 14–30. To calculate the biosolids loading rate based on pollutant loading use Eq. (14–8).

$$L_S = \frac{L_C}{CF} \tag{14–8}$$

where L_S = maximum amount of biosolids that can be applied per year, kg/ha·y (tons/ac·y)
L_C = maximum amount of constituent that can be applied per year, kg/ha·y (lb/ac·y)
C = pollutant concentration in biosolids, decimal (mg/kg)
F = conversion factor, 10^{-6} kg/mg (2000 lb/ton)

Land Requirements. Once the maximum biosolids loading rate is determined [by comparing the values from Eqs. (14–7) and (14–8)], the field area can be calculated using Eq. (14–9).

$$A = \frac{B}{L_S} \tag{14–9}$$

where A = application area required, ha
B = biosolids production, kg of dry solids/y

Table 14–29
Typical nitrogen uptake values for selected crops[a]

	Nitrogen uptake			Nitrogen uptake	
Crop	**lb/ac·y**	**kg/ha·y**	**Crop**	**lb/ac·y**	**kg/ha·y**
Forage crops			Tree crops		
Alfalfa	200–600	220–670	Eastern forests		
Brome grass	115–200	130–220	Mixed hardwoods	200	225
Coastal Bermuda grass	350–600	390–670	Red pine	100	110
Kentucky bluegrass	175–240	195–270	White spruce	200	225
Quack grass	210–250	235–280	Pioneer succession	200	225
Orchard grass	220–310	250–350	Aspen sprouts	100	110
Reed canary grass	300–400	335–450	Southern forests		
Ryegrass	160–250	180–280	Mixed hardwoods	250	280
Sweet clover[b]	155	175	Loblolly pine	200–250	225–280
Tall fescue	130–290	145–325	Lake states forest		
Field crop			Mixed hardwoods	100	110
Barley	110	120	Hybrid poplar	140	155
Corn	155–180	175–200	Western forest		
Cotton	65–100	70–110	Hybrid poplar	270	300

EXAMPLE 14–4 **Metals Loadings in Land Application** A community has stockpiled biosolids in a storage lagoon. The lagoon needs to be cleaned and the biosolids disposed of to make room for a plant expansion. The metals concentrations (mg/kg) in the lagoon are as follows:

As = 45	Hg = 5
Cd = 30	Ni = 350
Cu = 1,200	Se = 15
Pb = 250	Zn = 3100

Determine if the biosolids are acceptable for land application.

Solution

1. Compare the concentrations for the above metals to the ceiling concentration (column 2) and the pollutant concentration for exceptional quality (column 4)
   a. All metals concentrations are under the ceiling limits in column 2. The biosolids are suitable for land application.
   b. Arsenic and zinc exceed the values for exceptional quality. Calculations of annual loadings are necessary.
2. Calculate the allowable annual biosolids loading rates, using Eq. (14–8), for the two metals using the annual pollutant loading rates in Table 14–30.
   a. Arsenic-based loading rate ($L_C = 2\text{ kg/ha·y}$)

$$L_S = \frac{L_C}{L_C(10^{-6})} = \frac{(2\text{ kg/ha·y})}{(45\text{ mg/kg})(1\text{ kg}/10^6\text{ mg})} = 44{,}444\text{ kg/ha·y}$$

b. Zinc based loading rate ($L_C = 140$ kg/ha·y)

$$L_S = \frac{(140\ \text{kg/ha·y})}{(3100\ \text{mg/kg})(1\ \text{kg}/10^6\ \text{mg})} = 45{,}161\ \text{kg/ha·y}$$

3. Compare the whole biosolids loading rates to determine the limiting rate. The 44,444 kg/ha·y biosolids loading based on arsenic is limiting.

Comment Nitrogen loadings typically are more limiting than metals loadings. If the nitrogen loading rate exceeds 20 Mg/ha·y (U.S. EPA, 1995), then the arsenic loading rate will determine the whole biosolids loading rate.

Application Methods

Application methods for biosolids range from direct injection of liquid biosolids to surface spreading of dewatered biosolids. The method of application selected will depend on the physical characteristics of the biosolids (liquid or dewatered), site topography, and the type of vegetation present (annual field crops, existing forage crops, trees, or preplanted land).

Liquid or Thickened Biosolids Application. Application of biosolids in the liquid or thickened state is attractive because of its simplicity. Dewatering processes are not required, and the liquid or thickened biosolids can be transferred by pumping. Typical solids concentrations of liquid or thickened biosolids applied to land range from 1 to 8 percent. Liquid or thickened biosolids may be applied to land by vehicular application or by irrigation methods similar to those used for wastewater distribution.

Vehicular application may be by surface distribution, subsurface injection or incorporation. Limitations to vehicular application include limited tractability on wet soil and potential reduction in crop yields due to soil compaction from truck traffic. Use of high-flotation tires can minimize these problems.

Surface distribution may be accomplished by tank truck or tank wagon equipped with rear-mounted spreading manifolds or by tank trucks mounted with high-capacity spray nozzles or guns. Specially designed, all-terrain biosolids application vehicles with spray guns are ideally suited for biosolids application on forest lands. Vehicular surface application is the most common method used for field and forage croplands. The procedure used commonly for annual crops is to (1) spread biosolids prior to planting, (2) allow the biosolids to dry partially, and (3) incorporate the biosolids by disking or plowing. The process is repeated then after harvest.

Liquid biosolids can be injected below the soil surface by using tank wagon or tank trucks with injection shanks or incorporated immediately after surface application by using plows or disks equipped with biosolids distribution manifolds and covering spoons (see Fig. 14–35). Advantages of injection or immediate incorporation methods include minimization of potential odors and vector attraction, minimization of ammonia loss due to volatilization, elimination of surface runoff, and minimum visibility leading to better public acceptance. Injection shanks and plows are very disruptive to perennial forage crops or pastures. To minimize such effects, special grassland biosolids injectors have been developed (Crites and Tchobanoglous, 1998).

Figure 14–35

Land application of liquid sludge: (a) self contained vehicle used to haul and to inject the liquid sludge into the ground. Self-contained vehicles of the type shown are used for relatively small amounts of liquid sludge and (b) tractor equipped with subsurface liquid sludge injection tines. The liquid sludge to be injected is supplied by a hose connected to the injection device. The tethered sludge supply hose is dragged along by the tractor. The injected liquid sludge is disked in the ground using the tractor and disk such as shown on Fig. 14–36(b).

(a) (b)

Irrigation methods include sprinkling and furrow irrigation. Typically, large-diameter, high-capacity sprinkler guns are used to avoid clogging problems. Sprinkling has been used mainly for application to forested lands and occasionally for application to dedicated disposal sites that are relatively isolated from public view and access. Sprinklers can operate satisfactorily on land too rough or wet for tank trucks or injection equipment and can be used throughout the growing season. Disadvantages to sprinkling include power costs of high-pressure pumps, contact of biosolids with all parts of the crop, possible foliage damage to sensitive crops, potential odors and vector attraction problems, and potentially high visibility to the public.

Furrow irrigation can be used to apply biosolids to row crops during the growing season. Disadvantages associated with furrow irrigation are localized settling of solids and the potential for ponding of biosolids in the furrows, both of which can result in odor problems.

Dewatered Biosolids Application. Application of dewatered biosolids to the land is similar to an application of semisolid animal manure. The use of conventional manure spreaders is an important advantage because farmers can apply biosolids on their lands with their own equipment. Typical solids concentrations of dewatered biosolids applied to land range from 20 to 30 percent. Dewatered biosolids are spread most commonly using tractor-mounted box spreaders or manure spreaders followed by plowing or disking into the soil (see Fig. 14–36). For high application rates bulldozers, loaders, or graders may be used. For forest application, a side-slinging vehicle has been tested that can apply dewatered biosolids up to 60 m (200 ft) (Leonard et al., 1992).

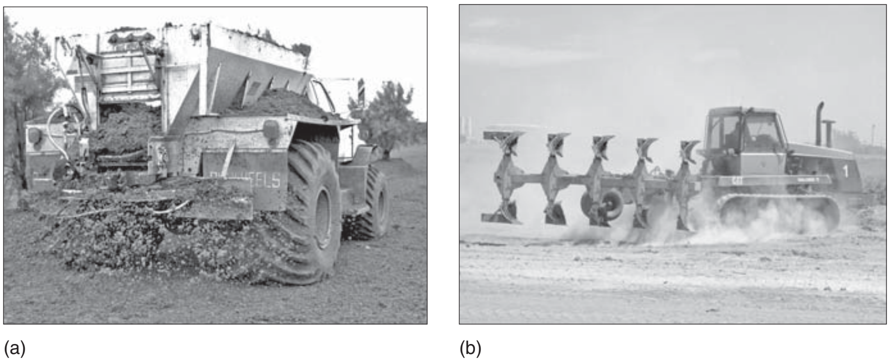

Figure 14–36

Land application of dewatered sludge: (a) typical example of vehicle used to apply dewatered sludge on the surface of the soil and (b) typical tractor and rotating two-way disk used to disk dewatered and/or liquid sludge into the ground.

(a) (b)

Table 14–31

Criteria for dedicated land disposal (DLD) sites for biosolids[a]

Parameter	Unacceptable condition	Ideal condition
Slope	Deep gullies, slope $>12\%$	$<3\%$
Soil permeability	$>1 \times 10^5$ cm/s[b]	$\leq 10^{-7}$ cm/s[c]
Soil depth	<0.6 m (2 ft)	>3 m (10 ft)
Distance to surface water	<90 m (300 ft) to any pond or lake used for recreational or livestock purposes, or any surface water body officially classified under state law	>300 m (1000 ft) from any surface water
Depth to groundwater	<3 m (10 ft) to groundwater table (wells tapping shallow aquifers)[d]	>15 m (50 ft)
Supply wells	Within 300 m (1000 ft) radius	No wells within 600 m (2000 ft)

[a] From U.S. EPA (1983).

[b] Permeable soil can be used for DLD if appropriate engineering design preventing DLD leachate from reaching the groundwater is feasible.

[c] When low-permeability soils are at or too close to the surface, liquid disposal operations can be hindered due to water ponding.

[d] If an exempted aquifer underlies the site, poor quality leachate may be permitted to enter groundwater.

Application to Dedicated Lands

Disturbed land reclamation and dedicated land disposal are two types of high-rate land application. Disturbed land reclamation consists of a one-time application of 110 to 220 Mg/ha (50 to 100 dry tons/ac) to correct adverse soil conditions. Lack of soil fertility and poor physical properties can be corrected by biosolids application to allow revegetation programs to proceed. For disturbed land reclamation to be the sole avenue for biosolids reuse, a large area of disturbed land must be available on an ongoing basis. Dedicated land disposal requires a site where high rates of biosolids application are acceptable environmentally on a continuing basis. Biosolids for a dedicated land disposal (DLD) operation should meet at least Class B requirements.

Site Selection. Siting criteria for a dedicated land disposal (DLD) site are presented in Table 14–31. Major issues in DLD siting are nitrogen control and the avoidance of groundwater contamination. Groundwater contamination can be avoided by (1) locating sites remote from useful aquifers, (2) intercepting of leachate, and (3) constructing an impervious geological barrier. Low percolation rates and deep aquifers will substantially reduce or eliminate potential contamination effects.

Where groundwater nondegradation restrictions apply, it has been found that for most DLD sites it is less costly to excavate the site entirely, install a geomembrane liner, and replace the excavated material, than to dispose of the sludge by some other means (e.g., dewatering and landfilling). The limited amount, if any, of leachate collected from the liner is returned to the treatment plant for processing.

Loading Rates. Annual biosolids loading rates have ranged from 12 to 2250 tonne/ha (5 to 1000 tons/ac). The higher rates have been associated with sites that

- Receive dewatered biosolids
- Mechanically incorporate the biosolids into the soil

- Have relatively low precipitation
- Have no leachate problems because of site conditions or project design

Design loading rates for DLD can be estimated using Eq. (14–10).

$$L_S = \frac{E(TS)F}{100} - TS \qquad (14\text{–}10)$$

where L_S = annual biosolids loading rate, Mg/ha (ton/ac)
E = net evaporation rate from soil, mm/y (in./y)
TS = total solids content, percent by weight
F = conversion factor, 10 Mg/mm (113.3 ton/in.)

The net soil evaporation can be estimated from Eq. (14–11).

$$E = (f)E_L - P \qquad (14\text{–}11)$$

where E = net evaporation rate from soil, mm/y (in./y)
$f = 0.7$
E_L = pan evaporation rate, mm/y (in./y)
P = annual precipitation, mm/y (in./y)

It should be noted that infiltration into the soil is not considered in Eq. (14–10). If infiltration is allowed, the term E should be increased by the annual infiltration rate in mm/y.

Once the annual loading rate is calculated, the field area can be determined using Eq. (14–9) (dividing the biosolids production by the loading rate). Other area requirements include buffer zones, surface runoff control, roads, and supporting facilities.

Landfilling

Landfilling of biosolids in a monofill is covered under 40 CFR Part 503. Landfilling of biosolids in a sanitary landfill with municipal solid waste is regulated by the U.S. EPA under 40 CFR 258. If an acceptable site is convenient, landfilling can be used for disposal of biosolids, grit, screenings, and other solids. Stabilization may be required depending on state or local regulations. Dewatering of biosolids is usually required to reduce the volume to be transported and to control the generation of leachate from the landfill. In many cases, solids concentration is an important factor in determining the acceptability of biosolids in landfills. The sanitary landfill method is most suitable if it is also used for disposal of the other types of solid wastes. In a true sanitary landfill, the wastes are deposited in a designated area, compacted in place with a tractor or roller, and covered with a 350 mm (14 in.) layer of clean soil. With daily coverage of the newly deposited wastes, nuisance conditions, such as odors and flies, are minimized.

PROBLEMS AND DISCUSSION TOPICS

14–1 A wastewater treatment plant is producing 55,000 L/d of thickened biosolids containing 2.8 percent solids. A belt-filter press installation is to be designed based on a normal operation of 8 h/d and 5 d/wk, a belt-filter press loading rate of 280 kg/m·h, and the following data. Compute the number and size of the belt filters, and the expected solids capture, in percent. Determine the daily hours of operation required if a sustained 5-d peak solids load occurs.

1. Total solids in dewatered sludge = 26 percent.
2. Total suspended solids concentration in filtrate = 800 mg/L.

3. Washwater flowrate = 90 L/min per m of belt width.
4. Specific gravities of sludge feed, dewatered cake, and filtrate are 1.02, 1.08, and 1.01, respectively.
5. Use Fig. 3–14 to estimate the peaking factor for a sustained 5-d peak solids load

14–2 The ultimate elemental analysis of a dried sludge yields the following data:

Element	Percent
Carbon	52.1
Hydrogen	2.7
Oxygen	38.3
Nitrogen	6.9
Total	100.0

How many kg of air will be required per kg of sludge for its complete oxidation?

14–3 Compute the fuel value of the sludge from a primary settling tank having a composition (by weight) of 64.5 percent carbon, 8.5 percent hydrogen, 21.0 percent oxygen, and 4 percent sulfur.

14–4 Calculate the theoretical heat requirement to dry 1000 m^3/d of sludge cake from solid contents of 15, 20 or 25 percent (to be selected by instructor) to 92 percent. Assume feed sludge temperature at 20°C and final temperature at 100°C. Latent heat of evaporation is 2260 kJ/kg H_2O. Assume a specific gravity of the dewatered cake is 1.05. Assume dry solids heat capacity of 1.5 kJ/kg·°C. Estimate the fuel requirement assuming 5 percent heat loss and 85 percent heater efficiency.

14–5 A community of 25,000 persons has asked you to serve as a consultant on their sludge disposal problems. Specifically, you have been asked to determine if it is feasible to compost waste activated sludge with the community's solid waste. If this plan is not feasible, you have been asked to recommend a feasible solution. Currently the waste sludge from the WWTP is dewatered on a belt filter press. Assume the following data are applicable:

Solid waste data:
  Waste production = 2 kg/person·d (wet basis)
  Compostable fraction = 55%
  Moisture content of compostable fraction = 22%

Sludge production:
  Net sludge production = 0.12 kg/person·d (dry basis)
  Concentration of sludge out of the belt filter press = 22%
  Specific gravity of dewatered cake = 1.05

Compost:
  Final moisture content of composted biosolids/solid waste mixture = 55%

14–6 A municipality with a population of 200,000 has hired you as a consultant to investigate alternative mechanical sludge dewatering options. The three alternatives to be investigated are belt press dewatering, centrifugation, and pressure filter press dewatering. The biosolids to be dewatered are stabilized by anaerobic digestion, are a mixture of primary sludge and waste activated sludge, and have a solids concentration of 5 percent. Ultimate disposal is by landfilling at a site located 50 kilometers from the treatment plant. Compare the various dewatering alternatives and recommend one. State the reasons for your recommendation. Should newer technologies such as rotary presses or screw presses be considered?

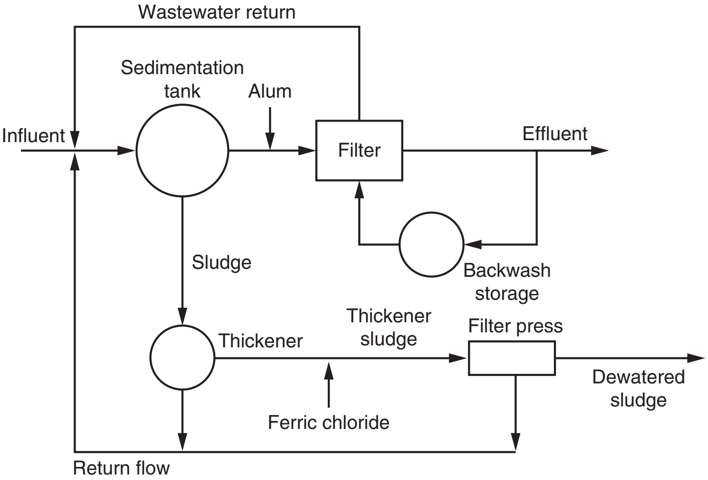
14–7 Prepare a solids balance for the peak loading condition for the treatment plant used in Example 14–3 for one of the data sets to be selected by instructor. Enter your final values on the solids balance figure in Example 14–3.

	Data set			
	1	2	3	4
Peak flowrate, m^3/d	54,000	60,000	50,000	54,000
Average BOD at peak flowrate, mg/L	340	300	350	300
Average TSS at peak flowrate, mg/L	350	320	330	320
TSS after grit removal, mg/L	325	300	310	300

Use data given in Example 14–3 for other parameters.

14–8 Prepare a solids balance, using the iterative technique delineated in Example 14–3, for the following treatment process flow diagram and one of the following data sets to be selected by instructor. Also determine the effluent flowrate and suspended solids concentration.

	Data set			
	1	2	3	4
Influent characteristics				
Flowrate, m^3/s	10,000	20,000	30,000	40,000
Suspended solids, mg/L	1000	350	400	300
Sedimentation tank				
TSS removal efficiency, %	75	60	65	60
Underflow TSS concentration, %	7	6.5	6	5.5
Specific gravity of sludge	1.1	1.1	1.1	1.1
Alum addition				
Dosage, mg/L	10	10	20	15
Chemical solution, kg alum/L of solution	0.5	0.5	0.5	0.5
Filters				
TSS removal efficiency, %	90	90	95	92
Washwater solids concentration, %	6	6	6.8	6.5
Specific gravity of backwash	1.08	1.08	1.089	1.085
Thickener				
Supernatant TSS, mg/L	400	300	200	250
Concentration of solids in underflow, %	12	8	9	8
Chemical addition				
Dosage, percent of underflow solids from thickener	0.8	1.0	1.0	1.0
Chemical solution, kg/L of solution	2.0	2.0	2.0	2.0
Filter press				
TSS concentration in filtrate, mg/L	200	300	250	200
Concentration of dewatered solids, %	40	38	42	42
Specific gravity of sludge cake	1.6	1.5	1.65	1.65



In preparing the solids balance assume that all of the unit operations respond linearly such that the removal efficiency for recycled solids is the same as that for the solids in the influent wastewater. Also assume that the distribution of the chemicals added to improve the performance of the filter and filter press is proportional to the total solids in the return flows and the effluent solids.

14–9 Assume the HHV value of biosolids as derived in Example 14–2, and compute the energy contents in biosolids with 25, 65 and 90 percent solid contents (to be selected by instructor). Compare the results with the heat requirements to vaporize water in the biosolids for each solids content level. Discuss supplemental energy requirements for the incineration process in relation to the solids contents of the feed biosolids.

14–10 Determine the dry sludge application rate for Reed canary grass on the basis of satisfying crop nitrogen uptake. Assume that biosolids containing 3 percent organic nitrogen by weight are applied to a soil that has an initial nitrogen content of zero. Use a mineralization rate of 30 percent for the first year, 15 percent for the second year, and 5 percent for the third and subsequent years.

14–11 Biosolids containing 50 ppm of cadmium on a dry basis are to be applied to land. If the limiting mass loading to the soil is set at 10 kg/ha, what would be the safe loading rate for 50 y of application?

14–12 Compare the advantages and disadvantages of land application of liquid biosolids to dewatered biosolids. Assume the land application site is located 15 km from the treatment plant in primarily an agricultural area and the biosolids are transported by truck. The biosolids are stabilized by anaerobic digestion and the liquid biosolids concentration is 6 percent and the dewatered solids concentration is 25 percent.

14–13 In problem 14–13, what would be the advantages and limitations of conveying the liquid biosolids by pipeline to the land application site? What types of facilities, i.e., structures, equipment, and vehicles, would be required and what are the operating and maintenance considerations?

The following two problems are best solved in groups of two or three.

14–14 A treatment plant is treating an average wastewater flowrate of 500,000 m^3·d with 430 mg/L TSS, 345 mg/L VSS, and 335 mg/L BOD. The volatile part of TSS is 80 percent. The peaking factors are 1.3, 1.4, and 1.5 for max month, max week, and max day, respectively. The main treatment processes include primary clarifiers and activated sludge system for secondary treatment. Primary sludge is thickened via gravity thickener while waste activated sludge is thickened by gravity belt thickening. Combined thickened sludges are stabilized via anaerobic digestion. The primary clarifier is expected to remove 50 percent of the TSS and 30 percent of the BOD. Students are encouraged to solve this problem through establishing a spreadsheet mass and energy balance.

1. Determine the average amount of primary sludge produced in kg/d at a TS concentration of 1.5 percent.
2. Determine the average amount of WAS produced in kg/d assuming the BOD effluent from the secondary clarifier to be 10 mg/L and a sludge yield of 0.6. Assume the mean cell residence time or SRT of the secondary treatment is 10 d; endogenous decay rate, k_d, is 0.06 d^{-1}; the VS content in the mixed liquor suspended solids is 70 percent.
3. Determine the average amount of primary thickened sludge in kg/d at a TS concentration of 5 percent and assuming a solids capture of 95 percent in the gravity thickener.
4. Determine the average amount thickened WAS in kg/d at a solids concentration of 6 percent assuming a 95 percent capture rate in the gravity belt thickener. Assume the WAS from the secondary clarifier is 1 percent TS.
5. The two thickened sludges are mixed in a combined primary and activated sludge (CPAS) tank with a volume of 40 m^3. Determine the combined sludges percent TS content out of the CPAS, and percent volatile solids content out of the CPAS. Determine the HRT of the CPAS tank in min.
6. The anaerobic digestion complex achieves 50 percent volatile solids destruction. Digesters are cylindrical with cone bottom. The dimensions of each digester are 37 m diameter, 11 m side water depth, 1.2 m freeboard, and cone bottom slope of 1:10. Assuming all sludge filled digester volume is usable:
   a. Determine the number of digesters if the HRT of all digesters is not reduced below 15 d HRT to meet max month per MOP 8 design criteria. Assume the digesters are high rate complete mix with no decant.
   b. Determine the number of digesters to process annual average sludge production.
   c. Determine the annual average and max month VS loading to the digester complex in $kg/m^3 \cdot d$ and compare it to typical design criteria
   d. Determine the amount of heat needed to maintain the mesophilic temperature within the digestion complex during the winter months assuming minimum income sludge temp to be 5°C and assuming no heat loss from the digesters.
   e. If you are the operations manager do you recommend processing the maximum day sludge in the digester complex? If not what do you recommend an operation strategy?
7. Determine the amount of biogas production in m^3/h assuming 0.95 m^3/kg VS destroyed.
8. The plant produces electricity from the biogas system through an internal combustion engine of 38 percent electrical efficiency and 40 percent thermal energy recovery.
   a. Determine the amount of electricity produced in KW if the generated biogas has 22,400 kJ/m^3.
   b. Is the recovered heat from the engine enough to supplement the energy used to keep the digesters heated during winter months?
9. If a portion of the biogas is used to supplement the energy needed for the digesters' heating through a boiler system with 80 percent energy efficiency prior to feeding the engine, determine the amount of electricity generated.
10. Provide your thoughts on which energy management system through comparing results from 8 and 9 above.

11. The biosolids produced from digestion process are dewatered via centrifuges. Determine the following:
    a. Dry solids loading to the centrifuge complex following digestion in kg/d
    b. Volatile solids content of the biosolids out of digestion in kg/d
    c. The percent solids total solids (%TS) content of the biosolids after digestion
    d. The volumetric flowrate of the biosolids in m^3/h going to the centrifuges.
    e. Determine the amount of wet tonnes produced daily from the centrifuge and the concentration (%TS) and the centrate flowrate (m^3/h) if the centrifuge complex is producing a solids cake of 23 percent with a 95 percent solids recovery. Assume the BOD concentration in the centrate is 1500 mg/L and is recycled to the primary clarifier.

Plant Recycle Flow Treatment and Nutrient Recovery

WORKING TERMINOLOGY

Term	**Definition**
Acid absorption	The absorption of constituents from an air stream into an acid solution.
Air stripping	The use of air to remove (transfer) constituents from a liquid stream to an air stream.
Anaerobic ammonium oxidation (Anammox)	Biological oxidation of ammonia under an oxygen-free environment with nitrite as the electron acceptor.
AOB	Ammonia oxidizing bacteria.
Bioaugmentation	The introduction of a selected or engineered group of microorganisms to enhance treatment.
Crystallizers	A liquid-solid separation technique in which solid crystals are formed from constituents in solution.
Deammonification	A two-step biological process consisting of partial nitritation and the Anammox reaction.
Denitritation	Biological conversion of nitrite to nitrogen gas and other intermediate compounds containing nitrogen.
Denitratation	Biological conversion of nitrate to nitrite.
Fermentation	A biological process in which organic matter is converted under anaerobic conditions to volatile fatty acids.
Integrated sidestream-mainstream treatment	An integrated system is any process where the sidestream reactor waste solids are fed to the mainstream secondary process or mixed liquor solids are interchanged between the two processes.
Limit of technology	Represents the lowest achievable concentration of a specific constituent by the best available technology.
Nitratation	The conversion of nitrite to nitrate.
Nitritation	The conversion of ammonia to nitrite.
NOB	Nitrite oxidizing bacteria.
Sidestream	The collective term used to describe all recycle streams. Sidestreams derived from digestion are also known in some countries as liquor or reject water.

Term	Definition
Separate sidestream treatment process	Biological treatment process that is isolated from the mainstream treatment process and dedicated to treat sidestream flows.
Struvite	A precipitated compound form of magnesium ammonium phosphate hexahydrate, $MgNH_4PO_4{\cdot}6H_2O$.
Steam stripping	The use of steam to remove a constituent from a waste stream.

The separation of water from primary, secondary, combined, or digested sludges during solids processing generates a liquid stream, which has characteristics that prevent direct discharge of the stream with the wastewater treatment plant final effluent. At facilities that thicken primary and secondary waste sludges before aerobic or anaerobic digestion and dewater the digested solids, multiple recycle streams are generated, each with a different composition, flowrate, and impact on the treatment plant. Because anaerobic and aerobic digestion result in the release of soluble organic nitrogen-containing compounds, ammonium and orthophosphate into the bulk liquid, the post-digestion recycle stream generated by the dewatering of the digested solids will have elevated nutrient concentrations resulting in an increased nutrient loading to the primary and secondary treatment processes. In addition, the release of orthophosphate and ammonium during solids digestion often results in the formation of insoluble inorganic compounds such as magnesium ammonium phosphate, also known as struvite, which can cause operational and maintenance problems in mechanical dewatering equipment and pipes that convey the recycle stream.

Current practice at most wastewater treatment plants is to recycle these sidestreams to the head of the plant or directly to the secondary process for treatment. However, because these sidestreams can impact significantly the performance of the secondary treatment process, many treatment plants now treat these streams separately. Interest in reducing nutrient loadings from plant recycle streams rich in ammonium and phosphate through the implementation of dedicated or *sidestream* treatment processes has been increasing since the late 1980s due to more stringent effluent discharge limits on ammonium-N, total nitrogen (TN) and total phosphorus (TP) and a desire to reduce plant operating costs (energy, chemicals, and maintenance). In addition, the impact of suspended solids and colloidal material present in some recycle streams on treatment plant effluent quality must be considered.

The types of recycle streams commonly found in conventional wastewater treatment plants, their characteristics, and their potential impacts on the operation of wastewater treatment facilities are reviewed in this chapter. Following the review of types of recycle streams and their characteristics, the focus of the remainder of the chapter is on physiochemical and biological treatment technologies that have been developed and implemented to treat separately the nutrient-rich streams, which are typically the primary recycle streams of concern for nutrient removal facilities. Typical process design and performance information are also provided.

15–1 SIDESTREAM IDENTIFICATION AND CHARACTERIZATION

Recycle sidestreams from the thickening and dewatering of raw and digested solids are typically identified with the particular process or mechanical equipment from which they originate. The composition of each recycle sidestream also varies depending on the source of the solids being thickened or dewatered. For the purpose of simplifying terminology, all recycle streams discussed in this chapter will be called *sidestream*, but specific terminology that allows for the distinction of one type of recycle stream from another will be retained as needed and used interchangeably with the general name. Common sources of sidestreams, typical flowrates, and typical sidestream characteristics [total suspended solids (TSS), total Kjeldahl nitrogen (TKN), ammonium nitrogen (ammonium-N), total phosphorus (TP) and orthophosphate (ortho-P)] are summarized in Table 15–1. Additional characteristics that distinguish one type of sidestream from another are discussed below.

Sidestreams Derived from Primary and Secondary Sludges

The soluble nutrient concentrations in sidestreams generated from the thickening of primary and waste activated sludges (gravity thickening; dissolved air flotation; centrifugation) and the filtration of secondary effluent generally represent the soluble composition of the liquids from which they originate. The partial fermentation of sludges that often occurs in gravity thickeners, will generate volatile fatty acids, decrease the alkalinity, and increase the ammonium and phosphate concentrations. The wide ranges for the ammonium and orthophosphate concentrations shown in Table 15–1 for these sidestreams represent the typical range of weak to untreated domestic wastewaters (Table 3–18) and nitrifying and non-nitrifying secondary treatment systems. Concentrations of TKN, TP, and BOD are strongly dependent on the TSS concentration. In general, the daily mass nutrient loadings contributed by these sidestreams to the secondary process are relatively minor in comparison to the raw influent or primary tank effluent. The major impact of their return to the primary and/or secondary treatment process is on the solids mass balance for the treatment plant, as discussed in Sec. 14–7 in Chap. 14. The solids impact is dependent on the solids capture efficiency of the thickening or dewatering process. For most treatment facilities, sidestream flowrates from the thickening of primary and secondary sludges and backwash from final filtration are continuous or near-continuous.

Sidestreams Derived from Fermented Primary and Digested Primary and Secondary Sludges

Sidestream characteristics resulting from the fermentation of primary sludge and the digestion of primary and waste activated sludges are significantly different than sidestreams generated from the thickening and dewatering of primary and waste activated sludges. The principal reason is the release of organic nitrogen-containing compounds, ammonium and phosphate into the bulk liquid. The soluble nutrient concentrations in these higher strength sidestreams are, as indicated in Table 15–1, dependent on the process from which they originate. For example, in the fermentation of primary sludge to generate volatile fatty acids (VFAs) for the enhancement of biological phosphorus removal, the ammonium and orthophosphate concentrations in the fermentate are far lower than the concentrations in the sidestreams resulting from aerobic and anaerobic digestion. Further, the ammonium and orthophosphate concentrations resulting from digestion are dependent on the feed solids concentrations to the digester and the volatile solids destruction efficiency, as reflected in the broad concentration ranges shown in Table 15–1. For example, if thermal hydrolysis is applied in the pretreatment of sludge before anaerobic digestion, the total solids (TS) concentration in the feed to the digesters will be 8 to 11 percent by weight. With the higher TS concentration and enhanced volatile solids destruction efficiency in the digester associated with this advanced digestion process, the digester ammonium-N concentration will be two to three times the concentration observed in typical conventional anaerobic digesters.

Table 15–1

Characteristics of various sidestreams from the thickening, stabilization and dewatering of raw and digested solids

Operation	Flowrate, Percent of plant influent	Value, mg/L						
		TSS[a]	BOD[a]	TKN	NH4-N	NOx	TP	Ortho-P
Gravity thickening supernatant:								
Primary sludge	2–3	80–350	100–400	19–70	12–45	0	4–11	3–8[e]
Primary sludge + waste activated sludge	3–5	100–350	60–400	20–70	8–45	0–8	4–15[b]	2–7[b,e]
Primary sludge fermentate, including elutriation water	3–4	700–900	2000–2500	80–120	60–100	0	10–20	5–15
Flotation thickening subnatant (waste activated sludge)	0.7–1	100–2500	50–1200	8–250	0–45	0–30	2–50	0.05–8
Centrifuge thickening centrate (waste activated sludge)	0.7–1	500–3000	170–3000	40–280	0–45	0–30	8–60	0.05–8
Screw press–filtrate + pressate (alkaline and heat stabilization for Class A)[d]	0.3–0.5	400–500	600–1300	120–250	10–20	0–5	6–14	< 1
Aerobic digestion supernatant (mesophilic; continuous and intermittent aeration)	0.1–0.5	100–10,000	100–1700	100–1200	20–400	0–400	200–350[b,c]	200[b,c]
Anaerobic digestion supernatant (two-stage, high-rate)	0.1–0.5	1000–11,500	500–5000	850–1800	800–1300	0	110–470[b,c]	100–350[b,c]
Centrifuge dewatering centrate:								
Two-stage, high rate anaerobic digestion	0.5–1	200–20,000	100–2000	810–2100	800–1300	0	100–550[b,c]	100–350[b,c]
Thermal hydrolysis + single stage mesophilic anaerobic digestion	0.2–0.5	1500–10,000	1500–3000	2200–3700	2000–3000	0	220–800[b,c]	200–700[b,c]
Belt-filter press filtrate: two-stage, high rate anaerobic digestion, including belt washwater	1–2	100–2000	50–500	410–730	400–650	0	50–200[b,c]	50–180[b,c]
Recessed-plate-filter press filtrate	0.5–1	50–1000	50–250		800–1300	0		100–350[b,c]
Sludge lagoon supernatant		5–200	100–200

Table 15–1 (*Continued*)

Operation	Flowrate, Percent of plant influent	Value, mg/L						
		TSS[a]	BOD[a]	TKN	NH4-N	NOx	TP	Ortho-P
Incinerator scrubber water		600–8000	30–80					
Depth filter washwater		100–1000	50–500					
Microscreen washwater		240–1000	100–500					
Carbon adsorber washwater		100–1000	50–400					
Dryer condensate								

[a] Adapted, in part, from U.S. EPA (1987b) and WEF (1998).

[b] Orthophosphate concentration does not include potential phosphorus release from waste activated sludges derived from plants operating with biological phosphorus removal.

[c] Orthophosphate concentration does not include reduction by chemical precipitation within the digester through the natural formation of salts such as hydroxyapatite and magnesium ammonium phosphate (struvite), through the addition of ferric or ferrous salts to the digester to control struvite formation in dewatering equipment and pipes conveying sidestream or for facilities that practice chemically enhanced primary or secondary treatment for phosphorus removal.

[d] Based on unpublished data collected from the stabilization and dewatering of waste activated sludge with the FKC Class A process at the Sequin, WA, wastewater treatment plant in July-August, 2011 (no primary sedimentation; oxidation ditch secondary process).

[e] Orthophosphate concentration does not reflect facilities that practice chemically enhanced primary treatment.

Nitrogen Content. In addition to a higher ammonium concentration, soluble organic nitrogen-containing compounds are released into the bulk liquid during digestion, accounting for roughly 10 percent of the soluble TKN. Of this soluble organic nitrogen fraction, approximately 50 percent is considered essentially non-biodegradable or recalcitrant dissolved organic nitrogen (rDON). Recalcitrant DON is typically less than 1 mg/L in plant effluents due to rDON in the raw influent and the production of soluble microbial products in the secondary treatment process. In general, the presence of rDON is not of concern for most nutrient removal plants. However, for limit of technology (LOT) plants with a low effluent TN limit (e.g., 3 mg/L), rDON becomes a larger fraction of the plant effluent TN. Typical digester sidestream will add approximately 0.2 mg N/L of rDON to the plant effluent, assuming no removal by adsorption onto the activated sludge in the secondary process or capture in primary tanks where chemically enhanced clarification is being performed. The concentration of rDON in digester sidestream will be higher if thermal hydrolysis is applied for sludge pretreatment before digestion; the concentration being dependent on the hydrolysis reactor temperature (Dwyer et al., 2008).

Phosphorus Content. The orthophosphate concentration range, as noted in Table 15–1, for the various digestion sidestreams does not include phosphate released by waste activated sludge from biological phosphorus removal processes, nor do the ranges account for reduction in phosphate due to precipitation within digester or in downstream mechanical equipment and pipes conveying sidestream. The values shown in Table 15–1 represent the stoichiometric amounts of phosphorus expected to be released into the bulk liquid for the various operating and performance conditions considered. For example, at facilities performing chemically enhanced primary treatment with ferric salts and anaerobically digesting the combined primary and waste activated sludges, the orthophosphate concentration in digester sidestream will typically be below 10 mg P/L due to precipitation or absorption onto iron floc in the digester. For facilities where ferric or ferrous salts are added directly to the anaerobic digester for control of hydrogen sulfide, partial removal of orthophosphate would also be expected. At facilities where no iron salts are added, partial precipitation of released phosphate as magnesium ammonium phosphate (struvite) at the digester outlet structure, in the biosolids dewatering process and in the pipes that convey digester sidestream is common. The amount that is formed is dictated by the ion molar concentrations of the struvite constituents and the elevated pH induced by CO_2 release from the bulk liquid at these locations.

Alkalinity Content. The alkalinity in sidestreams will vary depending on the source. The concentration of alkalinity in a sidestream is of importance in the operation of separate sidestream treatment processes. In sidestreams generated from fully aerated conventional low rate aerobic digesters, the alkalinity concentration is anticipated to be low due to the acidification of the digester sludge by nitrification. For aerobic digesters that operate with intermittent aeration to allow denitrification, the residual alkalinity in the digester will be slightly higher. In contrast, anaerobic digestion and autothermal thermophilic aerobic digestion (ATAD) sidestreams typically contain higher alkalinity concentrations, primarily in the form of bicarbonate. The cause of the high alkalinity concentrations is due to the retention of carbon dioxide in the digester bulk liquid to balance the positively charged ammonium ion at the typical pH range of the digesters (7.2 to 7.8). Therefore, the bicarbonate and ammonium-N concentrations will be equal on a molar basis. In terms of the standard measurement as $CaCO_3$, the alkalinity to ammonium-N mass ratio is 3.5 to 1 (kg $CaCO_3$/kg N).

Total Suspended Solids Content. Total suspended solids in digester sidestreams are composed largely of stabilized biologically inert solids with a relatively low volatile solids content (e.g., 65 percent). If the digester sidestream is sent to the primary sedimentation tanks, the TSS will settle readily and will be recycled to the solids processing train. If the sidestream is sent directly to the secondary treatment process, the solids will accumulate in the activated sludge. If the dewatering equipment is not working well, resulting in poor capture efficiency, the inert solids loading to the main plant can be substantial, potentially inducing foaming in the secondary process and effectively reducing the active fraction of the sludge in the secondary system.

Colloidal Material Content. Depending on the secondary treatment system configuration, digestion sidestreams, which can also contain colloidal material, can impact plant effluent quality. In addition to the potential for inorganic precipitate formation (e.g., struvite, hydroxyapatite), the presence of the colloidal material, can make the use of membrane-based technologies for separate treatment of digestion sidestream difficult due to membrane fouling, unless coagulation and filtration of these materials precedes the membrane process.

Temperature. Sidestream temperatures will vary depending on the source. The sidestream resulting from centrifugation of anaerobically-digested solids will typically have a temperature near the digester temperature (e.g., 30 to 35°C), depending on heat losses from a digested sludge holding tank and from the dewatering equipment. If a belt filter press is used for dewatering the same digested sludge, the temperature will typically be lower (e.g., 20 to 30°C) due to the inclusion of cooler belt washwater in the sidestream, unless warm filtrate is recycled and used as the washwater source. For aerobic digestion sidestreams, the temperature is also dependent on the type of process and the operating conditions. For example, a sidestream derived from ATAD process would have a higher temperature than a conventional non-insulated aerobic digester operating at a long hydraulic retention time. For the anaerobic sludge lagoons, the supernatant will be near ambient temperatures. The importance of temperature for the design of separate sidestream treatment processes is discussed in the individual sections dealing with physiochemical and biological treatment processes.

Flowrate. Sidestream flowrates from digestion processes, as reported in Table 15–1, are typically less than 1 percent of the daily average raw influent flow based on a continuous 7 d/wk operation. However, at facilities where digested sludge is not dewatered every day nor operate the dewatering equipment continuously (i.e., 24 h/d), the sidestream flow can result in a high instantaneous flow to the primary and secondary treatment processes if discharged directly without equalization. Estimation of peak sidestream flow is illustrated in Example 15–1.

EXAMPLE 15–1 **Estimate Peak Sidestream Flow** The sidestream from an anaerobic digester contributes 0.7 percent of the daily average influent flow of 0.5 m^3/s (11.4 Mgal/d), on a continuous basis, and is generated 5 d/wk, 8 h/d. What would be the instantaneous flow to the primary tanks? What percentage of the average influent flow would the instantaneous flow represent?

Solution

1. Determine the sidestream flowrate (SSF).

$$\text{SSF} = (0.5\ \text{m}^3/\text{s})(0.007) = 0.0035\ \text{m}^3/\text{s}$$

2. Determine the peak sidestream flowrate.

$$\begin{aligned}\text{Peak SSF} &= (0.0035\,\text{m}^3/\text{s})[(7\,\text{d/wk})/(5\,\text{d/wk})][(24\,\text{h/d})/(8\,\text{h/d})]\\ &= 0.0147\,\text{m}^3/\text{s}\end{aligned}$$

3. Determine the percentage of the flow represented by the instantaneous flow.

$$\text{Percent of total flow} = [(0.0147\ \text{m}^3/\text{s})/(0.50\ \text{m}^3/\text{s})](100) = 2.94$$

Comment Although the facility likely has sufficient hydraulic capacity to receive this sidestream flow over the 8-h sludge dewatering period, the primary concern is the nutrient loading associated with this sidestream flow, particularly if the sidestream load occurs during the peak diurnal nutrient loading to the facility. The impact of the 8-h sidestream peak nutrient load can be dampened through flow equalization or by treating the sidestream load in a separate process to minimize the nutrient loading to the secondary process.

15–2 MITIGATING RECYCLE FLOWS AND LOADS

Recycle streams from sludge thickening, digestion, dewatering and storage processes may have negative impacts on the performance of the mainstream process. These impacts vary in degree and are specific to each facility. Summary information on the impact of recycle streams on the mainstream plant and potential mitigation measures is provided in Table 15–2.

Sidestream Pretreatment

Sidestreams will increase the solids load to the mainstream process, affecting solids inventory and the mixed liquor solids concentration., Some sidestreams, as noted previously, will also contain colloidal material which may impact plant effluent quality. Depending on the plant operating condition and performance, sidestream pretreatment to reduce its suspended solids and colloidal material content may be beneficial. The reduction of suspended solids and colloidal material in sidestreams is discussed in Sec. 15–3.

For treatment plants with stringent nutrient removal requirements, pretreatment of the nutrient-rich sidestreams prior to return to the mainstream process may be cost effective. Physiochemical and biological treatment options for these sidestreams are discussed in Sec. 15–4 through 15–11. As demonstrated in Example 15–1, the hydraulic load contributed by sidestream generated by dewatering operations only performed 7–8 h/d will increase the instantaneous hydraulic load through the mainstream facility. However, this hydraulic load increase is typically not a concern.

Equalization of Sidestream Flows and Loads

Digested sludge dewatering operations are commonly carried out as a batch operation, over several hours during the daytime hours five or six days per week. Consequently, nutrient-rich sidestream constituent loads to the mainstream plant will increase near instantaneously and will coincide with the diurnal influent load peak period. Where nitrification, denitrification, chemical phosphorus removal or biological phosphorus removal are practiced, the contribution of the sidestream nutrient load will increase peak air and chemical demands (external organic carbon, iron salts or alum), and may deteriorate plant effluent quality if control systems are not adequate to respond to the sudden and significant increase in nutrient loads. Nitrification may also be destabilized if the alkalinity concentration in the plant influent is relatively low and no supplemental alkalinity is available.

Table 15–2

Major impacts and potential mitigation measures for return flows from sludge and biosolids processing facilities[a]

Source of return flow	Impact	Process impacted	Mitigation measure
Sludge thickening	Effluent degradation by colloidal SS	Sedimentation	Add flocculent aid ahead of sedimentation tank Separately thicken primary and biological sludges Optimize gravity thickener dilution water
	Floating sludge	Sedimentation	Minimize gravity thickener detention time Remove sludge continuously and uniformly
	Odor release and septicity	Recycle point	Reduce gravity thickener detention time Return flows ahead of aerated grit chamber Provide odor containment, ventilation, and treatment (scrubber or biofilter)
		Biological	Return odorous flows to aeration tank Remove sludge continuously and uniformly Provide separate return flow treatment (with other recycle streams)
	Solids buildup	Sedimentation	Increase thickening unit operation time or capacity to maintain desired solids inventory in sedimentation units
		Biological	Remove sludge continuously and uniformly Include recycle loads in mass balance analysis
Sludge dewatering	Effluent degradation by colloidal suspended solids	Sedimentation	Optimize dewatering unit solids capture by improved sludge conditioning Add flocculent aid ahead of sedimentation tank Return centrate/filtrate to thickener Provide separate return flow treatment (with other recycle streams)
	Solids buildup	Sedimentation	Increase dewatering unit operation time or capacity to maintain desired solids inventory in sedimentation units
		Biological	Remove sludge continuously and uniformly Reduce trickling-filter recycle rate Include recycle loads in mass balance analysis
Sludge stabilization	Effluent degradation by excessive BOD load	Biological	Optimize supernant/decant removal, i.e., remove smaller amounts over a longer period of time, or reschedule removal to off-peak periods Provide separate return flow treatment Increase RBC speed Increase MLVSS in activated sludge system (decrease F:M ratio) Increase dissolved oxygen level in activated sludge process
	Effluent degradation by nutrients	Biological	Regulate digester supernatant/decant removal Thicken sludge before stabilization Provide separate return flow treatment
Washwater from depth filters	Hydraulic surges	Sedimentation	Provide backwash storage for flow equalization Schedule filter backwashing for off-peak periods

[a] Adapted, in part, from U.S. EPA (1987*b*).

To minimize these potential impacts, sidestream flow equalization can be employed. In larger facilities, where sludge is dewatered continuously, the benefit of sidestream equalization depends on the variability of the sidestream nutrient loads.

Equalization of sidestream flow is also commonly used to reduce the peak air demand in a biological pretreatment process. As discussed in Sec. 15–11, flow equalization will also have a direct impact on the sidestream reactor volume requirement. For batch treatment processes, where interruption in sidestream flow to the treatment process will occur intermittently during the treatment cycle, flow equalization is required if no release of raw sidestream to the mainstream plant is desired.

Equalization Volume Requirement. The general principles of flow and load equalization discussed in Sec. 3–7 in Chap. 3 apply to nutrient-rich sidestreams, but the basis for calculating the equalization volume requirement is slightly different. The equalization volume may be based on full equalization where sidestream is returned continuously to the mainstream plant or sent to a pretreatment process at a relatively stable, but adjustable, flowrate. The required equalization volume can be estimated using Eq. (15–1).

$$V = (N)(Q_{\mathrm{dw}})(D_{\mathrm{dw}}/7) \tag{15–1}$$

Where V = equalization tank volume, m^3
N = maximum number of consecutive days without dewatering, d
Q_{dw} = average daily sidestream volume generated, m^3/d
D_{dw} = number of days per week sludge is dewatered, d

Depending on the sidestream constituent concentrations, the alkalinity of the mainstream plant influent, and the treatment objectives of the mainstream plant, capturing sidestream in an equalization tank and returning the non-pretreated sidestream load to the mainstream plant in the off-peak hours when the facility influent flow and loads are at their minimum may be sufficient. However, for facilities that perform nitrate and phosphate removal, continuous return of the sidestream load at a steady rate is recommended. Where space constraints and tank costs are of concern, a smaller equalization tank volume may be used if the sidestream load variability does not impact plant performance. Dynamic process modeling is commonly used to assess the feasibility of using a smaller tank volume. Depending on the results of such an assessment, it may also be found that increasing the number of days each week or the hours per day that sludge is dewatered is the most cost-effective option.

Design Considerations. The features of a sidestream equalization tank vary depending on the design objectives. For an ideally equalized stream, mechanical mixing is provided to return a uniform composition to the mainstream plant. A mixing power input of 8 to 13 $\mathrm{kW}/10^3\ \mathrm{m}^3$ (0.3 to 0.5 $\mathrm{hp}/10^3\ \mathrm{ft}^3$) may be required if high suspended solids concentrations of suspended solids frequently occur ($>$ 1000 mg/L). The mixing power input may be decreased by 50 percent if high suspended solids concentrations are infrequent. Aeration is not provided typically, unless the tank is performing a dual function of equalization and biological treatment, in which case the tank design is dictated by the desired biological treatment performance.

Depending on the sidestream characteristics, the tank may be covered and equipped with an odor control device to minimize odorous emissions. Liquid level sensors with high and low alarms, an overflow to the plant drain system, a sloped floor with drain line, and a variable speed return pump or control valve with flow metering are common features in equalization tank design. Struvite formation in the tank is a potential concern and will impact the design of the mixer and selection of pipe or pipe liner material. The flexibility of adding iron salts to the tank to limit struvite formation may be a consideration. Configuring sidestream piping systems to avoid introduction or contact with air will also help limit struvite formation.

Equalization and TSS Reduction. Equalization tanks for sidestream pretreatment processes often are used to reduce the TSS concentration if solids reduction is a requirement for the physiochemical or biological pretreatment process. In this design, mechanical mixing is not provided, the liquid level is greater and the operating liquid level range limited as to not disturb solids settling and thickening in the bottom section of the tank. Thickened solids are pumped intermittently to the solids processing facility. Because the tank is performing the dual function of sidestream storage and suspended solids reduction, the tank volume requirement may be greater than a tank only performing equalization, but a separate solids removal process is avoided.

Equalization and Biological Pretreatment. Sidestream equalization and biological pretreatment can be accomplished within a single tank. In a process called storage and treat (SAT), the tank is designed as a sequencing batch reactor but has the flexibility to operate in a continuous overflow mode during short periods of peak sludge dewatering. Tank volume and aeration capacity are dictated by the treatment objectives, rather than the equalization requirement. At full scale, SAT has been used to provide partial treatment, resulting in pretreated sidestream containing a reduced ammonium concentration and a mixture of nitrite and nitrate (Laurich, 2004). Biological treatment of sidestream is discussed in Sec. 15–7 through 15–11.

EXAMPLE 15–2 **Impact of Full Sidestream Equalization on Plant Influent Ammonium-N Concentration and Calculation of Equalization Tank Volume** Anaerobically digested sludge is normally dewatered from 8:00 a.m. to 4:00 p.m., 5 d/wk. Sidestream is produced at an average rate of 0.006 m^3/s during each 8-h period and contains an ammonium-N concentration of 1000 mg/L. The sidestream is sent to the facility's headworks. The longest number of consecutive days in which no sludge is dewatered is 3 d. For the average hourly facility influent flows and ammonium-N concentrations shown in the table below: (1) develop concentration-versus-time graphs for non-equalized and fully-equalized sidestream and (2) calculate the equalization tank volume required for full equalization.

Time period	Given data	
	Average flowrate during time period, m^3/s	Average NH_4^+-N concentration during time period, mg/L
M–1	0.275	20.0
1–2	0.220	18.8
2–3	0.165	17.9
3–4	0.130	20.2
4–5	0.105	17.3
5–6	0.100	15.6
6–7	0.120	15.3
7–8	0.205	13.4
8–9	0.355	19.6
9–10	0.410	27.0

11–M	0.345	20.6
Average	0.307	

Note: $m^3/s \times 35.3147 = ft^3/s$.
$m^3 \times 35.3147 = ft^3$.
$mg/L = g/m^3$.

Solution

1. Calculate the fully equalized average sidestream flowrate.

$$\begin{aligned}\text{Equalized flowrate} &= (0.006\ m^3/s)(3600\ s/h)(8\ h/d)\ (5\ d/wk)/[(7\ d/wk)\\ &\quad (86{,}400\ s/d)]\\ &= 0.00143\ m^3/s\end{aligned}$$

2. Using the non-equalized and fully-equalized sidestream flows, calculate the hourly average ammonium-N in the facility headworks.

	Plant Influent without sidestream		No Sidestream Equalization		Sidestream Equalization

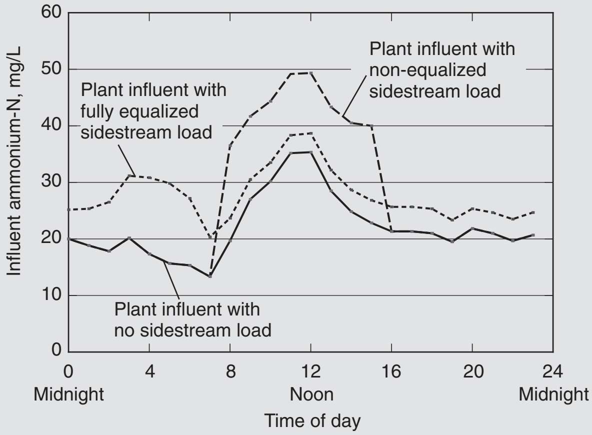
3. Plot the resulting influent ammonium concentration.



4. Calculate the equalization tank volume required for full equalization with 3 consecutive days with no sludge dewatering.

$$V = (N)(Q_{\text{dw}})(D_{\text{dw}}/7)$$

$$V = (3)\,[(0.006\ \text{m}^3/\text{s})(3600\ \text{s/h})]\,(8\ \text{h/d})\,[(5\ \text{d/wk of sludge dewatering})/(7\ \text{d/wk})] = 370\ \text{m}^3\ (13{,}066\ \text{ft}^3)$$

15–3 REDUCTION OF SUSPENDED SOLIDS AND COLLOIDAL MATERIAL

The solids balance for a wastewater treatment plant, as illustrated in Sec. 14–7 in Chap. 14, is influenced by the TSS in the sidestreams derived from sludge thickening and biosolids dewatering processes. Sidestreams are commonly returned to the headworks where solids settle in primary sedimentation tanks. In plants that do not have primary sedimentation or return the sidestreams directly to the mainstream secondary process, the solids become integrated into the mixed liquor suspended solids. Because the majority of the post-digestion sidestream TSS are biologically inert, they will contribute directly to the secondary solids inventory and will exert only a minor oxygen demand on the process. The impact of these solids on the primary tank effluent or the secondary process operating conditions and performance varies with the sidestream solids loading rate, the operating conditions of the primary process, and the type of the secondary process employed.

Some sidestreams, particularly from post-digestion dewatering processes, contain colloidal matter that may impact the plant effluent quality, depending on the type of secondary process in the facility and its operating conditions. The particles will contribute to turbidity and may negatively impact effluent disinfection. Plant effluent colloidal particles are a particular concern for facilities that provide treated effluent for reuse.

Common practices used for the management of TSS and colloidal matter in thickening and dewatering sidestreams, at full scale, are discussed below.

Sidestreams Derived from Sludge Thickening

Thickeners that suffer from poor capture efficiencies will generate sidestreams with a high TSS concentration. The elevated sidestream solids may negatively impact the solids removal efficiency across the primary sedimentation tanks or contribute an unacceptable solids loading rate to a secondary process. Thickener operating conditions are commonly adjusted to improve solids capture to resolve this problem rather than installing a separate solids reduction process for the sidestream.

Sidestreams Derived from Biosolids Dewatering

Reducing the TSS concentration in post-digestion sidestream before the sidestream is sent to the mainstream plant is uncommon. If the dewatering sidestream solids concentration is frequently high and the solids returned to the mainstream plant prove detrimental, the dewatering process operating conditions must be adjusted to improve solids capture. A solids balance should be performed to assess its contribution to the mixed liquor solids inventory and concentration and determine if a sidestream solids reduction step would be beneficial. Life cycle cost analyses can be performed comparing operating costs of power, aeration, and chemicals in mainstream treatment with that of a sidestream pretreatment step.

Reduction of TSS is more common when sidestream is pretreated to reduce the nutrient load returned to the mainstream plant. The pretreatment requirement is specific to the physiochemical or biological process employed for nutrient reduction, as discussed in Sec. 15–4 through 15–11.

Process Options. Reduction of TSS before sidestream pretreatment has been accomplished in practice through gravity settling in sidestream equalization tanks. The suspended solids concentration in the clarified sidestream is typically sufficient for biological treatment processes that benefit from suspended solids less than 200 mg/L. If higher removal efficiency is required, separation processes such as Lamella inclined plate settlers or high rate clarification processes (see Sec. 5–7 in Chap. 5 for process descriptions) may be applied where chemically enhanced flocculation can be employed optimally to improve solids removal. Experience is largely limited to inclined plate settlers, without chemical addition, as the majority of the pretreatment processes applied at full scale do not require a low suspended solids concentration. Filtration is rarely used on sidestream due to the high fouling potential of the colloidal material and residual polymer and the formation of inorganic foulants such as struvite.

In belt filter presses, belt washwater contains the majority of the uncaptured solids and the filtrate has a TSS concentration less than 500 mg/L. Belt filter presses can be designed for separate collection of washwater and filtrate, potentially eliminating the need for a solids reduction step. Separate collection of washwater and filtrate results in higher nutrient concentrations in the filtrate, which will improve the nutrient removal efficiency in the pretreatment process. Some pretreatment processes may also benefit from the elevated temperature of the filtrate, which is no longer being cooled by washwater.

Removal of Colloidal Matter

Sidestreams derived from post-digestion dewatering processes commonly contain colloidal particles that may impact the facility effluent. Typically, the colloids are not removed by primary sedimentation. If chemically-enhanced primary treatment is employed, partial or complete capture of the colloidal particles may occur. In the absence of chemical addition, the colloidal particles will enter the secondary treatment process where some portion of the particles will be captured by the mixed liquor suspended solids. The degree of capture is dependent on the type of secondary process and its operating conditions. If a sidestream pretreatment process is employed for nutrient reduction, a portion of the colloidal particles may be removed before the stream is sent to the mainstream plant.

Removal of sidestream colloidal particles by chemically-enhanced flocculation in a separate pretreatment process is not a common practice. If colloidal particles derived from post-digestion dewatering sidestream are identified as a primary source of turbidity in a plant effluent, addressing the problem by sidestream pretreatment may be the most cost-effective option as the colloids are present at their highest concentration in the sidestream and the sidestream flow is less than 1 percent of the mainstream flowrate. A process configuration could consist of solids reduction by gravity settling in an unmixed sidestream equalization tank, followed by an advanced chemically-enhanced filtration process. Filtration options are presented in Chap. 11. Bench or pilot-scale testing is recommended to assess feasibility and chemical requirements.

15–4 PHYSIOCHEMICAL PROCESSES FOR PHOSPHORUS RECOVERY

Phosphate ore, which serves as the primary source of phosphorus for modern agricultural practices is a limited resource. Significant depletion of known global reserves had been projected to occur as early as the end of the 21st century (Cordell et al., 2009), but based on the most recent projections known reserves will be available for the next 300 to 400 years (Van Kauwenbergh, 2010). However, as demand for phosphorus increases and the exploration for new reserves, the mining of lower quality ores, and the adoption of more expensive processing equipment occur, the price of phosphorus will continue to escalate in the future. Consequently, the phosphorus in wastewater treatment facility sludges and return flows may be viewed increasingly as an asset that should be recovered and reused as fertilizer rather than a nutrient that must be treated and disposed.

The primary focus of this section is on phosphorus recovery processes that have been developed and demonstrated at a full-scale on nutrient-rich sidestreams and industrial wastewaters. Other technologies have been developed to recover phosphorus from sludge ash, but these processes are not presented here. The phosphorus recovery processes, based on crystallization, considered in this section include those for the recovery of magnesium ammonium phosphate (struvite) and calcium phosphate (hydroxyapatite). Descriptions of the following crystallization processes that have been demonstrated in full-scale facilities are presented in Table 15–3.

AirPrex® process
Cone-shaped fluidized bed crystallizer
Crystalactor®
NuReSys® process
Pearl® process
Phosnix® process
PHOSPAQ™ process

However, before discussing these processes in greater detail, it will be useful to consider the fundamental aspects of the crystallization process. The beneficial reuse of recovered nutrients as fertilizers is discussed in Sec. 15–6.

Description of the Crystallization Process

All of the technologies presented in Table 15–3 are based on the three fundamental stages that occur within the physical environment of the crystallizer (reactor): (1) supersaturated ion concentrations, (2) primary and secondary nucleation processes, and (3) crystal growth. The phosphate removal efficiency, crystal size distribution achieved within the reactor, and the purity of the final product are all influenced by the temperature, pH, ionic composition, and hydrodynamic conditions within the reactor. In the recovery of phosphate for reuse, a larger crystalline product is desired rather than an amorphous solid phase consisting of fine particles that are difficult to recover from the liquid and process to generate a reusable product.

Supersaturation. In supersaturated solutions, the product of the ion molar concentrations (expressed as activities) of the desired product exceeds the value of its solubility constant at given reaction conditions. As the degree of supersaturation increases, there is increased potential of forming fine particles through primary nucleation, not a desirable condition, as discussed below. Therefore, the supersaturated condition within a crystallizer is controlled to avoid fine particle formation and to provide sufficient driving force for mass transfer of ions to the surface of the growing crystals. Supersaturation is the driving force for subsequent processes of nucleation and crystal growth.

Nucleation. The process by which ions come together under supersaturated conditions and aggregate into a solid form, or “nuclei,” according to their solubility at a given temperature and pH is known as *nucleation.* The nucleation process cycles through

Table 15–3

Processes for recovery of sidestream phosphorus as magnesium ammonium phosphate (struvite)

	Description
(a) AirPrex® process  	The AirPrex® process was, developed by Berliner Wasserbetriebe (Germany) in collaboration with the Berlin Institute of Technology. In this process, struvite is crystallized directly from the sludge stream from an anaerobic digester, rather than from sidestream, to prevent struvite formation in the sludge dewatering process. AirPrex® consists of a dual-stage aerated tank configuration, either as separate tanks or as a single tank with a dividing wall, with a hydraulic retention time (HRT) of approximately 8 h. An air-lift aeration design is used in each stage to induce sludge mixing and strip CO_2 to increase pH. Magnesium chloride is used as the magnesium source and is added to the first, second or both stages. As struvite forms and develops into particle sizes of sufficient settling velocity, it settles into the bottom conical section of each stage. The product is withdrawn intermittently or continuously from each stage and transferred by a screw conveyer to a sand washer. Washed product is stored wet or is subsequently dried. Aerated sludge overflows the second stage and is sent to a sedimentation vessel where additional struvite may be recovered or to the dewatering process. Processing the exhaust air through an odor control system may be required.
(b) Cone-shaped fluidized bed crystallizer  	A cone-shaped fluidized bed crystallizer was developed by Multiform Harvest Inc. (USA). The crystallizer consists of a conical section and a solids-liquid separation zone located at the top. The dimensions of the conical section are selected to provide a desired range of superficial upflow velocities. The HRT is typically less than 1 h. As struvite crystals grow, they settle towards the bottom of the cone where they are removed intermittently, processed through a sieve shaker or drum screen, disinfected, and bagged for off-site processing. Magnesium chloride and sodium hydroxide are added through a proprietary injection system at the bottom of the cone to provide supersaturated conditions and to increase pH to the desired range.
(c) Crystalactor®  	The Crystalactor® is a fluidized bed crystallizer developed by DHV (The Netherlands). The crystallizer consists of a cylindrical reactor with a solids-liquid separation zone located at the top. Effluent is recirculated to the bottom of the reactor where it is blended with sidestream and injected into the crystallizer through nozzles to achieve optimum cross-section liquid distribution. The effluent recirculation rate is adjusted to maintain a superficial upflow velocity in the range of 40 to 75 m/h (130 to 250 ft/h) in the reaction section of the vessel. The HRT based on sidestream flow is typically less than 1 h. Quartz sand is added initially as seed material to accelerate startup, but further sand addition is not required once struvite crystals form. As the pellets grow, they settle to the bottom of the crystallizer, where a portion of the pellets is removed at regular intervals, dewatered, and stored for offsite transport.

(*continued*)

Table 15–3 (*Continued*)

	Description
(d) NuReSys® process 	The NuReSys® process (NUtrient REcovery SYStem) was developed by Akwadok/NuReSys (Belgium). The process consists of a CO_2 stripping tank followed by a mechanically stirred crystallizer and a sedimentation zone. A HRT of 0.5 to 1 h is provided in the stripping tank where mechanical agitation and air are provided to strip CO_2 from the sidestream. Mixer speed and air flow are adjusted to control the pH to limit the formation of fine crystals in the stripping tank. In the crystallizer, mechanical stirring provides mixing and creates the hydrodynamic environment conducive to pelletized struvite formation. Stirrer speed and the product withdrawal rate are adjusted to provide the desired pellet size of the harvested product. Magnesium chloride is used as the magnesium source and NaOH is added to control the pH in the range of 8.1 to 8.3. A crystallizer HRT of 0.5 to 1 h is typical. Smaller crystals are settled in the sedimentation zone where they are returned to the crystallizer. Processing the exhaust air through an odor control system may be required.
(e) Pearl® process 	The Pearl® process was developed at the University of British Columbia for the crystallization of magnesium ammonium phosphate and was introduced at full-scale by Ostara Nutrients Recovery Technologies Inc. (USA). The Pearl® reactor is a fluidized bed crystallizer with a segmented construction where the segment or zone diameter increases from the bottom of the reactor to the top to reduce the upflow liquid velocity incrementally and retain struvite crystals of various sizes within each zone. A liquid/solids separation section is located at the top of the reactor. Effluent is recirculated to the bottom of the reactor to maintain the upflow velocity profile within the desired range. The HRT based on sidestream flow, is typically less than 1 h. As struvite pellet diameter increases, the pellets gradually sink from one zone to the next. The final product is removed from the bottom zone, separated from the liquid by screening, dried, and bagged. The effluent recirculation rate and struvite retention time are adjusted to control the pellet size in the final product. The magnesium source is typically magnesium chloride. Sodium hydroxide is used to maintain the pH within the desired range.
(f) Phosnix® process 	The Phosnix® crystallizer, developed by Unitika Ltd (Japan), consists of a cylindrical reaction zone with a conical bottom section and a larger diameter solids-liquid-gas separation section at the top. The crystallizer is aerated to provide mixing and to increase the pH by stripping CO_2 from the liquid. If required, the exhaust air is treated with an odor control system. The HRT in the reaction zone is less than 1 h. Magnesium hydroxide is typically used as the magnesium source and sodium hydroxide is added to control pH within the desired range. Larger struvite pellets that settle into the conical section of the reactor are pumped intermittently to a rotary drum screen. Liquid and associated smaller struvite particles that pass through the screens are sent to the mainstream plant or returned to the crystallizer to allow the fine particles to serve as seed material for struvite pellet growth.

(*continued*)

Table 15–3 (*Continued*)

	Description
(g) PHOSPAQ™ process 	PHOSPAQ™ was developed by Paques (The Netherlands). The process consists of an aerated reaction zone and a proprietary solids-liquid-air separation device in the upper section of the vessel. An air-lift aeration design is used to (1) provide mixing, (2) strip CO_2 from the liquid to increase pH, and (3) provide dissolved oxygen (DO) for biological treatment. The HRT is approximately 5 to 6 h. Magnesium oxide is typically used as the magnesium source. Struvite is harvested from the bottom of the reactor by pumping struvite-rich mixed liquor through a hydrocyclone. The recovered product is dewatered in a screw press and transferred to a container as a 70 percent dry material. The separation device above the reaction zone allows smaller struvite particles and biomass to settle and return to the reaction zone. An odor control system may be required for the exhaust air.

aggregate formation and dissolution until an aggregated cluster is of sufficient size to remain stable and provide a surface for crystal growth. Nucleation is subcategorized into primary and secondary processes. Primary homogeneous nucleation is a spontaneous formation of nuclei from supersaturated solution, while primary heterogeneous nucleation occurs on foreign solid surfaces (interior reactor surfaces, crystals, sand, colloids, dust). Of the two forms of primary nucleation, the latter is dominant in real applications.

Secondary nucleation also occurs in two fundamental forms: “fluid shear” nucleation and “contact” nucleation. In the fluid shear process, hydrodynamic forces sweep small nuclei from the crystal surface or cause breakage of branched protrusions from the crystal, resulting in the generation of a new “seed” surface for nucleation and growth of new crystals. Contact nucleation is a result of crystal attrition where physical forces fracture crystals, increasing the number of crystals and surface area for growth.

Crystal Growth. The growth of crystals comprises the third primary stage of the crystallization process. Under supersaturated conditions, ions diffuse through the boundary layer near the surface of each crystal and then integrate onto the crystal surface through a complex mechanism. As the dimensions of the crystal increase, it approaches a terminal size dictated by the hydrodynamic conditions in the reactor that cause fluid shearing and crystal attrition. Settling velocity increases with crystal size, which is advantageous as it allows the product to be separated more easily from the liquid and other solids within the reactor, a feature common to all of the processes shown in Table 15–3.

Recovery of Phosphorus as Magnesium Ammonium Phosphate (Struvite)

Magnesium ammonium phosphate, commonly known as struvite, has limited water solubility and forms encrustations in anaerobic digester outlet structures and downstream processes (dewatering equipment, pipes conveying sidestream) causing significant operational and maintenance problems. The objectives of struvite phosphorus recovery processes are to form struvite and produce a crystallized product with sufficient purity and physical characteristics that it qualifies for reuse as a fertilizer. The value of struvite in the fertilizer market is discussed in Sec. 15–6.

Reaction Stoichiometry. The chemistry of struvite formation is presented in detail in Sec. 6–5 in Chap. 6. The stoichiometry of the struvite precipitation reaction is shown in Eq. (6–25), repeated here for convenience.

$$Mg^{2+} + NH_4^+ + PO_4^{3-} + 6H_2O \rightarrow MgNH_4PO_4{\cdot}6H_2O \qquad (6\text{–}25)$$

Typically, the product of the ion molar concentrations of the struvite constituents in the anaerobic digester bulk liquid is not high enough to induce a substantial level of struvite formation, thus limiting the phosphate recovery efficiency. To overcome this limitation in the processes described in Table 15–3, a magnesium salt is added to the crystallizer. As discussed below, the addition of magnesium is not the only requirement for successful production of struvite. The pH and hydrodynamic conditions within the crystallizer must be controlled to optimize phosphate removal and generate a product of sufficient size that can be separated easily from the liquid phase and other suspended solids.

Calcium Inhibition. Calcium competes with magnesium for phosphate under conditions conducive to precipitation of calcium phosphates and magnesium ammonium phosphate. A Mg/Ca molar ratio of less than 2/1 results in a longer induction time and a lower struvite crystal growth rate. As the ratio decreases below 1/1, amorphous calcium phosphate formation is dominant (Le Corre et al., 2005).

Operational Considerations. The principal operational requirements that must be considered in the application of phosphorus recovery as struvite include (1) pretreatment requirements, (2) pH and temperature control, (3) chemical requirements, (4) seed requirements, and (5) mixing and hydraulics. Each of these factors is considered in the following discussion.

Pretreatment Requirements. Sidestream pretreatment to reduce TSS and colloidal material has not been standard practice. Upflow fluidized bed crystallizers can tolerate sidestream TSS concentrations ranging from 1500 to 5000 mg/L, depending on the technology. The upflow velocities are high enough to prevent digested biological solids from settling. Based on operating experience with the AirPrex® process, struvite crystals can be produced and separated from anaerobic digester effluent (biosolids), albeit with a larger reactor.

pH and Temperature Control. Struvite solubility decreases with increasing pH, reaching a minimum solubility near pH 10.3 (see Sec. 6–5 in Chap. 6). However, in practice, struvite crystallizers do not operate at pH greater than 9.0. Typically, pH is controlled in the range of 8.0 to 8.8 to minimize the addition of base chemicals, limit the degree of supersaturation, and limit the potential formation of other solids such as calcium carbonate and calcium phosphate (hydroxyapatite). These solids would lead to greater impurity of the final crystalline product. A reduction in the phosphorus recovery efficiency may also occur due to the formation of fine amorphous calcium phosphate precipitate that will exit the crystallizer with the treated effluent. In the pH range of 8.0 to 8.8, phosphorus recovery efficiencies greater than 80 percent and the production of a highly pure struvite product have been demonstrated.

The formation of struvite at a pH less than 8.0 has also been demonstrated. In the AirPrex® process, where struvite is formed directly from anaerobic digester effluent (sludge), operating in a pH range of 7.2 to 7.4 results in a high phosphorus recovery efficiency and generation of struvite crystals of sufficient size that allows separation from the sludge in the conical section of the reactor (Nieminen, 2010). The crystal growth rate is reduced as the operating pH decreases, which results in a longer residence time in the crystallizer to achieve the same level of phosphorus recovery and crystal sizes. In sidestreams derived from the digestion of WAS from biological phosphorus removal processes, the orthophosphate concentration and the resulting level of supersaturation are sufficiently high that a pH greater than 8.0 may not be required to achieve the desired level of phosphorus recovery.

The strategies used in attaining the desired operating pH range varies by process as summarized in Table 15–3 and the sidestream characteristics. Aeration of the crystallizer has been shown to be an effective method for increasing pH through stripping of CO_2. Anaerobic digester effluent and sidestream are supersaturated with CO_2 due to the high CO_2 content of the digester gas. Once exposed to air under atmospheric conditions, CO_2 will diffuse from the liquid and pH will increase above 8.0. In the AirPrex®, PHOSPAQ™, and Phosnix® technologies described in Table 15–3, aeration is applied directly to the crystallizer to strip CO_2 from the liquid. Aeration also provides mixing and induces hydrodynamic conditions conducive to developing crystals over a range of sizes that allows separation and processing. In the NuReSys® process, CO_2 is stripped from the sidestream through aeration and mechanical agitation in a vessel preceding the crystallizer. The application of high speed mechanical agitation and aeration reduces energy consumption and limits the amount of air that may require treatment in an odor control process. Mixer speed and air flow are adjusted to limit the formation of fine struvite crystals before the sidestream enters the crystallizer.

The dominant forms of orthophosphate in an anaerobic digester and sidestream are HPO_4^{2-} and $H_2PO_4^-$, with PO_4^{3-}, the form required for struvite formation, existing at a low concentration. As shown in Eq. (15–2), as struvite forms, HPO_4^{2-} and $H_2PO_4^-$ shift towards PO_4^{3-}, resulting in proton release or an increase in acidity.

$$H_2PO_4^- \rightleftarrows HPO_4^{2-} + H^+ \rightleftarrows PO_4^{3-} + 2H^+ \tag{15–2}$$

If magnesium chloride is used as the source of magnesium, additional acidity is generated through the chloride ions remaining in solution. The acidity generated by these chemical reactions will be buffered by neutralization with bicarbonate, but if sufficient acidity is generated, pH will decrease and a target pH above 8.0 may not be achieved by aeration alone. Magnesium oxide or hydroxide may be selected as the magnesium source as an alternative to magnesium chloride to provide alkalinity or sodium hydroxide can be added for pH control. Depending on the amount of acidity created as a result of struvite formation, magnesium oxide (or hydroxide) and sodium hydroxide may be required to control the process.

Struvite solubility is a function of temperature, but temperature control is not practiced in the processes presented in Table 15–3. Cooling or heating the reactor to operate at an ideal temperature to maximize the phosphate removal efficiency is not justified economically.

Chemical Requirements. The source of magnesium is typically magnesium chloride, magnesium hydroxide, or magnesium oxide, which forms magnesium hydroxide upon contact with water. The choice of chemical for each process varies and is based on vendor or end user preference and chemical cost.

Magnesium chloride has the advantage of disassociating faster than magnesium hydroxide, leading to higher reaction rates. Consequently, an optimized chemical feed dispersion system is required for the reactor to prevent localized excessively high supersaturated conditions near the chemical addition point.

Magnesium oxide and hydroxide provide both magnesium and alkalinity to the crystallizer. The primary role of both compounds is to provide magnesium. The alkalinity provided by the chemical is advantageous, but may not increase the pH and stabilize it within the desired operating range. In this case, sodium hydroxide addition will be required for pH control. Magnesium oxide and hydroxide have limited water solubility and are fed to the crystallizer as suspensions in water. Consequently, the solubilization rate of the compounds may control the level of supersaturation and the crystal growth rate. Nucleation may also occur on the surface of undissolved reagent leading to reduced purity of the harvested product.

Magnesium is added to the process in molar excess to maintain a supersaturated condition for crystal growth. A molar ratio of Mg^{2+} to PO_4^{3-} in range of 1.1 to 1.6 has been used in practice for municipal sidestreams, with a value of 1.3 being typical. If excess magnesium is added, resulting in a higher level of supersaturation, excessive primary nucleation will occur, leading to the formation of small crystals that may not be retained in the crystallizer, depending on its hydraulic design. At the Mg^{2+}/PO_4^{3-} molar ratio and operating pH range used in crystallizing struvite from municipal sidestreams, inhibition by calcium and the formation of calcium phosphate is minimal, leading to a high recovery efficiency and high purity of the harvested product.

Sodium hydroxide is used typically to adjust and control pH, depending on the process technology and desired operating pH. Sodium hydroxide is preferred due to ease of handling, and it can be stored at concentrations as high as 50 percent by weight.

Chemical requirements are specific to the sidestream as operating conditions in the mainstream process and solids processing facility dictate the phosphate concentration in the digester and its variability. Pilot or demonstration-scale testing of the selected crystallization technology is also commonly performed to assess the chemical requirements and other operating conditions for design of the full-scale process.

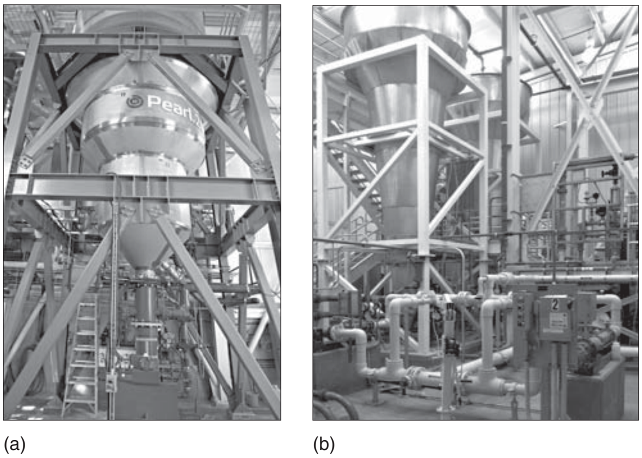
Seed Requirements. A seed material such as sand or struvite crystals is often added to a crystallizer to rapidly start the process. After a certain level of crystal inventory is achieved in the reactor, the process is self-sustaining at the target operating conditions (e.g., level of supersaturation, pH) and further seed addition is not required.

Mixing and Hydraulic Requirements. The mixing and hydraulic conditions within the reactor have an impact on the size of the crystals harvested from the process. In the AirPrex®, PHOSPAQ™ and Phosnix® processes, an air-lift aeration design is used to strip CO_2 and induce a mixing pattern within the reactor, resulting in the development of crystal sizes sufficient for separation and processing. In the AirPrex® and Phosnix® reactors, a conical bottom provides an environment where the larger struvite crystals can separate and thicken prior to their removal. Alternatively, solids from the bottom of the reactor can be intermittently pumped through a hydrocyclone to recover the product for further processing, as done in the PHOSPAQ™ process.

In the Pearl® and Crystalactor® processes, effluent from the crystallizer is recycled to maintain the upflow liquid velocity within the desired range to develop crystals and a pelletized product with a specific range of sizes. If the size of the crystals or pellets harvested from the reactor is of less importance, effluent recirculation may not be required. In the cone-shaped fluidized bed crystallizer (Table 15–3), where no internal recirculation is applied, crystals develop of sufficient size that allows separation from the liquid. The

Figure 15–1

Examples of full scale struvite crystallizers: (a) Ostara Pearl® reactor, Tigard, OR and (b) Multiform Harvest cone-shaped reactor, Yakima, WA (courtesy of Multiform Harvest Inc.).



(a) (b)

struvite is removed intermittently and processed offsite to generate product characteristics specific to a particular end use.

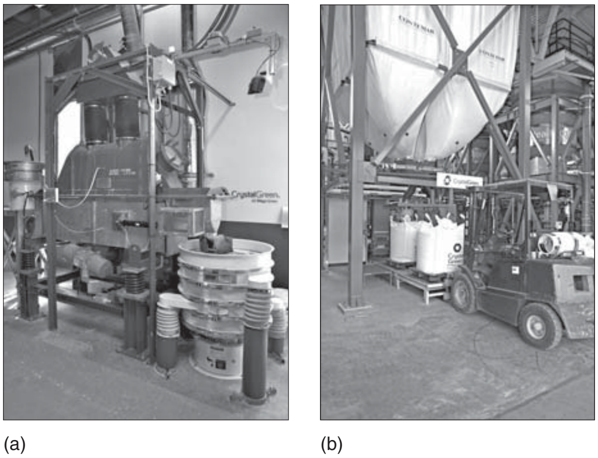
The specific geometry of the crystallizer may also be designed to create a range of upflow velocities that impact the characteristics of the harvested product and allow retention of smaller crystals, which continue to grow and sink into the lower sections of the crystallizer. The Pearl and cone-shaped crystallizers shown on Figs. 15–1(a) and (b) are examples of processes that create variable upflow velocities through an increasing cross-sectional diameter. In the Phosnix®, Crystalactor® and PHOSPAQ™ processes, the smaller crystals are retained in low upflow velocity zones or sedimentation zones in the upper section of the reactors and gradually return to the main reaction zone.

The hydrodynamic conditions required for crystallization and pellet formation can also be achieved through mechanical mixing. In the NuReSys® process, a mechanical mixer with a three-blade impeller has been used successfully to provide mixing and generate a pelletized final product.

Product Separation and Purification. Crystals are allowed to grow to sizes that allow separation from the liquid and other suspended solids and are easy to process after harvesting (e.g., screening, washing). Separation and recovery of product with a mean crystal size of 0.2 mm or greater from the liquid has been demonstrated. Depending on the crystallizer design, the hydrodynamic conditions will enhance crystal agglomeration and form spherical pellets with a mean diameter up to 2–4 mm. The mean diameter of the product is controlled by adjusting the product harvesting rate to increase or decrease the product residence time in the crystallizer.

Processing requirements for the struvite product vary. The product may be concentrated by screening, disinfected with chlorinated water or heat, rinsed, dewatered, and dried. Product purity typically exceeds regulatory requirements and no further purification steps are required. The degree to which the final product is processed is dependent on the end user requirements. Examples of processing equipment for the pelletized product harvested from a Pearl crystallizer are shown on Fig. 15–2.

Struvite Phosphorus Recovery Limitations. In practice, the orthophosphate is not recovered completely and a crystallizer effluent concentration below 5 mg P/L is not typical. For fluidized bed reactors with a relatively low hydraulic retention time (less than 1 hour), consistently achieving an effluent concentration below 10 mg P/L in these systems



(a) (b)

Figure 15–2

Processing of pelletized struvite from a Pearl crystallizer: (a) drying; (b) product bagging.

requires greater chemical addition to maintain sufficient supersaturated conditions throughout the crystallizer as orthophosphate decreases. Based on economic considerations, i.e., chemical cost versus higher recovery efficiency, an effluent orthophosphate concentration in the range of 10 to 25 mg P/L is typical. In processes such as AirPrex® where the hydraulic retention time is much higher (e.g., 8 h), effluent concentrations below 10 mg P/L have been demonstrated, but at the expense of requiring a larger reactor.

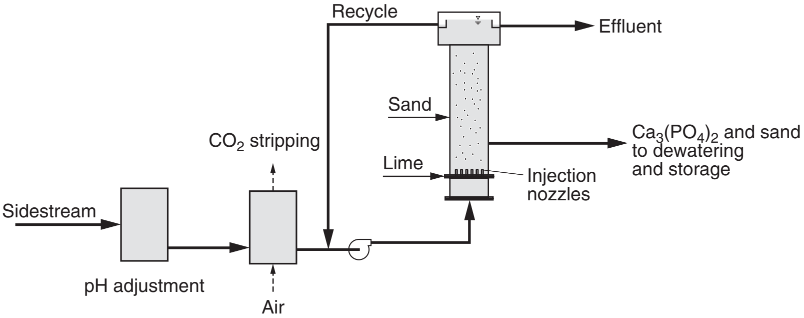
Recovery of Phosphorus as Calcium Phosphate

Phosphorus can be recovered from sidestream flows through precipitation as calcium phosphate. A typical process flow diagram for the recovery of phosphorus as calcium phosphate is presented on Fig. 15–3. The process was developed initially and demonstrated successfully in The Netherlands in the 1980s (Piekema and Giesen, 2001). However, the rise in chemical costs has made this process generally uneconomical, especially as compared to the recovery of phosphorus as struvite. Although the recovery of phosphorus as calcium phosphate is now largely limited to industrial, food, and dairy applications, there are still wastewater applications. Phosphate recovery from mainstream processes with lime precipitation continues to be used in several facilities and is discussed following the discussion of the recovery of calcium phosphate.

Reaction Stoichiometry. Calcium phosphate can exist in several forms depending on pH and the ionic composition of the sidestream. The basic chemistry of phosphate precipitation with lime is presented in Sec. 6–5. The primary product generated during

Figure 15–3

Process flow diagram for the production of calcium phosphate from nutrient-rich sidestream.



crystallization is hydroxyapatite [$Ca_5(PO_4)_3OH$], the most thermodynamically stable form of calcium phosphate.

Operational Considerations. The principal operational requirements that must be considered in the application of phosphorus recovery as calcium phosphate include (1) pretreatment requirements, (2) pH and temperature control, (3) chemical requirements, and (4) seed requirements. Each of these factors is considered in the following discussion.

Pretreatment Requirements. Most high-strength sidestreams contain a high bicarbonate concentration that will cause significant formation of calcium carbonate precipitate in the crystallizer. To limit the formation of calcium carbonate, the sidestream is pretreated through acidification to a pH less than 5 with a strong inorganic acid, and the acidified stream is subjected to air stripping to remove CO_2. The pretreated stream is then treated with calcium hydroxide slurry to precipitate phosphate.

pH and Temperature Requirements. Calcium phosphate crystallization is performed over a pH range of 8.0 to 9.0. The optimum pH for a given application is developed through pilot-scale tests. In practice, the crystallizer temperature is not controlled, due to economic considerations.

Chemical Requirements. An inorganic acid is required for sidestream pretreatment. The amount of acid can be estimated preliminarily by assuming complete conversion of bicarbonate to CO_2. Quick lime (CaO) is used typically as the calcium source for the crystallizer and fed as slurry (forming calcium hydroxide upon addition to water). Lime is added to increase the pretreated sidestream pH from 5.0 or less to the crystallizer pH setpoint and provide the desired level of supersaturation in the crystallizer. A lime overdose in the range of 0.5 to 5.0 mM has been used in practice (Piekema and Giesen, 2001). The inorganic acid and lime requirements are determined through pilot-scale tests.

Seed requirements. Calcium phosphate crystallization through primary nucleation creates a fine microcrystalline product that is difficult to separate from water. However, in the presence of seed material such as sand and under well-controlled supersaturated conditions, nucleation will occur on the surface of the sand particles and crystal growth on the newly formed pellet is sustained. By controlling the hydrodynamic conditions within the fluidized-bed crystallizer, a pelletized product with a mean diameter of approximately 1-mm is harvested from the bottom of the crystallizer. As pelletized product is removed intermittently, virgin seed material is added. The superficial upflow velocity through the crystallizer is in the range of 40 to 75 m/h (130 to 250 ft/h).

To eliminate the need for inorganic carbon removal via acidification and air stripping, alternative seed materials have been proposed. Calcite and calcium silica hydrates have been shown to be effective in the recovery of phosphorus by means of hydroxyapatite crystallization (Berg et al., 2006; Donnert and Salecker, 1999). The intermittent addition of seed material is a requirement, as it is with sand, as pelletized product is removed from the crystallizer. To date, the advantages of this approach, if any, for phosphorus recovery as compared to struvite crystallization have yet to be demonstrated at full scale.

Phosphorus Recovery from Mainstream Processes

Phosphate removal from the mainstream wastewater through chemical precipitation and adsorption with ferric and alum salts has been practiced widely. The chemical sludge produced by this reaction is amorphous and is formed in primary sedimentation tanks or in the activated sludge process where it is intimately blended with primary sludge or activated sludge. The form of the chemical sludge and its intimate mixing with non-chemical sludges makes phosphate recovery more challenging. Technologies for recovering phosphate from sludges and incinerator ash have been developed, but are not discussed in this chapter.

Phostrip Process. One of the first processes used for the recovery of phosphate from the mainstream process is the Phostrip process, developed specifically for enhanced biological phosphorus removal (EBPR). A description of the Phostrip process is presented in Table 8–27 in Sec. 8–8. In the Phostrip process, a portion of the phosphorus-rich return activated sludge (20 to 40 percent) from the EBPR process is subjected to anaerobic conditions at a sludge retention time in the range of 12 to 20 h. Under these conditions, endogenous production of readily biodegradable COD (rbCOD) causes release or *stripping* of orthophosphate from the sludge to the bulk water. The phosphate *stripper* tank typically consists of a gravity thickener with thickened sludge recirculation to elutriate the released phosphorus from the sludge to the thickener overflow. For nitrifying mainstream processes, a prestripper tank is provided prior to phosphate stripping to denitrify the RAS flow and optimize phosphate release. Thickened RAS is returned to the mainstream process or a portion is sent to the solids processing facility as waste activated sludge (WAS).

Traditionally, stripper overflow has been subjected to chemical precipitation with lime at a pH of 9.0–9.5 to remove phosphate. Due to the presence of bicarbonate in the stripper overflow, calcium carbonate formation will also occur, resulting in a mixed solids composition. Typically, the chemical solids are removed separately or settled in the primary sedimentation tanks. Alternatively, the overflow from the stripper tank can be blended with sidestream from post-digestion dewatering and fed to a crystallization process to produce magnesium ammonium phosphate.

Release of Phosphate from Waste Activated Sludge. The Phostrip concept can be adapted for waste activated sludge derived from an EBPR process where WAS is subjected to anaerobic conditions to allow solids hydrolysis and fermentation, which results in the release of phosphate. Releasing phosphate from WAS prior to anaerobic digestion significantly reduces struvite formation in the digester and digester overflow. The WAS fermenter or stripper may be configured as a WAS thickener with internal thickened sludge recycle, similar to the Phostrip process. The thickener overflow is blended with post-digestion sidestream for struvite recovery. Magnesium is also released from the WAS at a mass ratio of approximately 0.25 g Mg/g PO_4^{3-}-P released, reducing the magnesium chloride or magnesium oxide/hydroxide requirement in the struvite crystallizer.

Enhanced Release of Phosphate from Waste Activated Sludge. The addition of primary sludge fermentate or acetic acid to the WAS stripper will enhance the phosphate release rate and reduce the sludge residence time in the stripper from 12–20 h (endogenous process) to 2–5 h. A VFA to VSS ratio of 0.02 to 0.04 g/g is required (Schauer et al., 2011; Corrado, 2009). In general, the phosphate release rate is insensitive to the VFA concentration in the WAS stripper. The optimal configuration for the enhanced release WAS stripping process is a complete mixed tank followed by a solids thickening step, as shown in the process flow diagram presented on Fig. 15–4. Depending on the operating conditions, the Phostrip thickener configuration with thickened sludge recycle may also provide enhanced phosphate release.

15–5 PHYSIOCHEMICAL PROCESSES FOR AMMONIA RECOVERY AND DESTRUCTION

Physiochemical processes for sidestream ammonium treatment are alternatives to biological treatment, which is the dominant method for ammonium removal in practice. Recovery of ammonia from wastewaters to produce aqueous ammonia or an ammonium salt (e.g., ammonium sulfate, ammonium nitrate) for use in industrial and agricultural applications has been of interest for decades, and a number of processes have been developed, demonstrated, and practiced at a full scale. Where ammonia reuse is not desired, a thermal catalytic destruction technology has also been developed and practiced at full scale where ammonia stripped from wastewater is catalytically converted to N_2 at high temperature.

Processes that have been demonstrated at a full scale and are currently used in recovering or destroying ammonia from wastewaters derived from industrial processes, municipal sludge digestion, landfill leachate treatment and animal manure digestion are described in this section. Technologies such as ion exchange and adsorption are rarely, if ever, practiced in the treatment of high strength wastewaters and are not considered in this section. Emerging technologies such as ammonia electrolysis to generate hydrogen for energy recovery (Vitse et al., 2005) and alternative ammonia stripping or volatilization technologies such as Vacuum Flash Distillation (Kemp et al., 2007) and Membrane Contactors (Membrana, 2007; du Preez et al., 2005) are also not considered as application at a full scale is limited or in development.

Recovery of Ammonia by Air Stripping and Acid Absorption

The recovery of ammonia from high strength wastewaters by air stripping–acid absorption technology has been used in both industrial and municipal applications. Most notable in the municipal sector is the process at the VEAS facility [3.5 m^3/s (80 Mgal/d)] in Oslo, Norway, where ammonium sulfate was produced from 1996 to 1998, and ammonium nitrate has been produced since 1998 (Sagberg et al., 2006). While this technology has not been applied widely in North America, several processes have been in operation in Europe since the late 1980s for the recovery of ammonia from municipal digester sidestreams, manure digestion sidestreams, landfill leachate, and industrial wastewaters.

Although sulfuric acid is the least expensive and most commonly used, other types of acids can also be used:

- Phosphoric acid—produces mono-ammonium phosphate (MAP) or di-ammonium phosphate (DAP)
- Hydrochloric acid—produces ammonium chloride (NH_4Cl)
- Acetic acid—produces ammonium acetate ($NH_4C_2H_3O_2$)
- Nitric acid—produces ammonium nitrate (NH_4NO_3)

The selection of a specific acid depends on local or regional demand for the resulting product and if revenue could be realized by the sale of the product. However, ammonium sulfate is the dominant product of choice from air stripping–acid absorption processes currently in practice, largely driven by chemical cost and market demand.

Process Description. The basic air stripping/acid absorption process flow diagram and an example of a full-scale process are shown on Fig. 15–5. The process is comprised of pH adjustment, TSS removal, a dual column air stripper–acid absorber system and chemical storage tanks with associated delivery systems and controls. As described in Sec. 11–10 in Chap. 11, stripping ammonia from wastewater with air requires ammonium to be converted to ammonia in the liquid phase through an increase in pH. The effects of temperature and pH on the percentage of ammonium in the form of ammonia for an aqueous ammonia solution are illustrated on Fig. 15–6. At the typical digestion sidestream temperature range of 25 to 35°C, a pH of 11 or higher is required to shift nearly 100 percent of the ammonium to ammonia. The ionic composition of the sidestream affects the chemical equilibrium illustrated on Fig. 15–6 due to non-ideal conditions created by

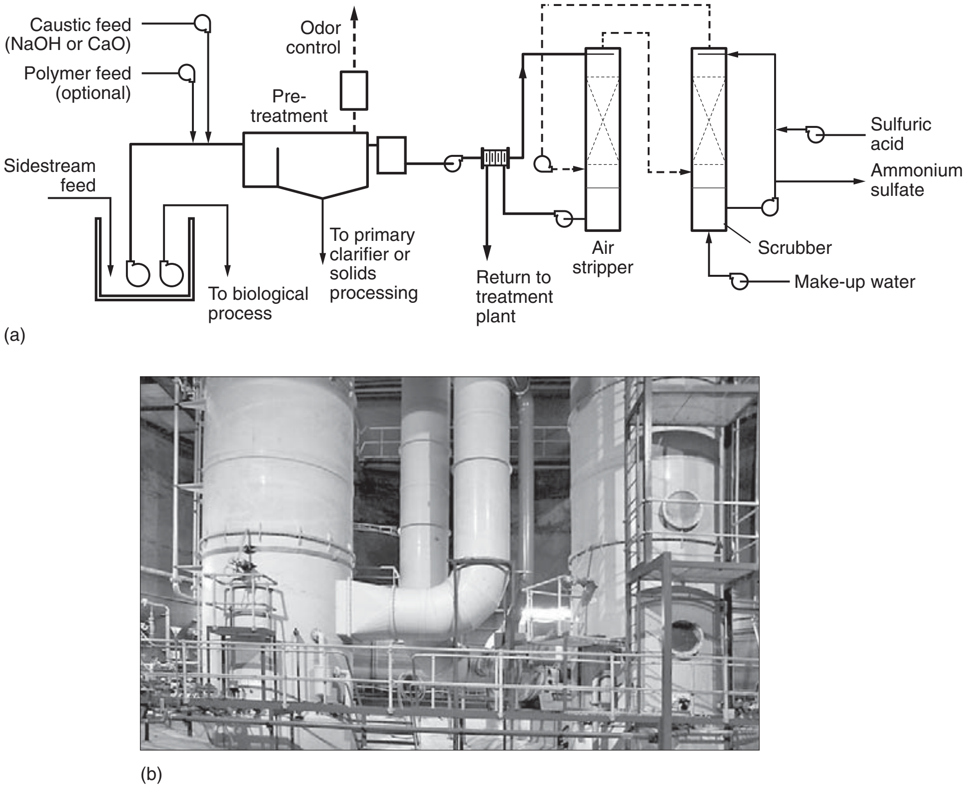

Figure 15–5

Air stripping–acid absorption process for recovery of ammonia and production of concentrated ammonium sulfate solution:

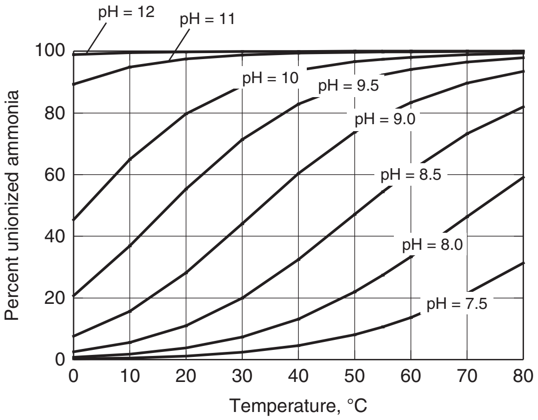
Figure 15–6

Ammonia-ammonium equilibrium as a function of pH and temperature.



ion-ion interactions. The impact of non-ideal conditions on ammonium-ammonia equilibrium is accounted for through the use of monovalent and divalent activity coefficients as multipliers on the ion concentrations. The calculation of activity coefficients is described in detail in Sec. 2–2 in Chap. 2.

Temperature Impacts. From the plots on Fig. 15–6 it would appear that as sidestream temperature increases, the required operating pH would be lower, resulting in a lower alkaline chemical requirement. However, as noted in Sec. 15–1, ammonium exists in digestion sidestream as ammonium bicarbonate in the pH range of 7.0 to 8.0. A shift from ammonium to ammonia due to an increase in temperature would be accompanied by the shift of bicarbonate to $CO_{2,\ aq}$ and subsequent release of CO_2 into the gas phase. Air stripping and acid absorption columns are typically designed as a closed air system, as illustrated on Fig. 15–5, to minimize the release of contaminated air to the atmosphere and eliminate evaporative cooling of the sidestream, which would impact the ammonia stripping efficiency. Because CO_2 would not be removed from the air with the ammonia in the absorption column, the CO_2 concentration in the air loop increases, resulting in the retention of CO_2 in the sidestream and pH suppression. Therefore, for an enclosed system, an elevated operating temperature cannot be used to reduce the operating pH and the alkaline chemical demand is unaffected.

Operationally, higher column temperatures are advantageous, as illustrated on Fig. 11–62 in Chap. 11. Higher temperatures increase the Henry's Law coefficient for ammonia, creating a higher driving force for mass transfer in the air stripping column. In addition, ammonia diffusivities in water and air increase with temperature, further increasing the mass transfer rate, mathematically expressed as the overall mass transfer coefficient, K_L, in the stripping column design calculations shown in Sec. 11–10 in Chap. 11. In total, higher operating temperatures have the net effect of lowering the air flowrate required to achieve the same ammonia removal efficiency (see Fig. 11–63). A reduction in the air requirement has the further effect of reducing the diameters of the stripping and absorption columns.

Alkaline Chemical Demand. Caustic soda (sodium hydroxide) and lime have been used in practice for adjusting the pH of digestion sidestream. The two primary reactions that govern the caustic soda requirement are

$$NH_4HCO_3 + NaOH \rightarrow NH_3 + H_2O + NaHCO_3 \qquad (15\text{–}3)$$

$$NaHCO_3 + NaOH \rightarrow Na_2CO_3 + H_2O \qquad (15\text{–}4)$$

Due to the solubility of sodium carbonate, the pH-adjusted sidestream contains a significant buffering capacity, allowing the air stripping column to operate at the desired pH throughout the column depth. For wastewater treatment facilities that require alkalinity addition to sustain nitrification, the sidestream processed by air stripping–acid absorption where caustic soda is used for pH adjustment can provide a portion or all of the alkalinity requirement for the secondary treatment system. Because the cost of caustic soda is a significant portion of the operating cost for an air stripping–acid absorption process, assuming partial or total credit for the alkalinity provided to the secondary treatment system is an important economic consideration.

Alternatively, lime (CaO) can be used for pH adjustment. The primary benefit of lime is the significantly lower cost compared to caustic soda. However, as described in Sec. 6–3 in Chap. 6, lime removes carbonate alkalinity through the precipitation of calcium carbonate. If a beneficial use of the calcium carbonate cannot be found (e.g., beneficially land applied as *Farmer's Lime*), disposal of the solids may result in an additional operating cost, offsetting the cost advantage lime has over caustic soda. The substantial loss in buffering capacity results in a decreasing pH gradient through the depth of the air stripping column as ammonia is stripped from the sidestream, reducing the effectiveness of the lower section of the column. The use of lime has the added disadvantage of increasing the air stripping column fouling rate, thereby increasing the frequency at which the air stripping column is removed from service for cleaning. Lime is also more difficult to handle in comparison to caustic soda.

Solids Removal for Enhanced Air Stripping. Digestion sidestreams contain TSS (see Table 15–1), which can cause significant fouling in the air stripping column. In addition, during pH adjustment, inorganic precipitates will form such as calcium carbonate, although the solids mass generated by pH adjustment with caustic soda will be far less than the amount of chemical sludge generated by lime. To reduce the negative impact of the TSS on the air stripping column, a solids removal step is recommended such as an inclined plate settler or a high rate clarification technology (see Sec. 5–7 in Chap. 5 for process descriptions). If lime is used for pH adjustment, the solids removal process is essentially conventional cold lime softening, which is commonly practiced in water treatment.

Air Stripping and Acid Absorption Column Operations. The basic design approach for determining the dimensions and packing depth of the air stripping column were introduced in Sec. 11–10 in Chap. 11. The design of the acid absorption column is more complicated because, in addition to mass transfer, a chemical reaction is occurring in the acidic ammonium salt solution recirculated through the column and heat is being generated, which affects the liquid and air temperatures in the column. An advanced chemical process model such as ASPEN+ or a similar modeling software package are typically employed to calculate the scrubbing efficiency, packing depth, column diameter, and temperature of the air returned to the air stripping column. Alternatively, an equipment provider may have a proprietary design method based on their experience that is specific to the type of mass transfer media being used in the column.

As illustrated on Fig. 15–5, the two columns contain randomly placed plastic medium and a closed air system where air blown through the stripper column, countercurrent to the sidestream flow, is sent to the absorber and air from the top of the absorber flows to the inlet of the fan. Sizing of the two columns, the fan and product recirculation pump is dependent on the sidestream flow and ammonia concentration, the desired sidestream ammonia removal efficiency and the operating conditions in the two columns (pH, temperature). Typically, the diameters of the stripper and absorption columns are equivalent, but the height of the absorption column and its associated packing depth is roughly 80 percent of stripping column. As the operating temperature increases beyond 40°C, the absorption column height and packing depth will increase and approach those of the stripping column. The air stripping–acid absorption process is typically controlled by pH (pretreated sidestream and recirculated product solution in absorption column) and the density of the recirculated product solution.

In the absorption column, acid is dosed into the product solution recirculation loop to maintain an acidic pH, which provides sufficient driving force for absorption. Real time measurement of the recirculated product solution density is used to fine tune pH control. The product solution is removed continuously from the bottom of the column. For the production of ammonium sulfate, the water content of the 93 percent sulfuric acid (by weight) typically used in larger applications is insufficient to meet the water requirement of a 40 percent (by weight) ammonium sulfate solution. Therefore, water is added continuously to the absorption column, primarily controlled by the density of the recirculated solution. The addition of concentrated sulfuric acid and the subsequent formation of ammonium sulfate results in significant chemical heat generation. A portion of this heat can be used to elevate the temperature of both columns by allowing the temperature of the absorption column to increase, which transfers heat to the air being recirculated back to the stripper column. Less chemical heat is generated with the use of concentrated nitric acid to produce ammonium nitrate.

The direct addition of low pressure waste steam to the stripper column can also be done as higher operating temperatures reduce the fan capacity and the column diameters up to a temperature limit of approximately 70°C. Beyond this temperature, the ammonia removal efficiency in the absorption column will begin to deteriorate and this is the temperature limit for the fiberglass reinforced plastic used for column construction.

Economic Considerations. As discussed in the overview of the air stripping–acid absorption process, concentrated inorganic acid is used in the absorption column and caustic soda or lime is used for pH adjustment of the digestion sidestream. Because these chemicals represent a major operating cost, the future pricing trends of these chemicals are critically important information to obtain to assess the economic viability of this process, in comparison to biological treatment. To offset the costs of the caustic soda or lime and the acid, selling the product to generate revenue will improve the economics of ammonia recovery. The use of ammonium sulfate or ammonium nitrate as a fertilizer is discussed further in Sec. 15–6.

Recovery of Ammonia by Steam Stripping

The use of steam to volatilize ammonia from water is practiced at several industrial installations, however, the implementation of steam stripping for municipal sidestreams has been limited. The only performance data reported are from pilot or demonstration-scale studies (Teichgräber and Stein, 1994; Gopalakrishnan et al., 2000). An ammonia concentration of 100 mg N/L in the steam-stripped sidestream is the practical limit for the process with energy consumption and associated operating cost being the limiting condition.

Process Description. As shown on Fig. 15–7, the steam stripping process consists of contacting sidestream with low pressure steam in a packed column with random-dumped media. At an operating temperature in the range of 95 to 100°C, ammonium bicarbonate is decomposed thermally into ammonia and carbon dioxide in the column and the dissolved gasses are subsequently stripped from the sidestream into the vapor phase.

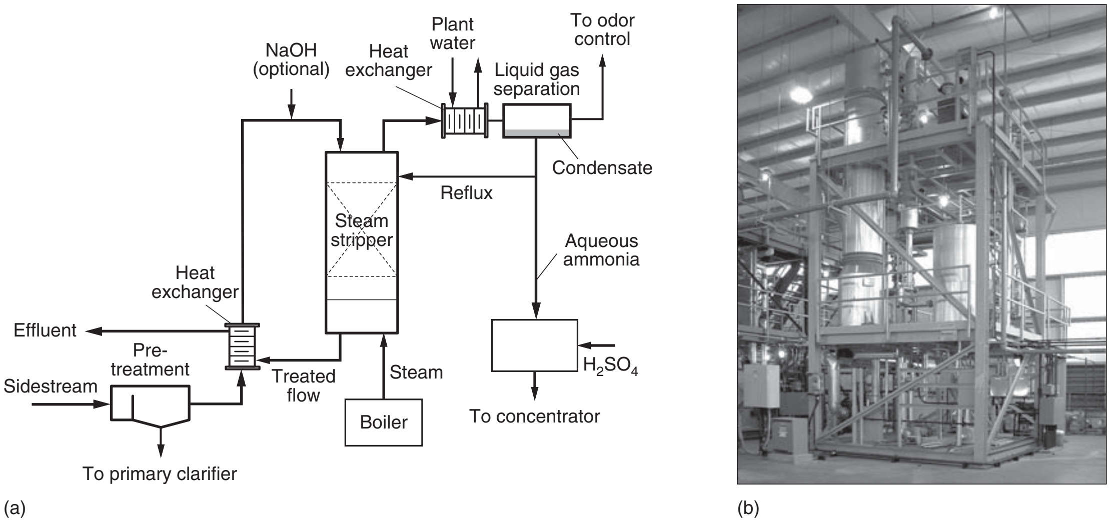


Figure 15–7

Steam stripping process for recovery of ammonia from sidestream for production of aqueous ammonia or ammonium sulfate: (a) process flow diagram and (b) view of pilot-plant facility (courtesy of The New York City Department of Environmental Protection).

The stripped sidestream is used to preheat the sidestream influent to reduce energy consumed by the process.

The vapor phase from the column is cooled in a condenser to a two-phase mixture using plant effluent as single-pass cooling water. The liquid and gas phases are separated and a portion of the liquid is returned to the stream stripping column ("reflux"). The remainder of the ammonia-rich liquid is processed further to produce concentrated aqueous ammonia or the liquid is neutralized with sulfuric acid to produce an ammonium sulfate or ammonium nitrate solution, which is further processed to generate a concentrated solution for reuse as a fertilizer. Due to the high volatility of carbon dioxide at the condenser temperature, the majority of the carbon dioxide remains in the gas phase, limiting the reformation of ammonium bicarbonate in the liquid. The gas is highly odorous and requires treatment.

Volatilizing CO_2 from the preheated sidestream in a "decarbonization" packed column prior to the steam stripping column may be beneficial. By removing the majority of the CO_2 before the stripping column, a pH of 9.5 to 9.9 can be sustained throughout the full packing depth resulting in a higher mass transfer rate and lower steam demand (Teichgräber and Stein, 1994). Steam is added to the decarbonization column to increase the sidestream temperature and enhance CO_2 volatilization, but the steam volume requirement does not induce significant ammonia stripping.

Energy Requirements. Approximately 0.15 to 0.18 kg of low pressure steam is required per kg of sidestream to achieve a stripped sidestream ammonia concentration of approximately 100 mg N/L, if energy is recovered from the stripped sidestream to preheat the sidestream influent. The steam demand will be lower if CO_2 is removed from the preheated sidestream in a decarbonization step. Additional energy is consumed to process the low strength aqueous ammonia to a higher concentration or to produce higher strength ammonium sulfate solution for reuse.

Chemical Requirements. Because ammonium bicarbonate is thermally decomposed into ammonia and carbon dioxide, sodium hydroxide is not a strict requirement in the process. However, addition of sodium hydroxide will increase pH throughout the packed column, which will increase the mass transfer rate and lower steam demand. In the process configuration where CO_2 is volatilized in a decarbonization column, sodium hydroxide addition to the steam stripping column may also lower steam demand.

Pretreatment Requirements. Reduction of suspended solids and colloidal material in the sidestream to less than 100 mg/L is advantageous to reduce fouling of the column media.

Off-gas Treatment. The CO_2-rich gas from the condenser (or decarbonization column) contains highly odorous reduced sulfur compounds and requires treatment. Volatile organic compounds will also be present in the off-gas, which also may require treatment, depending on the air quality regulations applicable to the facility.

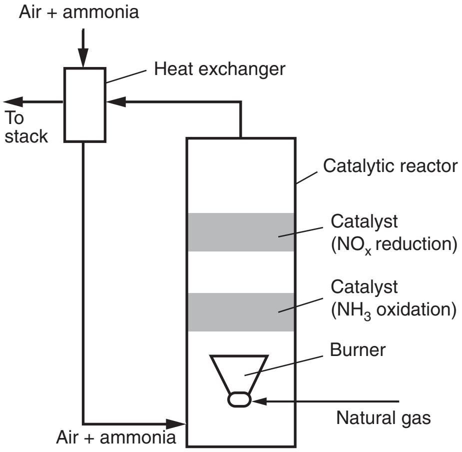
Operating Problems. Operating problems that have been encountered with steam stripping include: (1) extensive fouling (iron deposits, for example) within the heat exchanger and in the stripper due to the presence of waste constituents at elevated temperatures, (2) maintaining the required pH for effective stripping, (3) controlling the steam flow, and (4) maintaining the stripping tower temperature. Because of the importance of temperature, steam stripping should be carried out in enclosed facilities. Spiral wound heat exchangers have proven to be effective. In Europe, an acid wash is used to clean the piping, the heat exchanger, and the stripping column.

Air Stripping with Thermocatalytic Destruction of Ammonia

As an alternative to capturing the stripped ammonia to produce a fertilizer, the ammonia-laden air from the stripping column can, as shown on Fig. 15–8, be subjected to thermocatalytic oxidation (TCO). In TCO up to 98 percent of the ammonia is oxidized selectively to N_2 (~95 percent selectivity) with the balance of the oxidation products primarily being N_2O or NO, depending on the catalyst temperature. This process has not been applied to municipal sidestreams, but has been used for landfill leachate treatment applications where waste heat is available from the combustion of landfill gas to meet the thermal demand of the stripping column (Organics Limited, 2009).

Figure 15–8

Schematic of catalytic reactor used for the thermocatalytic destruction of ammonia in air.



The air stripping column is operated similarly to the column in the air stripping–acid absorption process, only the air is single-pass ambient air that must be heated via steam injection to compensate for evaporative cooling of the column to maintain the desired temperature. In full-scale applications on landfill leachate, sufficient waste heat is available to increase the stripping column temperature high enough to induce thermal decomposition of ammonium bicarbonate, similar to the steam stripping process (Organics Limited, 2009). Consequently, the caustic soda requirement is greatly reduced or eliminated and the air requirement for stripping is reduced.

The ammonia-laden air is then subjected to oxidation at temperatures in the range of 288 to 316°C (550 to 600°F) with a catalyst typically composed of mixtures of transition metals or transition metal oxides on silica or alumina supports and doped with a noble metal such as platinum. The reaction is exothermic (generates heat), reducing or eliminating the natural gas input to the oxidizer required to sustain the target temperature, depending on the ammonia concentration in the air. The primary reactions of interest in this process are:

$$NH_3 + 0.75\ O_2 \rightarrow 0.5\ N_2 + 1.5\ H_2O \tag{15–5}$$

$$NH_3 + O_2 \rightarrow 0.5\ N_2O + 1.5\ H_2O \tag{15–6}$$

$$NH_3 + 1.25\ O_2 \rightarrow NO + 1.5\ H_2O \tag{15–7}$$

Temperatures above 350°C (660°F) are avoided to limit the formation of NO_2. Even when operating within the desired temperature range, a certain portion of the ammonia will convert to NO, which must be reduced by selective catalytic reduction (SCR). Unoxidized ammonia will react with NO in the downstream SCR, but there is likely a need for supplemental addition of urea or anhydrous ammonia to maximize NO removal. Exhaust from the TCO/SCR process is used to preheat the ammonia-laden air to the TCO.

The application of air stripping/TCO is limited to cases where waste heat is available from gas engine exhaust or can be generated from otherwise unused digester gas. For leachate treatment applications, the energy demand has been estimated at 450 MJ per m^3 of leachate (Organics Limited, 2009). Depending on the ammonia concentration in the inlet to the TCO, the injection of natural gas to the TCO may also be required to maintain the temperature within the required range. An energy balance across the stripping/TCO system and a life cycle cost analysis is required to assess the economic viability of the process.

15–6 BENEFICIAL USE OF RECOVERED PHOSPHATE AND AMMONIUM PRODUCTS

Phosphate and ammonia recovered from sidestream can be reused as fertilizers or for other industrial applications. The principal products recovered from sidestreams include:

1. Magnesium ammonium phosphate hexahydrate (struvite)
2. Calcium phosphate (hydroxyapatite)
3. Ammonium sulfate
4. Ammonium nitrate

The beneficial use of these products is considered in this section.

Magnesium Ammonium Phosphate Hexahydrate (Struvite)

Struvite has been recognized as a fertilizer for over 150 years and is considered a slow-release fertilizer due to its low water solubility. The low dissolution rate into the soil limits high soluble nutrient concentrations around the root structure and the occurrence of "fertilizer burn," and minimizes the loss of nutrients due to surface runoff and groundwater percolation.

Struvite is only a minor contributor to the overall slow-release fertilizer market, dominated by slowly soluble urea-aldehyde reaction products and polymer and sulfur-coated controlled-release fertilizers. Due to high manufacturing costs, slow-release fertilizers have been predominately used in high valued-added applications in non-agricultural markets such as nurseries, greenhouses and golf courses. Struvite is currently available in a blend with potassium magnesium phosphate under the tradename of MagAmp or MagAmp®-K, typically defined as a 7 percent N, 40 percent P_2O_5, 6 percent K_2O fertilizer with 12 percent Mg.

Demand for slow-release fertilizers has been increasing world-wide to improve fertilizer utilization efficiency and limit the release of nutrients into water bodies. Consequently, struvite recovered from municipal sidestreams is being viewed increasingly as an asset rather than a nutrient that must be treated and disposed. As presented in Sec. 15–4, several struvite crystallization and recovery processes are in full-scale operation. Product purity reported from these facilities has been high, generally greater than 99 percent, with low heavy metal concentrations and coliform counts after the product is washed and decontaminated (Nawa, 2009; Baur et al., 2011; Moerman, 2011). Purity requirements and product accreditation vary by country, state or region, but the product purities have not limited their introduction into regional markets. The product is not considered an organic fertilizer, as it is derived from a wastewater treatment facility.

The recovered struvite may be sold directly by the municipality to a fertilizer blender who markets slow-release fertilizers, but it is a common business model by struvite crystallizer technology providers to assume this responsibility as part of their contract with the municipality. The fertilizer company will blend the struvite with other chemicals to create the desired nutrient blend for a specific application. The fertilizer application may also dictate the required physical characteristics of the product. For example, a pelletized product with a large mean diameter may be specified for a particular application. Consequently, the crystallizer operating conditions and processing requirements for the harvested product will be adjusted to generate a product that complies with this specification. Alternatively, the harvested product will be processed offsite to generate the desired physical characteristics.

Calcium Phosphate (Hydroxyapatite)

Although the recovery of phosphorus from municipal sidestreams as hydroxyapatite has fallen out of favor due to chemical pretreatment costs and the more favorable economics of struvite recovery, hydroxyapatite will continue to be favorable for certain industrial and dairy waste streams. If the use of calcite and calcium silica hydrate as seed materials for hydroxyapatite crystallization is proven to be successful at a full-scale, the production of hydroxyapatite may become a viable alternative to struvite production from municipal sidestreams.

As demonstrated in The Netherlands in the 1990s, hydroxyapatite can be crystallized from sidestream using a seed material such as sand to generate a granular product of high purity and low heavy metals content (Piekema and Giesen, 2001). The sand content of the harvested product is 5 percent by weight or less. The product can be used as feed stock by a phosphate rock processor to generate other phosphate compounds for the fertilizer market such as $Ca(HPO_4^{2-})_2$ (*Superphosphate*), it can also be blended with other nutrients to produce a formulated fertilizer or applied directly as a slow-release fertilizer. Similar to struvite, the pelletized product can be easily dewatered and stored.

Ammonium Sulfate

The primary use of ammonium sulfate is as a fertilizer, but there is no established market for ammonium sulfate produced from wastewater treatment plants. However, there is an established market for ammonium sulfate as a byproduct of various industries, primarily from the production of nylon. The product is typically marketed worldwide and produced in a crystallized form due to customer preference and to reduce shipping costs. Ammonium sulfate can be used in a direct application, it can be blended in custom fertilizer solutions, and it can be blended with biosolids as discussed below. For example, ammonium sulfate has been blended with urea ammonium nitrate (UAN) to produce a fertilizer solution that will increase the sulfur content of the solution fertilizer blend. While the use of sulfur-containing fertilizers are increasing due to the substantial reduction in atmospheric sulfur deposition in certain regions, the use of nitrate and anhydrous ammonia based fertilizers are decreasing due to security issues, ammonia volatilization, and a general shift to liquid fertilizers.

Use of Ammonium Sulfate (AS). Although used throughout the year, the highest use of AS (50–75 percent of annual usage) will typically occur in the late spring and early summer. Smaller amounts would be used in late summer and in the fall. For the remainder of the year (approximately six months), AS must be stored. Typically, a fertilizer blender/distributor will have storage capability, thus avoiding the need to install storage tanks at the wastewater treatment facility.

Blending Ammonium Sulfate with Biosolids. If biosolids are to be reused beneficially, the 40 percent by weight AS solution can be mixed with the dewatered solids to enhance N and S content. However, there are several potential concerns with this approach:

1. Blending the AS solution with the biosolids will the increase the mass of the biosolids and its associated hauling costs.
2. Where biosolids are land applied at an agronomic rate based on nitrogen content, the acreage needed will be larger as the nutrient content will be higher.
3. Increased potential for hydrogen sulfide odors: Because the solution has a high level of sulfate, there is a potential to generate hydrogen sulfide if the mixed biosolids becomes anaerobic during storage.

Marketing Ammonium Sulfate. The ammonium sulfate supply chain contains three distinct groups: manufacturer, blender/distributor, and applier/end-user. A treatment facility would sell their product, as a manufacturer, to a blender/distributor for them to either incorporate into a fertilizer blend or sell it as is.

The most critical issue with marketing AS for the fertilizer suppliers and farmers is its quality and consistency. The fertilizer/chemical suppliers generally will not accept the AS unless the quality and consistency are known and meet their specifications. However, product quality is anticipated to be higher than the standard specifications based on current experience with ammonium nitrate (Sagberg, 2006) and ammonium sulfate (ThermoEnergy, 2009), where the products were found to have low levels of heavy metals (<1 ppm and largely attributed to the quality of the commercial grade acids used in the process) and low total organic carbon (TOC < 50 ppm). Typically, TOC content is tightly specified for ammonium nitrate and monitored to limit explosion potential, but this would not be a factor with ammonium sulfate. Based on the data from operating processes, the TOC in the product is most likely methylamine, which is stripped from the digestion sidestream and absorbed into the product solution along with the ammonia.

Ammonium Nitrate

Ammonium nitrate is an important fertilizer used extensively throughout the world and is commercially available in both dry and liquid forms. Because ammonium nitrate can be used in explosives, the handling and purchase of dry ammonium nitrate is strictly regulated to prevent misuse. This regulation would not apply to "liquid" form, and liquid usage is increasing substantially. However, most nitric acid capacity is "captive," i.e., manufactured for internal use, and, therefore, the price and availability are uncertain. Based on experience in Norway, the fertilizer manufacturer would supply the nitric acid to the wastewater treatment plant and take the ammonium nitrate product; however, this arrangement results in a less cost competitive environment compared to ammonium sulfate production as the fertilizer manufacturer has more extensive control of the acid supply and purchase of the ammonium nitrate.

15–7 BIOLOGICAL REMOVAL OF NITROGEN FROM SIDESTREAMS

Sidestreams resulting from sludge and biosolids processing are most commonly treated in the mainstream plant. Typically, the sidestreams are returned to the headworks, the inlet of primary sedimentation tanks or directly to a location near or in the secondary treatment process (e.g., channels conveying primary effluent or RAS to the activated sludge reactors), depending on the nutrient, BOD and suspended solids loadings associated with the sidestream, and physical constraints such as the plant piping configuration and the location of the dewatering process relative to the process units associated with the main liquid treatment train.

Treatment of the nitrogen-rich sidestreams derived from the dewatering of digested solids, a principal focus of this chapter, can occur in separate treatment processes or in a treatment processes that are integrated with the mainstream treatment process. Both separate and integrated treatment processes are introduced and discussed in this section. The biological treatment processes used for the removal of nitrogen, introduced in this section, are described in greater detail in the subsequent three sections.

Nitrogen Removal Processes

Inorganic nitrogen can be removed biologically by three general processes:

1. Nitrification-denitrification
2. Nitritation-denitritation
3. Partial nitritation-anaerobic ammonium oxidation (deammonification)

Although these processes have been described previously in Chaps. 7 through 10 for the treatment of wastewater, the discussion in this chapter deals with the application of these processes for treatment of sidestreams containing high concentrations of ammonium. For the purpose of comparison, the pathways involved in each of these processes are illustrated on Fig. 15–9 and described below.

Nitrification-Denitrification. In the nitrification-denitrification process, as illustrated on Fig 15–9(a), ammonium is first oxidized to nitrite (nitritation) and subsequently to nitrate (nitratation). Ammonia oxidizing bacteria (AOB) and nitrite oxidizing bacteria (NOB) are responsible for the two steps in the nitrification process. In the denitrification process nitrate is first reduced to nitrite and subsequently to nitrogen gas. As shown on Fig. 15–9(a), oxygen must be added to complete the oxidation of ammonia to nitrate and a carbon source must be available to complete the reduction of nitrate to nitrogen gas.

Nitritation-Denitritation. In the nitritation-denitritation process, as illustrated on Fig 15–9(b), ammonium is first oxidized to nitrite (nitritation). In the next step, nitrite, under anoxic conditions, is reduced to nitrogen gas (denitritation). Short-circuiting the nitrification-denitrification pathway, as illustrated on Fig. 15–9(b), through the restriction

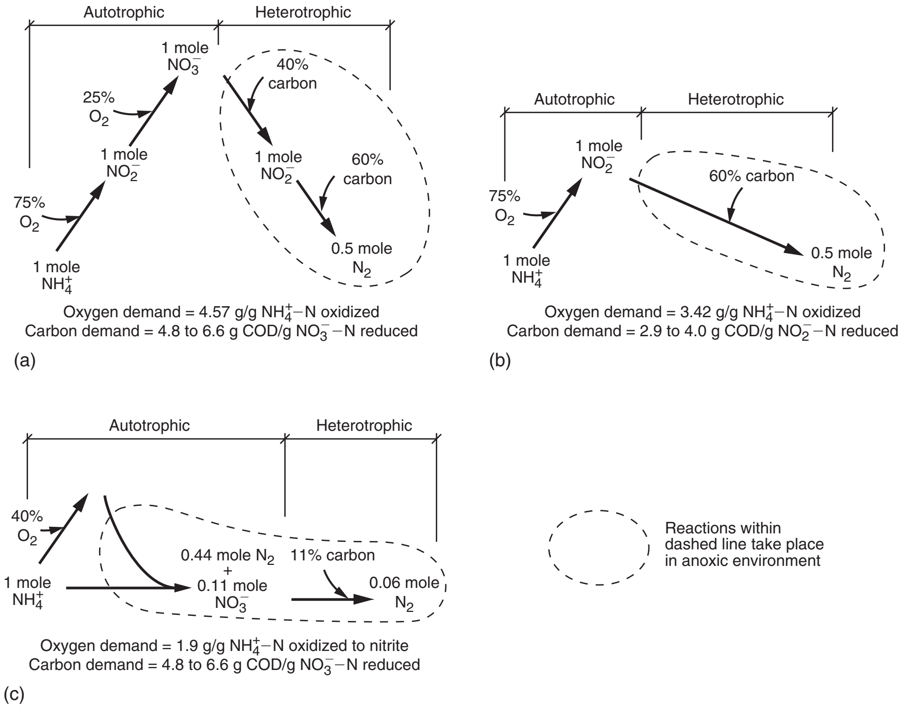


Figure 15–9

Biological reaction pathways for ammonium oxidation and inorganic nitrogen removal: (a) nitrification-denitrification, (b) nitritation-denitritation; and (c) deammonification.

or prevention of nitrite oxidation to nitrate, reduces the stoichiometric oxygen demand and associated aeration energy by 25 percent. In the subsequent anoxic step, the heterotrophic bacteria require 40 percent less degradable organic carbon to reduce nitrite to nitrogen gas. Reducing the aeration power and chemical requirements for sidestream treatment has been the primary driver in the development of alternative advanced biological treatment processes.

Partial Nitritation-Anaerobic Ammonium Oxidation (Deammonification). In the deammonification process, as illustrated on Fig 15–9(c), a portion of the ammonium is first oxidized to nitrite (partial nitritation). In the next step of the process, ammonia and nitrite are converted to nitrogen gas and nitrate under oxygen-free conditions (anaerobic ammonium oxidation) by a special group of autotrophic bacteria collectively known as anaerobic ammonium oxidizers (Anammox). As illustrated on Fig. 15–9(c), deammonification further reduces the organic carbon requirement.

Process Design Considerations. Although there are distinct differences in the three different nitrogen removal processes, there is commonality in the design approaches used to determine aeration, chemical, heat removal and tank volume requirements. A unified section on process design for the three major types of sidestream processes is presented in Sec. 15–11. Additional information on the specific design requirements for proprietary processes is provided in the process descriptions in Sec. 15–8 through 15–10.

Separate Treatment Processes for Nitrogen Removal

A sidestream treatment process is considered *separate* from the mainstream plant if the mixed liquor suspended solids in the sidestream reactor are isolated from the mainstream secondary treatment process [see Fig. 15–10(a)]. Waste solids from the sidestream treatment

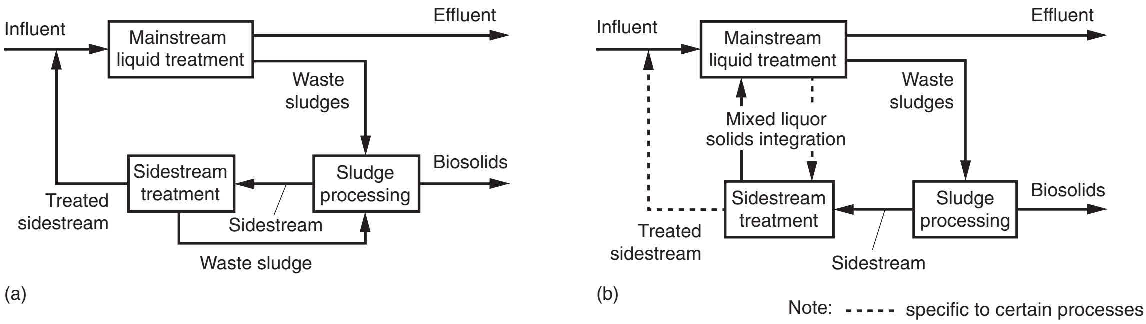

Figure 15–10

Biological process definitions: (a) separate sidestream treatment and (b) integrated sidestream-mainstream treatment.

process, as shown on Fig. 15–10(a), are sent directly to the solids processing train and no mixed liquor suspended solids from the mainstream secondary process are constantly or intermittently sent to the sidestream process.

Advantages and Disadvantages of Separate Sidestream Treatment. Biological treatment in a dedicated separate reactor presents two primary advantages. First, the nutrient and particulate loadings associated with the sidestream are greatly diminished, resulting in a stream that is less likely to impact the performance of the main treatment plant. Second, treatment in a dedicated reactor provides an opportunity to operate under conditions that can limit the final nitrification product to nitrite. This mode of operation results in lower oxygen and COD requirements for inorganic nitrogen removal (Sec. 15–9); it also provides an ideal environment for the growth of bacteria that possess unique characteristics and biochemistry that can be exploited to further reduce the cost of inorganic nitrogen removal (Sec. 15–10).

A separate sidestream treatment process may also be advantageous or cost-effective for facilities where a required marginal reduction in the plant effluent total nitrogen (TN) concentration or loading can be achieved by treating the sidestream alone and bioaugmentation via an integrated sidestream treatment process does not provide any distinct advantages in terms of overall plant performance (integrated systems are described below). The cost effectiveness of separate sidestream treatment, in comparison to alternative secondary process upgrades that achieve the same improvement in TN removal, is dependent on site specific factors unique to the specific facility, e.g., available footprint for plant expansion, constructability of the various plant upgrade options.

Historically, many separate sidestream treatment processes were designed to provide only nitrification. In these cases, the mainstream plant has limited nitrification capacity and full or partial nitrification of the sidestream ammonium load was the most cost effective option.

From an operations perspective, a separate sidestream treatment system is an additional process at the facility that requires operational oversight and maintenance, which may not be desirable. Also, some separate sidestream nitrification-denitrification processes require the addition of an alkalinity source, a supplemental COD source or both. Chemical consumption would only be a disadvantage if other sidestream nitrification-denitrification options do not require chemical addition for the facility to achieve the desired effluent discharge quality.

Impact of Other Treatment Processes. However, despite the isolation of the sidestream mixed liquor solids from the mainstream secondary process, the sidestream treatment process can be affected by the operating conditions of the other process units in the facility. For example, if the operation of the anaerobic digesters is disturbed or mechanical or performance problems are encountered with the post-digestion dewatering process, the quality and quantity of the sidestream may change, potentially resulting in a perturbation in the sidestream treatment process operating conditions and performance. However, as discussed in Sec. 15–2, the inclusion of sidestream equalization and solids removal will minimize the impact on the downstream process. Because the quality of the effluent from the sidestream treatment process is typically not sufficient to allow blending with the mainstream secondary effluent, the treated sidestream is sent to the mainstream secondary process for further treatment.

Integrated Sidestream-Mainstream Treatment and Bioaugmentation

A sidestream treatment process is defined as "integrated" when mixed liquor suspended solids in the mainstream secondary and sidestream processes are interchanged or nitrifier-enriched waste solids from the sidestream process are fed to the mainstream secondary process to induce bioaugmentation. An integrated configuration, as illustrated on Fig. 15–10(b), would be represented by a flow scheme where a portion of a mainstream return activated sludge (RAS) is fed to the sidestream reactor or, similarly, the sidestream is fed to a RAS reaeration tank. An integrated system would also be represented by any process where sidestream reactor waste solids are fed to the mainstream secondary process.

Advantages and Disadvantages of Integrated Sidestream Treatment. The main advantage of integrating the sidestream and mainstream processes is the enhancement and stabilization of mainstream nitrification with nitrifier-enriched mixed liquor solids from the sidestream reactor. The optimum configuration is dependent on the mainstream process configuration, operating conditions, and the desired plant effluent quality. Operating costs associated with chemical addition are also a consideration during process selection. A disadvantage of integrating the sidestream and mainstream processes is the introduction of additional inert solids into the secondary process mixed liquor; however, if the sidestream is equalized and the majority of the solids are removed and recycled to the solids processing train, the effect of the sidestream on the mainstream process solids balance is greatly diminished.

Augmentation of Mainstream Treatment Process. The augmentation of the mainstream process with nitrifier-enriched sidestream mixed liquor solids has been documented, yet a unified mechanistic model that can be used to predict the impact of bioaugmentation for all process configurations has not yet been developed. In general, the effectiveness of nitrifying biomass grown in a sidestream reactor in enhancing nitrification performance in the mainstream secondary process may be greatly impacted by the bulk liquid environment in which these organisms grow (e.g., osmotic pressure, temperature, pH, ionic composition and strength, substrate concentration). In integrated configurations where the sidestream is fed to a RAS reaeration tank, the nitrifying bacteria grow within the flocculated mixed liquor suspended solids in the RAS reaeration tank at the same temperature and nearly identical bulk liquid conditions as the mainstream secondary process; therefore, complete retention of nitrifier activity is anticipated as the nitrifier-enriched mixed liquor passes from the reaeration tank to the activated sludge tanks.

In process configurations where the difference in the bulk liquid sidestream and mainstream process environments are significant, the sidestream reactor operating conditions allow the growth and domination of specific types of nitrifying organisms over others, yet when placed in the mainstream environment, are at a competitive disadvantage to the nitrifying organisms that dominate under the mainstream operating conditions. Intuitively, the bioaugmentation effect would be lower with these configurations in comparison to the configurations where sidestream is substantially diluted into a RAS stream and only increase as the sidestream and mainstream processes are increasingly integrated through interchange of mixed liquor solids. However, an exact quantification of the effect has not been thoroughly demonstrated over a wide range of operating conditions.

Bioaugmentation Effect of Integrated Sidestream Treatment. The bioaugmentation effect of the sidestream mixed liquor solids is also impacted by the nitrifier mass discharge rate to the mainstream process. Therefore, operating conditions that lead to a reduced nitrifier mass in the sidestream process will reduce the mass in the waste sludge. For example, a higher operating temperature in the sidestream process will increase the decay rate of the nitrifying organisms. Enhanced decay also occurs as the sidestream process SRT is allowed to increase well above the minimum SRT required to sustain the desired sidestream treatment performance. In sidestream processes that operate at elevated temperatures and a high SRT, the combined effect of these two conditions will diminish the nitrifier mass available for bioaugmentation. Based on these observations operating the sidestream treatment reactor at (1) a temperature as close as practically possible to the mainstream process, (2) with a bulk liquid environment similar to the mainstream process and (3) at a low SRT that provides the desired performance will result in optimum retention of nitrifier activity and, hence, the greatest bioaugmentation effect.

15–8 NITRIFICATION AND DENITRIFICATION PROCESSES

Several biological treatment processes have been developed for sidestream treatment where the end product of ammonium oxidation is primarily nitrate and the nitrate is subsequently denitrified in part or in whole, depending on the treatment objective. The processes are subdivided into two categories: separate treatment and integrated sidestream-mainstream treatment, according to the definitions provided in Sec. 15–7. The implementation of one type of process over the other is dependent on the type of mainstream secondary process, its operating conditions, plant effluent quality objectives and economic considerations. The purpose of this section is to consider the application of nitrification and denitrification processes for the treatment of sidestreams.

Fundamental Process Considerations

To understand the nitrification-denitrification process, it is useful to consider (1) the process biology, kinetics, and stoichiometry, (2) the alkalinity requirements, (3) the importance of inorganic carbon, and (4) the need for degradable organic carbon.

Process Biology, Kinetics, and Stoichiometry. The microbiology, basic biochemical reaction stoichiometries and autotrophic growth kinetics associated with the oxidation of ammonium to nitrite and nitrite to nitrate are presented in Sec. 7–9 in Chap. 7. Although kinetic rates in sidestream biological treatment processes are influenced by the same environmental conditions as the mainstream nitrification processes, differences between ammonia oxidizing bacteria (AOB) and nitrite oxidizing bacteria (NOB) growth kinetics in the sidestream and mainstream environments must be considered for sidestream process design and operation. Specifically, the key differences are the impact of temperature on growth and decay, nitrous acid and free ammonia inhibition of AOB and NOB populations, and the effect of bicarbonate concentration on the autotrophic growth rates.

Biological denitrification reaction stoichiometry and kinetics are presented in Sec. 7–10 in Chap. 7. The pertinent stoichiometric reactions involved in nitrification-denitrification process, repeated here for convenience, are as follows.

Nitrification. The principal nitrification reactions are as follows.
Biological conversion of ammonium to nitrite

$$2NH_4^+ + 3O_2 \rightarrow 2NO_2^- + 4H^+ + 2H_2O \tag{7–88}$$

Biological conversion of nitrite to nitrate

$$2NO_2^- + O_2 \rightarrow 2NO_3^- \tag{7–89}$$

Total oxidation reaction:

$$NH_4^+ + 2O_2 \rightarrow NO_3^- + 2H^+ + H_2O \tag{7–90}$$

If cell tissue is neglected, the amount of alkalinity required to carry out the ammonium oxidation reaction is given by the following reaction, obtained by rewriting Eq. (7–90) as follows.

$$NH_4^+ + 2HCO_3^- + 2O_2 \rightarrow NO_3^- + 2CO_2 + 3H_2O \tag{7–91}$$

When cell mass synthesis is included in the overall oxidation of ammonium to nitrate, Eq. (7–91) becomes Eq. (7–93). The cell mass yield is based on yields of 0.12 g VSS/g NH_4-N and 0.04 g VSS/g NO_2-N for the nitritation and nitratation reactions, respectively.

$$\begin{aligned} &NH_4HCO_3 + 0.9852NaHCO_3 + 0.0991CO_2 + 1.8675O_2 \rightarrow \\ &\qquad 0.01982C_5H_7NO_2 + 0.9852NaNO_3 + 2.9232H_2O + 1.9852CO_2 \end{aligned} \tag{7–93}$$

Denitrification. The amount of biodegradable organic compound required to reduce nitrate to nitrogen gas is dependent on the carbon source as illustrated by the following equations where the organics in wastewater, methanol, or acetate are used for nitrate reduction.

Wastewater:

$$C_{10}H_{19}O_3N + 10NO_3^- \rightarrow 5N_2 + 10CO_2 + 3H_2O + NH_3 + 10OH^- \tag{7–110}$$

Methanol:

$$5CH_3OH + 6NO_3^- \rightarrow 3N_2 + 5CO_2 + 7H_2O + 6OH^- \tag{7–111}$$

Acetic Acid:

$$5CH_3COOH + 8NO_3^- \rightarrow 4N_2 + 10CO_2 + 6H_2O + 8OH^- \tag{7–112}$$

The above equations do not reflect the actual carbon requirement for denitrification as they do not include cell mass synthesis. When expressed as COD, the mass ratio of biodegradable COD to nitrate-N taking into account the biomass yield is given by Eq. (7–126).

$$\frac{\text{bsCOD}}{NO_3\text{-N}} = \frac{2.86}{1 + 1.42Y_n} \tag{7–126}$$

Where 2.86 = oxygen equivalent of nitrate-N (g O_2/g NO_3-N)
Y_n = net biomass yield, as defined by Eq. (7–121).

$$Y_n = \frac{Y}{1 + b(\text{SRT})} \tag{7–121}$$

Where b = heterotrophic anoxic decay rate

Based on these equations, the observed COD/N ratio is dependent on the SRT of the reactor and the value of b, which, in turn, is dependent on the reactor temperature. The reader should refer to Secs. 7–9 and 7–10 for more detailed discussions of the nitrification and denitrification reactions, respectively.

Alkalinity Requirements. The alkalinity requirements are given by Eqs. (7–91) and (7–93). Referring to Eq. (7–91), two moles of bicarbonate are required to neutralize the acidity generated per mole of ammonium oxidized during nitrification. When cell growth is included [see Eq. (7–93)], 1.98 moles of bicarbonate are required for acid neutralization and 0.099 moles of inorganic carbon are required for cell growth in the complete nitrification of one mole of ammonium-N. If nitrate is denitrified completely, 50 percent of the alkalinity destroyed during nitrification is recovered (see Sec. 7–10 in Chap. 7), resulting in a net alkalinity reduction of 1 mole of bicarbonate per mole of ammonium-N nitrified and denitrified (3.57 g $CaCO_3$/g NH_4-N).

For sidestreams derived from anaerobic digestion and ATAD processes, the alkalinity is primarily in the form of bicarbonate and is typically equal to the ammonium concentration on a molar basis, providing only one half of the alkalinity required for complete nitrification. The remaining alkalinity demand can be satisfied through the addition of an external alkalinity source (e.g., caustic soda; see Sec. 15–11), dilution of the sidestream into another stream with sufficient alkalinity (e.g., return activated sludge) or by generating alkalinity via denitrification. In the absence of sufficient alkalinity, a stoichiometric amount of the sidestream ammonium-N will be oxidized to a mixture of nitrite and nitrate in accordance with the available alkalinity.

The addition of a COD source, to enhance denitrification and generate alkalinity to support nitrification, may not eliminate the need for an external alkalinity source. For example, if ferric or ferrous chloride is added to the digesters to control struvite formation or to the sidestream to control struvite formation in the pipe or channel conveying sidestream, a reduction in sidestream alkalinity will occur due to the acidity associated with these chemicals. Therefore, in subsequent sidestream treatment, the addition of supplemental alkalinity may be required depending on the treatment objective.

Importance of Inorganic Carbon. The role of inorganic carbon in nitrifier growth is often ignored in mainstream nitrification processes where bicarbonate and CO_2 are readily available due to the degradation of abundant organic carbon compounds in the plant influent. However, the residual inorganic carbon concentration in separate sidestream reactors has an impact on the ammonium removal rate and removal efficiency due to the high autotrophic growth rates in the reactor. In high rate nitritation-denitritation sidestream treatment processes operated at high temperature (greater than 30°C) at a full-scale, the effect of inorganic carbon concentration on the autotrophic growth rate was not found to follow a conventional Monod kinetic form, but is represented by a logistic function ("S-curve") as defined by Eq. (15–8). Monod kinetic terms for dissolved oxygen, substrate concentration, free ammonia inhibition,and nitrous acid inhibition along with the decay rate and Arrhenius temperature function are not included in Eq. (15–8) for simplicity.

$$\mu_n = \mu_m \frac{e^{[(\mathrm{HCO}_3^- - k)/a]}}{e^{[(\mathrm{HCO}_3^- - k)/a]} + 1} \tag{15–8}$$

Where μ_n = growth rate of nitrifying bacteria, g new cells/g cells·d
μ_m = maximum specific growth rate of nitrifying bacteria, g new cells/g cells·d
HCO_3^- = bicarbonate concentration, mM
k = saturation constant, mM
a = constant (estimated value of 0.83 based on Wett and Rauch, 2003)

While the value of the saturation constant, *k*, for mainstream processes is 0.5 mM or less, the value has been estimated to be around 4 mM in the warm, high growth rate environment of a separate sidestream reactor (Wett and Rauch, 2003). Consequently, for sidestream biological treatment processes, the residual inorganic carbon concentrations in the reactor must be considered carefully when selecting the reactor operating conditions that provide optimum performance. Bicarbonate and CO_2 exist in equilibrium at concentrations dictated by the reactor bulk liquid conditions, such as temperature, pH, and calcium concentration (formation of calcium carbonate). As the reactor pH decreases below 7, more bicarbonate shifts to $CO_{2,aq}$, which is removed subsequently from the reactor via air stripping. Therefore, under increasingly acidic conditions in a sidestream biological reactor, a restricted nitrifier growth rate may occur due to an inorganic carbon limitation.

Need For Degradable Organic Matter. Depending on the COD source (e.g methanol, glycerol, volatile fatty acids, municipal wastewater), the observed sludge yield under anoxic conditions is typically in the range of 0.28 to 0.4 g VSS /g COD consumed, resulting in a degradable COD to nitrate-N ratio of 4.8 to 6.6 g/g [see Eq. (7–126)]. In a typical high strength sidestream, the ratio of degradable COD to TKN is less than 1. Thus, the available degradable COD for a sidestream treatment system is insufficient where a high denitrification efficiency is desired. Supplementation of the COD with commercially available organic carbon sources is an option; however, the use of COD sources within the facility (e.g primary sludge; endogenous decay of secondary mixed liquor solids) is desired as the purchase of a commercial COD source increases operating cost.

Treatment Processes

Over the past 20 years, a number of separate and integrated nitrification-denitrification treatment process configurations have been developed or implemented for sidestream treatment. The principal processes are

BAR/R-D-N process

InNitri® process

ScanDeNi® process

Sequencing batch reactor

Summary information on these processes, including process flow diagrams, is provided in Table 15–4.

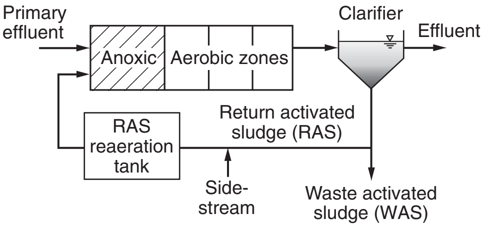
In addition to the process configurations described in Table 15–4, trickling filters have been used for sidestream treatment in a limited number of facilities, but typically their application has occurred where the mainstream process has been upgraded from trickling filters to a suspended growth activated sludge system, resulting in the availability of a

Table 15–4

Description of separate and integrated nitrification–denitrification processes for sidestream treatment

<table>
<tr><th>Process</th><th>Description</th></tr>
<tr><td>

(a) BAR and R-D-N process

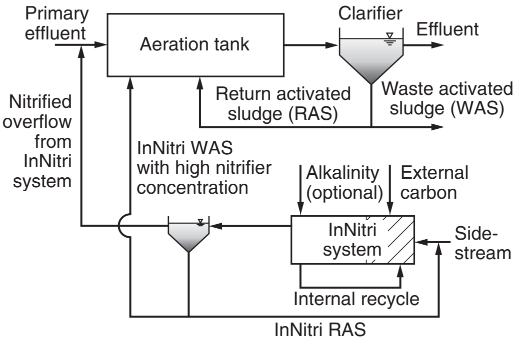


</td><td>

BioAugmentation Reaeration (BAR) or Regeneration-Denitrification-Nitrification (R-D-N) process consists of nitrification of the sidestream in a plug-flow return activated sludge (RAS) reaeration tank. In a typical design, the sidestream is mixed with the entire RAS flow at the head of the tank. An anoxic zone can be provided at the head of the tank with a HRT of 1 h to promote partial denitrification of the RAS and suppress odors associated with the sidestream. The aerobic zones that follow typically have a total hydraulic retention time (HRT) of 2 h to allow complete ammonium oxidation. A final anoxic zone may be provided at the end of the tank with a 1 h HRT to further promote endogenous denitrification if needed. Process modeling is used to refine the reaeration tank volume requirement. Addition of the entire RAS flow dilutes the sidestream ammonium-N and other constituents by 50 to 100-fold, creating a mixed liquor environment for nitrification that is similar to that in the mainstream activated sludge reactors. RAS alkalinity is typically sufficient to meet the alkalinity demand for full nitrification of the sidestream ammonium load. Ideally, mechanical mixers are used in the anoxic zone(s), but for large plants coarse bubble aeration has proven to be a cost-effective method of providing mixing with limited impact on denitrification.

</td></tr>
<tr><td>

(b) InNitri® process



</td><td>

The InNitri® process was developed with the key objective of bioaugmentating the mainstream process with nitrifier-rich waste sludge. The InNitri process is typically designed in a Modified Ludzack-Ettinger (MLE) configuration with a separate gravity clarification step. An external carbon source is added to promote denitrification and generate alkalinity to enhance the nitrification efficiency. The internal recycle rate from the aerobic to the anoxic zone depends on the desired total inorganic nitrogen (TIN) removal efficiency. An external alkalinity source may be added if a high nitrification efficiency is required to meet the treatment objective. Alternatively, the InNitri reactor may be operated entirely in an aerobic mode, which would require external alkalinity addition to achieve a high nitrification efficiency. Primary or plant effluent is fed to the reactor to prevent the operating temperature from exceeding 38°C or to maintain the reactor within a specific temperature range. To maximize the amount of nitrifier mass sent to the mainstream secondary process, the InNitri sidestream reactor is operated at an aerobic SRT in the range of 3 to 5 d, which provides stable sidestream performance, but limits the loss of nitrifier mass through decay.

</td></tr>
</table>

(*continued*)

Table 15–4 (*Continued*)

Process	Description
(c) ScanDeNi® process  	Similar to the BAR/R-D-N process, the ScanDeNi® process nitrifies the sidestream nitrogen load in a RAS reaeration tank. Unlike the other processes, a post anoxic zone is provided and an external carbon source is added to enhance denitrification. No internal recycle within the reaeration tank is provided since the RAS has sufficient alkalinity for complete nitrification. The design HRT of the anoxic zone will be impacted by the selected external carbon as the denitrification rates will vary with the source. The ScanDeNi process was developed to provide a means of nitrifying and denitrifying a sidestream ammonium load and provide a denitrified RAS flow to the mainstream process where biological phosphorus removal is performed.
(d) Sequencing Batch Reactor (SBR)  	Sequencing Batch Reactors (SBR) have been used most commonly for separate sidestream treatment. In the SBR configuration, sidestream is fed continuously during the *React* period or rapidly fed to the reactor at the beginning of the SBR cycle in a defined anoxic *Fill* period. Intermittent aeration is applied at defined time intervals to provide aerobic and anoxic periods for nitrification and denitrification. Typically, the total aerobic time is two-thirds of the *React* period. If a high ammonium removal efficiency is desired, an external alkalinity source is provided. If high ammonium and inorganic nitrogen removal efficiencies are desired, an external carbon source or a facility carbon source such as primary sludge/WAS is added for denitrification and to generate alkalinity for nitrification. Primary or plant effluent is fed to the SBR for temperature control as needed. At the end of the *React* period, the suspended solids are settled (*Settle* period), treated sidestream is decanted to the mainstream plant (*Decant* period) and waste sludge is pumped to the solids processing train. The total SRT is typically 10 d or higher.

trickling filter for sidestream treatment. Performance is largely limited to partial nitrification and a dilution water source (e.g., primary effluent) and a high internal recycle rate are required to maintain the desired hydraulic loading rate. Trickling filters are not considered further in this chapter.

Other attached growth process configurations such as moving bed biofilm reactors and rotating biological contactors, historically, have not been used for nitrification-denitrification of sidestreams, but have been proven effective for deammonification of sidestreams, as presented in Sec. 15–10. Submerged attached growth processes such as fluidized bed reactors and biological aerated filters have also not been applied full-scale for sidestream treatment. However, in pilot studies with submerged reactors with a sand medium nitritation-denitritation with methanol as the supplemental carbon source has been demonstrated successfully. The application of attached growth systems is considered further in Sec. 15–10.

Finally, activated sludge reactors have been applied successfully for the nitrification of digester sidestreams (Jeavons et al., 1998), but these systems have been decommissioned.

15–9 NITRITATION AND DENITRITATION PROCESSES

The development of the nitritation-denitritation processes in the 1990s was driven by the desire to reduce the energy and chemical requirements for high strength sidestream nitrogen removal. Nitritation-denitritation processes that have been implemented in full-scale facilities are described in this section along with general design information. Separate and integrated sidestream-mainstream processes and those that produce a mixture of nitrite and nitrate during the ammonium oxidation step are also included in this section.

Fundamental Process Considerations

To understand the nitritation-denitritation process it is useful to consider (1) the biological pathways, (2) process biology, kinetics, and stoichiometry**,** (3) the alkalinity requirements, (4) the need for biodegradable organic carbon, and (5) the operating modes that limit the oxidation of nitrite to nitrate.

Biological Pathways. As illustrated on Fig. 15–9(b), short-circuiting the nitrification-denitrification pathway through the restriction or prevention of nitrite oxidation to nitrate, reduces the stoichiometric oxygen demand and associated aeration energy by 25 percent. In the subsequent anoxic step, the heterotrophic bacteria require 40 percent less degradable organic carbon to reduce nitrite to nitrogen gas (*denitritation*), in comparison to the organic carbon required for nitrate reduction, as the oxidation state of nitrogen in nitrite (+3) is lower than nitrate (+5). The corresponding stoichiometry is given below.

Process Biology, Kinetics, and Stoichiometry. The microbiology, basic biochemical reaction and autotrophic growth kinetics associated with the oxidation of ammonium to nitrite are presented in this Section. Biological denitritation is discussed in Sec. 7–10 in Chap. 7. The pertinent nitritation-denitritation process stoichiometry is as follows.

Biological conversion of ammonium to nitrite (nitritation) is

$$\begin{aligned} &NH_4HCO_3 + 0.9852NaHCO_3 + 0.07425CO_2 + 1.4035O_2 \rightarrow \\ &\qquad 0.01485C_5H_7NO_2 + 0.9852NaNO_3 + 2.9406H_2O + 1.9852CO_2 \end{aligned} \tag{7–92}$$

The amount of biodegradable organic compound required to reduce nitrite to nitrogen gas is dependent on the carbon source as illustrated by the following reactions based on municipal wastewater, methanol, and acetate.

Wastewater:

$$C_{10}H_{19}O_3N + 16.66NO_2^- + 0.33H_2O \rightarrow 10CO_2 + NH_3 + 8.33N_2 + 16.66OH^- \tag{15–9}$$

Methanol:

$$5CH_3OH + 10NO_2^- \rightarrow 5N_2 + 5CO_2 + 5H_2O + 10OH^- \tag{15–10}$$

Acetic Acid:

$$5CH_3COOH + 13.33NO_2^- \rightarrow 10CO_2 + 3.33H_2O + 13.33OH^- \tag{15–11}$$

The equations given above can be compared to the nitrate reduction reactions in Eq. (7–110) through (7–112) given in Sec. 15–8. Comparing the corresponding equations, it can be seen that the mass of a specific organic compound can reduce a greater amount of inorganic nitrogen if nitrite is not allowed to oxidize to nitrate during the ammonium oxidation step in the process.

Similar to denitrification, the equations above do not reflect the actual carbon requirement for denitritation, as the reactions do not account for cell mass synthesis. When expressed on a COD basis, the actual biodegradable COD requirement for denitritation takes into account the effect of biomass yield and is calculated as follows.

$$\frac{\text{bsCOD}}{\text{NO}_2\text{-N}} = \frac{1.71}{1 - 1.42Y_n} \tag{15–12}$$

Where 1.71 = oxygen equivalent of nitrite (g O_2/g NO_2- N)
Y_n, = net biomass yield, calculated with Eq. (7–121), presented in Sec. 15–8.

Alkalinity Requirement. Alkalinity destruction during the complete oxidation of ammonium to nitrate occurs during the nitritation step. Therefore, the alkalinity demand for acid neutralization in a nitritation process is identical to a process performing complete nitrification. The alkalinity requirement for complete ammonium removal must be provided through an external alkalinity source or alkalinity generation through nitrite reduction. Providing the alkalinity requirement by diluting the sidestream into another plant stream (raw influent, primary tank effluent; plant effluent) is not a viable option, as dilution creates a growth environment where restriction of nitrite oxidation to nitrate is difficult to control. As discussed in Sec. 15-8, considering the impact of bicarbonate concentration on the autotrophic growth rate and the potential reduction in alkalinity through the use of chemicals (e.g. iron salts) upstream of the sidestream treatment process, the addition of supplemental alkalinity may be required depending on the treatment objective.

Need For Degradable Organic Matter. Despite a reduction in the organic carbon requirement, the amount of degradable organic carbon in a typical sidestream is insufficient to allow complete denitritation. An external organic carbon source or a carbon source from within the plant such as primary solids is required. In the absence of sufficient denitritation, an external alkalinity source is required for a high nitritation efficiency or incomplete ammonium oxidation to nitrite will occur.

Restriction of Nitrite Oxidation and the Impact of Nitrite Accumulation. Preventing or limiting NOB growth in a nitritation-denitritation process can be accomplished through four primary mechanisms: (1) low aerobic SRT at a reactor temperature greater than 20°C, (2) intermittent aeration at low dissolved oxygen (DO) concentration, (3) free ammonia inhibition, and (4) free nitrous acid inhibition, where the latter two inhibitory effects are dependent on reactor pH. The role of one or more of these mechanisms to restrict NOB growth is discussed in the process descriptions given in Table 15–5. For further discussion of ammonium and nitrite oxidizing bacteria growth kinetics and conditions that restrict NOB growth, refer to Sec. 7–9 in Chap. 7.

The accumulation of nitrite to high concentrations can result in a reduction in the ammonium oxidation rate through free nitrous acid inhibition. Therefore, inclusion of denitritation in the treatment process is preferred for very high strength sidestreams, or the sidestream can be diluted with primary or plant effluent, with the restriction that excessive dilution may result in sidestream reactor conditions that limit the control of nitrite oxidation to nitrate. Where a high residual nitrite concentration is present in the sidestream reactor effluent, the effluent should be discharged to an anoxic zone in the mainstream secondary process to prevent further oxidation of the nitrite to nitrate and to minimize the organic carbon demand for inorganic nitrogen removal.

Table 15–5

Description of nitritation–denitritation processes for sidestream treatment

Process	Description
(a) BABE® process  	The BABE® (Biological Augmentation Batch Enhanced) process is an integrated sidestream-mainstream configuration designed to provide a source of nitrifier-enriched sludge for bioaugmentation of the mainstream process, but is operated under conditions that limit the oxidation of nitrite to nitrate (Berends et al., 2005). The BABE reactor can be a sequencing batch reactor (SBR) operated with intermittent aeration, a plug-flow reactor with external clarification where alternating anoxic and aerobic zones are provided or a plug-flow reactor in a MLE configuration. Regardless of the reactor configuration, the distinguishing feature of the BABE process is the addition of a portion of mainstream return activated sludge (RAS) ($<$ 10 percent of the total RAS flow) to the reactor, which serves to integrate the BABE reactor with the mainstream process and control the BABE reactor temperature at or below 25°C. Sidestream ammonium is oxidized to a mixture of nitrite and nitrate, which are subsequently reduced through endogenous denitrification with the RAS solids and the addition of an external carbon source. Free ammonia inhibition and transient anoxia are believed to be the primary mechanisms that limit nitrite oxidizing bacteria (NOB) growth in the BABE reactor. Waste sludge from the BABE reactor is sent to the mainstream process. The reactor volume requirement and the RAS flowrate (or daily volume) required for the BABE process are dependent on the overall facility inorganic nitrogen removal objective and typically developed through process modeling.
(b) Sequencing Batch Reactor (SBR)  	Nitritation-denitritation can be achieved in a SBR configuration through pH-controlled or time-based intermittent aeration with the DO concentration controlled at 1 mg/L or less during the aerated periods (Wett, 1998). An external carbon source or a facility carbon source such as primary sludge is added during the anoxic phases to promote denitritation. Continuously feeding sidestream to the SBR during the *React* phase is typically practiced in full-scale systems. However, for sidestreams with a COD/N ratio approaching 1, an intermittent feeding strategy may be beneficial to minimize the external carbon demand. The SBR typically operates at temperatures above 30°C due to biological heat generation and may require heat removal through an external mixed liquor cooling loop or through the addition of dilution water to maintain the reactor temperature below 38°C. A total solids retention time (SRT) in range of 5 to 10 d is typical.

(*continued*)

Table 15–5 (*Continued*)

Process	Description
(c) SHARON® process 	The SHARON® (Stable reactor system for High Ammonia Removal Over Nitrite) process consists of anoxic-aerobic continuous stirred tank reactors (CSTRs) in a series configuration, without suspended solids retention. The process is operated in the temperature range of 35 to 38°C. The design SRT of the aerobic zone is 1.5 d under this elevated operating temperature and controlled at this value through intermittent aeration, which allows growth of ammonia oxidizing bacteria, but provides a washout rate that prevents the growth of nitrite oxidizing bacteria (Hellinga, 1998). The design anoxic SRT is typically 0.75 d. The anoxic and aerobic volumes are based on the sidestream design flow and their respective design SRT values. If the sidestream is diluted with primary and plant effluent, the diluted flowrate serves as the basis for the anoxic and aerobic zone volumes. An internal recycle flow of 13 times the feed flow (undiluted or diluted sidestream) is provided to supply nitrite to the anoxic zone. An external carbon source is supplied to the anoxic zone for denitritation and to generate alkalinity to support nitritation. The addition of an external alkalinity source may also be required to sustain the target inorganic nitrogen removal efficiency. Heat generated by the biological reactions is removed through an external mixed liquor cooling loop, which can also serve as a method for heat addition if heat losses during the winter period are excessive. Highly concentrated sidestreams are typically diluted with primary or plant effluent to lower the ammonium concentration to 1500 mg N/L or less.

Treatment Processes

Nitritation-denitritation processes have also been developed and implemented at a full-scale for separate sidestream treatment. Process development has also led to integrated sidestream-mainstream configurations where the oxidation of nitrite to nitrate is not controlled completely, but nitrite remains the dominant product that accumulates during the ammonium oxidation step. The principal separate and integrated processes are

BABE® process

Sequencing batch reactor

SHARON® process

Summary information on these processes, including process flow diagrams, is provided in Table 15–5.

15–10 PARTIAL NITRITATION AND ANAEROBIC AMMONIUM OXIDATION (DEAMMONIFICATION) PROCESSES

Further reduction in aeration energy and chemical demand for sidestream inorganic nitrogen removal can be achieved by implementing processes that perform partial nitritation and support the growth and enrichment of Anammox bacteria. Anammox bacteria are autotrophic organisms capable of oxidizing ammonium under anoxic conditions, using nitrite as the electron acceptor. The development and implementation of processes designed to perform sequential partial nitritation and anaerobic ammonium oxidation ("Deammonification") has accelerated since the first full-scale systems were commissioned in Germany and The Netherlands in 2001–2002.

In the initial development of deammonification processes, researchers found that stable deammonification can be achieved within a single reactor where the two primary reactions occur in a suspended biomass or a biofilm (Kuai and Verstraete, 1998; Olav Sliekers et al., 2002; Siegrist et al., 1998; Seyfried et al., 2001). Two early process names (1) Completely Autotrophic Nitrogen removal Over Nitrite (CANON) and (2) Oxygen-Limited Autotrophic Nitrification Denitrification (OLAND) soon fell out of use, as specific trademarked process names became the norm. The processes described in this section are summarized in Table 15–6.

Fundamental Process Considerations

To understand deammonification processes and the advantages they present in reducing the cost of removing inorganic nitrogen from sidestreams, the biology, kinetics and reaction stoichiometry of Anammox bacteria, and their syntrophic relationship with aerobic ammonium oxidizing bacteria are summarized briefly below.

Process Biology, Kinetics, and Stoichiometry. Anammox organisms have been detected in marine and fresh water environments, soils, sediments, wetlands, and of particular interest for the discussion of sidestream treatment, in wastewater treatment plants (Kuenen, 2008; Van Hulle et al., 2010). Activated sludges from conventional nitrification/denitrification plants have been used for the startup of bench, pilot, and full-scale processes that incorporate the Anammox reaction (Fux et al., 2002; Third et al., 2005; van der Star et al., 2007).

The biochemistry and growth kinetics of the anammox bacteria are provided in Chaps. 7 and 8. As discussed in these chapters and summarized below, anammox bacteria have a maximum specific growth rate that is approximately one-tenth of the growth rate of aerobic nitrifying organisms. Therefore, a long SRT is a key feature in the design of all deammonification processes. Additional environmental factors that control their growth are also summarized below. The stoichiometry of the partial nitritation and Anammox reactions is given below.

Partial Nitritation. If ammonium is oxidized partially to nitrite (*partial nitritation*) according to the stoichiometric reaction given by Eq. (7–92), the stoichiometric ratio of ammonium and nitrite needed for the anammox reaction is obtained as shown in Eq. (15–13). The neutralization of the acidity produced by the nitritation reaction with bicarbonate alkalinity is included in the partial nitritation stoichiometry for discussion purposes.

$$\begin{aligned}&2.34\mathrm{NH_4^+} + 1.87\mathrm{O_2} + 2.66\mathrm{HCO_3^-} \rightarrow \\ &\qquad 0.02\mathrm{C_5H_7NO_2} + \mathrm{NH_4^+} + 1.32\mathrm{NO_2^-} + 2.55\mathrm{CO_2} + 3.94\mathrm{H_2O}\end{aligned} \tag{15–13}$$

Anammox Reaction. Under oxygen-free conditions anammox bacteria will oxidize ammonium using nitrite as the electron acceptor. The principal stoichiometric reaction, including cell mass synthesis, is shown in Eq. (15–14) (Strous et al., 1998).

$$\begin{aligned}&\mathrm{NH_4^+} + 1.32\mathrm{NO_2^-} + 0.066\mathrm{HCO_3^-} + 0.13\mathrm{H^+} \rightarrow \\ &\qquad 1.02\mathrm{N_2} + 0.26\mathrm{NO_3^-} + 0.066\mathrm{CH_2O_{0.5}N_{0.15}} + 2.03\mathrm{H_2O}\end{aligned} \tag{15–14}$$

Table 15–6

Description of partial nitritiation—anaerobic ammonium oxidation (*deammonification*) processes

Process	Description
(a) ANITA™Mox–Single stage moving bed biofilm reactor process  	ANITA™Mox is a single-stage deammonification moving bed bioreactor (MBBR) system that is continuously aerated with a variable dissolved oxygen (DO) setpoint in the range of 0.5 to 1.5 mg/L, based on online reactor ammonium and nitrate measurements. DO setpoint adjustment is required to control nitrite oxidizing bacteria (NOB) growth and provide stable ammonium removal. Due to continuous aeration, mechanical mixing is only required during startup and periods of low ammonia loads. The fraction of the reactor volume occupied by the media does not exceed 50 percent to prevent insufficient mixing and media movement throughout the reactor volume. The AnoxKaldnes plastic media with an active specific area of 500 m^2/m^3 or higher have been used in this process.
(b) DeAmmon® moving bed biofilm reactor process  	DeAmmon® consists of a single or dual train reactor system with three stages per reactor (designed by Purac). The stages are operated in series, but piping flexibility is provided to allow parallel operation. Kaldnes (AnoxKaldnes/Veolia) K1 media has been used typically for biofilm support (active surface area of 500 m^2/m^3). Each stage is aerated intermittently to provide aerobic and anoxic periods for the partial nitritation and anammox reactions, respectively, and continuously mixed with mechanical mixers. The duration of the aerobic and anoxic periods are dependent on the ammonium loading to the system and the removal rate. Aeration and anoxic times of 20 to 50 min and 10 to 20 min, respectively, are typical. A DO concentration of 3 mg/L during the aeration periods is targeted, but higher concentrations are avoided to prevent the potential for NOB growth and to limit anammox inhibition. Typically, the fraction of the reactor volume occupied by the media does not exceed 50 percent to prevent insufficient mixing and media movement throughout the reactor volume.
(c) DEMON® Sequence Batch Reactor (SBR)  	The DEMON® SBR is a suspended growth reactor operated by pH-controlled or time-based intermittent aeration to provide aerobic periods for the partial conversion of ammonium to nitrite and anoxic periods for the anammox reaction (Wett, 2006). The peak DO concentration during each aerobic phase is controlled at approximately 0.3 mg/L to provide selective pressure against NOB growth and allow a rapid transition to an anoxic condition after the air is shut off to promote an optimal environment for the anammox bacteria. To minimize the impact of nitrite on anammox activity, the aeration period in each cycle is typically around 10 to 15 min (anoxic period is typically 5 to 10 min). If pH is used to control the aeration cycle, a pH interval of 0.01 or 0.02 units is applied. The mean operating pH is typically maintained above 6.8 to minimize inorganic carbon loss through air stripping of CO_2. The SBR is continuously fed during the *React* phase of each SBR cycle. Because the anammox bacteria grow in the SBR is in a dense granulated form, the waste sludge is pumped through hydrocyclones to separate the anammox granules from the remaining flocculated solids and return them to the reactor. Consequently, the solids retention time (SRT) of the anammox bacteria approaches 40 to 50 d and the SRT of the remaining solids [ammonia oxidizing bacteria (AOB), heterotrophs, inert solids] is maintained around 10 d, which provides further selective pressure against NOB growth and more stable performance over a range of loading conditions (Wett et al., 2010).

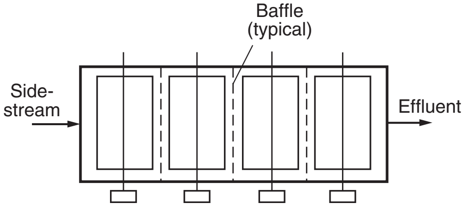
Table 15–6 (*Continued*)

<table>
<tr><th>Process</th><th>Description</th></tr>
<tr><td>

(d) Rotating Biological Contactors (RBCs)

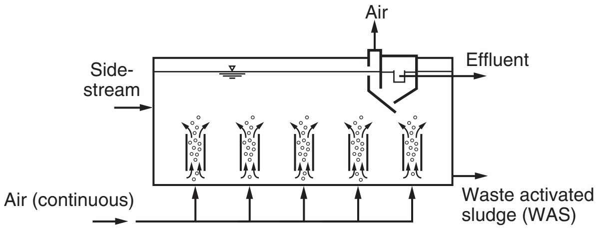


</td><td>

Rotating Biological Contactors (RBC) have been applied for leachate treatment and were found to promote the development of deammonification as the dominant nitrogen removal pathway (Seyfried et al., 2001). The deammonifying RBCs vary in configuration and media material, but demonstrated an average surface specific deammonification rate of approximately 2.5 g $N/m^2 \cdot d$ with peak rates up to 4.8 g $N/m^2 \cdot d$. The typical RBC bulk liquid DO concentration is 1 mg/L. For leachates rich in degradable organic carbon, biological removal of the carbon is required before the deammonification RBCs. Deammonification performance was stable at operating temperatures less than 20°C and a nitrogen removal efficiency of 70 percent was reported at temperatures as low as 10°C (Seyfried, 2002). Information is not readily available on submergence depth or rotational velocity required to induce or optimize deammonification performance.

</td></tr>
<tr><td>

(e) Single-Stage ANAMMOX® process

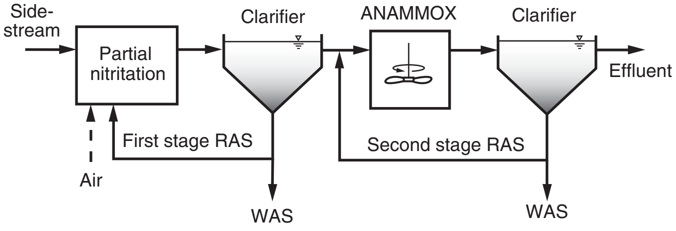


</td><td>

The single-stage ANAMMOX® reactor (designed by Paques BV, The Netherlands) was initially based on an air lift design where air is continuously applied to the bases of multiple riser tubes, resulting in upward liquid-solids movement through the risers and downward movement of liquid-solids outside the risers after gas disengagement. The hydrodynamic conditions favor the development of a thick well-granulated biomass where the AOB and anammox populations grow synergistically within the same granules. In a later development of this process, sludge granulation was shown to be stable without the need for riser tubes, simplifying the design. A proprietary gas-liquid-solids separator(s) located in the upper section of the reactor provides separation of the liquid-solids from the exhaust air and a settling zone for the granulated solids, which return to the main reaction zone. Pretreatment of the sidestream to remove denser inert solids is advisable to prevent their accumulation in the reactor. Online measurement of DO, nitrite and ammonium are used to control the process.

</td></tr>
<tr><td>

(f) Terra-N® process

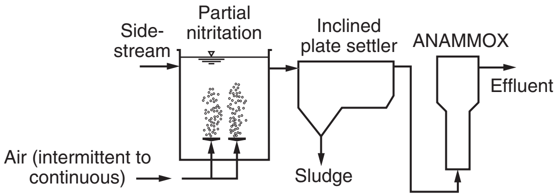


</td><td>

The Terra-N® MBBR process was developed by SÜD-Chemie/Clariant GmbH (Munich, Germany) where bentonite is used as the support media for biofilm growth (TERRANA® product; mean particle diameter in the range of 25 to 45 μm). Due to the rapid settling rate and compaction of the bentonite particles, gravity clarification is applied for separation of the media and biofilm from the bulk liquid. The process is designed in a two-stage configuration, with each stage consisting of a completely mixed reactor and a gravity clarifier (continuously aerated partial nitritation stage followed by a completely mixed anoxic stage for the anammox reaction), or as a single-stage SBR with intermittent aeration. In the SBR and the partial nitritation stage of the two-stage configuration, bentonite is added to a concentration of 10 to 12 g/L. With biomass attachment, the total suspended solids concentration is typically 15 to 20 g/L. In the anammox stage of the two-stage configuration, granulation of the anammox bacteria eliminates the need for a support media, although the addition of bentonite is not detrimental. Second-stage biomass concentrations of 5 to 7 g/L have been reported (Clariant/SÜD Chemie, 2012).

</td></tr>
</table>

(g) Two-stage SHARON®–ANAMMOX® process



Deammonification can be accomplished in a two-stage system consisting of partial nitritation followed by the anammox reaction. In the first stage, a CSTR is operated at an aerobic SRT of approximately 1.5 d (based on the SHARON® concept) at a temperature above 30°C, without alkalinity or organic carbon addition, to convert approximately 50 percent of the sidestream ammonium to nitrite. The partially nitritated sidestream is fed to the second stage ANAMMOX® reactor (provided by Paques BV, The Netherlands) operated in an upflow configuration. Under a high upflow superficial liquid velocity, anammox bacteria form dense granules with settling velocities greater than 100 m/h, which allows the development of a sludge bed in the lower section of the reactor with a solids concentration as high as 5 to 7 percent. Flocculated particles with lower densities and settling velocities are washed out. Solids separation between the two reactors is recommended to prevent the accumulation of denser inert solids in the ANAMMOX® reactor sludge bed. Internal liquid mixing within the ANAMMOX reactor is provided by a gas-lift mechanism where nitrogen gas produced by the sludge bed is collected through a proprietary gas collection system located above the mid-depth point of the tank, which conveys the gas to a central riser pipe, inducing gas-lift of liquid to a gas-liquid separator located on top of the reactor. De-gassed liquid is returned to the bottom of the tank to increase the superficial liquid velocity in the sludge bed and dilute the partially nitritated sidestream entering the reactor.

Because the Anammox bacteria use inorganic carbon as their source of carbon for growth and nitrite is used as the electron acceptor, inorganic nitrogen is removed without the addition of an organic carbon substrate. As illustrated in Eq. (15–14), nitrate is a product of the reaction; hence, some organic carbon is required for complete inorganic nitrogen removal. For every kg of ammonium-N that is removed by the two-step deammonification pathway [see Fig. 15–9(c)], 0.11 kg of nitrate-N is produced. Consequently, deammonification reduces the organic carbon demand to about 11 percent of the carbon demand required by heterotrophic reduction of nitrate to nitrogen gas in a nitrification-denitrification process. The corresponding oxygen requirement for deammonification is also reduced to approximately 40 percent of the oxygen required for complete oxidation of ammonium to nitrate by the two-step aerobic autotrophic pathway.

Alkalinity Requirement. Bicarbonate in a typical high strength sidestream is equal to the ammonium concentration on a molar basis. As shown in Eqs. (15–13) and (15–14) above, the total amount of bicarbonate required to neutralize acidity produced by ammonium oxidation to nitrite and to support autotrophic cell growth will exceed the amount available in the sidestream. Nitrate reduction in the sidestream reactor, in part or entirely, depending on the degradable COD in the sidestream, will generate bicarbonate alkalinity, but the amount is insufficient to provide the balance required to satisfy the overall bicarbonate stoichiometric demand. In practice, deammonification processes typically achieve sufficiently high ammonium removal efficiencies that no external alkalinity source is added (greater than 80 percent removal, with 90 to 95 percent being typical). If ferrous or ferric chloride is added to the digesters or other locations to control struvite formation, the addition of alkalinity to the deammonification system to compensate for the alkalinity destroyed by iron salt addition may be justified or required if a high inorganic nitrogen removal efficiency is required.

Solids Retention Time. Anammox organisms have a maximum specific growth rate that is less than one-tenth the rate of aerobic nitrifying bacteria (see also Table 7–13 in Chap. 7). Hence, a SRT greater than 20 d is required to sustain these organisms in a biological reactor. Fortunately, anammox bacteria produce an excessive amount of exocellular polymeric substances (Cirpus et al., 2006), which results in tightly bound aggregation and granule formation as the organisms are concentrated in a suspended growth reactor. The formation of a granulated biomass results in high solids settling rates and a high solids specific gravity which can be exploited to separate the granules from flocculated solids. These features allow process configurations that can easily retain the anammox bacteria within the processes. Integration of the organisms within a biofilm also occurs readily once the environment conducive to their growth and sufficient surface area are provided.

Implementation of Deammonification Processes and Challenges. The first deammonification processes were developed for high strength sidestreams where the warm sidestream temperatures are advantageous in enhancing the growth rate of the anammox organisms. For suspended growth sequencing batch reactors, intermittent aeration combined with a low dissolved oxygen (DO) concentration (0.3 mg/L) during the aerobic period of each aeration cycle has proven to be an effective way to provide conditions for the growth of aerobic ammonia oxidizing and anammox bacteria while restricting the growth of aerobic nitrite oxidizing bacteria (Wett, 2007).

Nitrite accumulation in biofilms can also be induced by operating the attached growth reactor at a reduced bulk liquid DO concentration, providing an environment within the biofilm where the Anammox organisms can thrive. Sustaining the growth of aerobic ammonia oxidizing and anammox bacteria within a single reactor, while preventing growth of aerobic nitrite oxidizing bacteria, has also been demonstrated with continuously aerated gas-lift reactors where the hydrodynamic conditions induced by the aeration system creates a granulated sludge, which can be retained to a high concentration (Olav Sliekers et al., 2003; Abma et al., 2010). With a low DO concentration, aerobic and anoxic zones within the granulated sludge provide environments for aerobic ammonia oxidizer and anammox growth.

Although the anammox reaction is attractive from the perspective of reducing the plant operating cost associated with inorganic nitrogen removal, incorporating anammox bacteria within a biological reactor system has presented a number of technical challenges. First and foremost, due to their low growth rate, a long reactor startup period is required in comparison to a nitrification-denitrification or nitritation-denitritation system and a long recovery period is also needed in the event of a significant reduction in anammox activity. However, seeding a new installation with anammox-enriched biomass has been demonstrated to facilitate startup (Wett, 2006; Abma et al., 2007; Schneider et al., 2009; Christensson et al., 2011). Due to the increasing number of deammonification plants, seed availability is increasing. The degree to which startup can be hastened depends on ammonium load to the startup plant and mass of seed that can be obtained.

The anammox bacteria are also sensitive to nitrite, which can cause irreversible loss of activity. Various levels of nitrite exposure, both in terms of concentration and exposure time, and the corresponding loss of activity have been reported (Fux et al., 2004; Wett et al., 2007), which indicate that nitrite toxicity is a function of both concentration and exposure time. Exposure to oxygen also results in the inhibition of anammox activity, but the effect is reversible. Finally, anammox organisms compete with NOB for nitrite; therefore, the reactor operating conditions must be well-controlled to limit NOB growth or provide an environment where anammox bacteria have a competitive advantage.

Treatment Processes

Process configurations designed for deammonification include

ANITA™Mox moving-bed biofilm reactor process
DeAmmon® moving-bed biofilm reactor process
DEMON® suspended growth sequencing batch reactor
Rotating biological contactors
Single-stage ANAMMOX® process
Terra-N® moving-bed biofilm reactor process
Two-stage SHARON®-ANAMMOX® process

Summary information on these processes, including process flow diagrams, is provided in Table 15–6.

15–11 PROCESS DESIGN CONSIDERATIONS FOR BIOLOGICAL TREATMENT PROCESSES

Process design considerations for the biological systems described in Sec. 15–8 through 15–10 are presented in this section. The principal design considerations include (1) sidestream characteristics and treatment objectives (2) design loadings and load equalization,

(3) sidestream pretreatment, (4) reactor volume requirements, (5) aeration system design, (6) sludge retention time and mixed liquor suspended solids concentration, (7) chemical addition (organic carbon requirements for denitrification and denitritation; alkalinity), (8) operating temperature and pH, and (9) heat removal. An example problem is presented following the discussion of the design considerations, to illustrate their application.

Sidestream Characteristics and Treatment Objectives

The characteristics of high strength sidestream, as noted in Sec. 15–1, are dependent on the process from which the sidestream is derived and the process operating conditions. Therefore, when designing a process for sidestream treatment, the characteristics of the specific sidestream should be measured. The sidestream parameters that should be considered are summarized in Table 15–7. Because nitrogenous oxygen demand is an important process design parameter, both soluble and total TKN measurements are included in sidestream characterization, to estimate the biodegradable organic nitrogen concentration. However, a significant fraction of the organic TKN in sidestreams may be comprised of recalcitrant dissolved organic nitrogen (rDON) and nitrogen associated with biologically inert suspended solids. Typically, about 50 percent of the soluble organic TKN (soluble TKN minus ammonium-N) in sidestream derived from anaerobic digestion is biodegradable. Of the particulate TKN, typically 10 to 15 percent of TKN fraction is biodegradable under aerobic conditions.

If the sidestream is to be generated in the future as a result of the implementation of a new solids processing system, a bench or pilot-scale sludge digestion study is recommended so that the soluble constituents in the sidestream reflect the conditions in the

Table 15–7

Parameters to consider when designing a sidestream treatment system

Parameter	Unit	Remarks
Flowrate (average/minimum/maximum)	m^3/d	
Dewatering operation frequency	d/wk	
Dewatering operation hours	h/d	
Temperature (average/minimum/maximum)	°C	
Total suspended solids	mg/L	Dependent on pretreatment requirements
Volatile suspended solids	mg/L	Dependent on pretreatment requirements
Alkalinity	mg/L as $CaCO_3$	
Total $cBOD_5$[a]	mg/L	
Soluble $cBOD_5$[a]	mg/L	0.45μm membrane filtered
Ammonium-N	mg N/L	Typically 90 to 95 percent of soluble TKN
Soluble TKN[b]	mg/L	0.45μm membrane filtered
Total TKN[c]	mg/L	
Soluble ortho-P	mg/L	

[a] A degradable-COD to cBOD5 ratio of 1.5 g/g can be assumed to estimate the degradable particulate and soluble COD fractions.

[b] Difference between the soluble TKN and ammonium-N is the soluble organic N of which roughly 50 percent is typically considered biodegradable for sidestream derived from anaerobic digestion of primary and secondary sludges.

[c] Difference between the total TKN and soluble TKN is the particulate TKN of which roughly 10 to 15 percent is typically considered biodegradable for sidestream derived from anaerobic digestion of primary and secondary sludges.

digestion process and the characteristics of the sludges and biosolids. The TSS concentration in the sidestream is estimated by the capture efficiency range anticipated in the full-scale dewatering process. In the absence of such tests, the ammonium-N and other constituent concentrations can be estimated based on digestion process modeling.

Treatment objectives for the sidestream process will differ with each facility and are dependent on the facility effluent permit limits on nutrients and the costs associated with the energy and chemical requirements. Selection of a treatment option is also dependent on the potential benefits associated with bioaugmentation of the mainstream plant. Typically, the separate and integrated processes being considered are subjected to a life cycle cost assessment to identify the most cost effective option.

Design Loading and Load Equalization

The sidestream nitrogen and degradable carbon mass loading rates will affect the process volume and the aeration and chemical requirements. For separate treatment processes that employ solids separation for SRT control, the sidestream TSS loading rate may also impact the design as the majority of the solids are biologically inert and will accumulate in the reactor. Therefore, the maximum oxygen demand and solids loading rate are used commonly for reactor design.

The peak sidestream loading rate for reactor design is dependent on the operation of the biosolids dewatering process. Dewatering facilities at smaller treatment plants are commonly operated during daytime hours for 5 or 6 d/wk. At larger facilities, the dewatering operation typically is continuous. Where biosolids dewatering is intermittent, the implementation of flow and load equalization is a cost-effective option for reducing the volume of the treatment process and the aeration energy associated with the peak oxygen demand. Equalization of sidestream flows and loads were discussed previously in Sec. 15–2.

Sidestream Pretreatment

The majority of the separate sidestream treatment processes described in Sec. 15–8 to 15–10 will benefit from a reduction in the sidestream TSS concentration before treatment. Most of the sidestream TSS are biologically inert and will, therefore, accumulate in the sidestream reactor, potentially elevating the solids concentration to a level that can negatively impact the solids-liquid separation process and the ability to control the SRT within the desired range. Pretreatment requirements are dependent on historical sidestream TSS concentration data and the specific process being used or considered for sidestream treatment. Dynamic process modeling of many of the sidestream processes is an effective tool in assessing the need for pretreatment for existing sidestream where sufficient TSS data are available. Pretreatment options were considered in Sec. 15–3.

Reduction in the sidestream TSS to an average concentration of 200 mg/L or less is typically sufficient. For the DEMON deammonification SBR where hydrocyclones are used to separate anammox granules from other suspended solids, removal of dense particulate matter is particularly important because the hydrocyclones will also separate this material from the waste sludge and retain it in the reactor. Removal of large inert debris is critical for MBBR systems that use screens for media retention as the debris will accumulate in the reactor over time.

Sidestream solids removal is typically not a requirement for the SHARON nitritation-denitritation process as solids retention is not performed. However, if the sidestream solids concentration is high ($>$ 2000 mg/L) periodically, the removal of solids may prove beneficial in reducing oxygen demand in the aerated zone. For integrated sidestream-mainstream processes, a solids balance across the facility should be conducted to assess the impact of sidestream solids on the mainstream process.

Sidestream Reactor Volume

The conditions that define the minimum reactor volume requirement vary with the type of sidestream treatment process and are dictated by the treatment objective, the maximum achievable oxygen transfer rate, and the biological kinetic rates, as well as other considerations such as solids-liquid separation. The volume requirement for a separate sidestream reactor is commonly estimated through the use of a specific nitrogen loading rate on the system, expressed as the nitrogen loading per unit reactor volume per day (as kg $N/m^3 \cdot d$) or, in the case of fixed-film systems per unit area of active media surface area per day (g $N/m^2 \cdot d$). The maximum nitrogen loading rate (kg N/d) is selected commonly for design. The specific loading rate for a given type of process is often developed through pilot or demonstration-scale studies and full-scale operating experience. Typical values for the specific loading rate for the processes discussed in Sec. 15–8 through 15–10 are provided in Table 15–8.

A more detailed analysis is required to determine the volume requirement for a SBR or a suspended growth process with external clarification. For SBRs, the minimum volume is dictated largely by the aeration system and its ability to provide sufficient oxygen to satisfy the peak oxygen demand imposed by the sidestream (design condition) during the aerobic periods of the *react* phase. Separation of solids from the treated liquid is an additional design consideration. The reactor volume determined through the aeration system analysis must be sufficient to ensure that settled sludge inventory is not disturbed during the decanting of the treated sidestream, which further ensures that the desired SRT can be maintained. Where the anoxic reaction is occurring in a separate stage, the volume requirement depends on the reaction kinetics and is determined through process modeling or pilot studies.

For the integrated sidestream-mainstream processes, process modeling is commonly used to determine the reactor volume requirement. The volume will be influenced significantly by the desired level of inorganic nitrogen removal across the facility and the mainstream operating conditions, which affect the biological kinetic rates in the reactor or zones nitrifying and denitrifying the sidestream nitrogen load. Typical loading rates or hydraulic retention times for the various processes are also presented in Table 15–8.

Where a mainstream process of a facility does not have sufficient capacity to treat sidestream and unacceptable deterioration of the facility effluent quality would result, division of the sidestream reactor volume into multiple tanks may be a design requirement, giving the facility operator the flexibility to remove a reactor from service for maintenance and inspection. Process modeling is often used to evaluate these operating scenarios.

Aeration System

The application of oxygen demand in the design of the aeration system is specific to the type of sidestream process. The oxygen demand is comprised of the oxygen requirement for the carbonaceous oxygen demand and the oxidation of ammonium to nitrite or nitrate. Typically, complete conversion of ammonium to nitrite or nitrate is assumed in the calculation of the design oxygen demand for nitritation-denitritation and nitrification-denitrification processes, respectively. Where processes have been shown to produce a mixture of nitrite and nitrate, a conservative design approach is to provide sufficient aeration capacity for complete oxidation of ammonium to nitrate. For deammonification, the nitrogenous oxygen demand is based on the stoichiometric conversion of ammonium to nitrite that provides complete ammonium removal across the process.

Aeration Requirements for Sequencing Batch Reactors. For sequencing batch reactors where aerobic and anoxic reactions are occurring within the same reactor through alternating aerobic and anoxic phases, the temporal distribution of oxygen demand

Table 15–8

Typical design and control parameters for the biological sidestream treatment processes

Process	Key design parameters	HRT, h Ammonium-N loading rate (ALR), kg N/m^3·d Media loading rate, g N/m^2·d	SRT[a], d	Process control parameters
Nitrification and denitrification processes				
BAR and R-D-N process (RAS reaeration tank)	SRT (total), HRT (reaeration tank)	HRT = 2 (aerobic)[b] 1–2 (anoxic)	8–15 (SS+MS, total)	DO, SRT
InNitri or short SRT process (2-stage)	SRT, ALR	ALR = 0.4–0.5[c]	3–5 (SS, total)	DO, external Alk or COD add., temp., SRT
ScanDeNi process (RAS reaeration tank)	SRT (total), HRT (reaeration tank)	HRT = 1–2 (aerobic)[b] 1–2 (anoxic)	8–15 (SS+MS, total)	DO, SRT, external COD add.
Sequence Batch Reactor (SBR)	SRT, ALR	ALR = 0.3–0.4[d]	10–15 (SS, total)	DO, external Alk or COD add., temp, SRT
Nitritation and denitritation processes				
BABE process (SBR)	SRT (total), ALR, temp.	ALR = 0.4	4–8 (SS+MS, total)	RAS flow to BABE reactor, temp. (25°C, max), DO
Sequencing batch reactor	SRT, ALR	ALR = 0.4–0.6[d]	5–10 (total)	DO (<1 mg/L); external Alk/COD add.
SHARON Process	SRT (aerobic, anoxic), temp.	ALR < 0.7[e]	1.5/0.75[e] (aerobic/anoxic)	Temp (35–38 °C); aerobic SRT; external COD add.
Partial nitritation and anaerobic ammonium oxidation processes				
ANITA™Mox	Media surface area, ALR	ALR = 0.7–1.2[f]	> 20	DO (0.5–1.5 mg/L)
DeAmmon®	Media surface area, ALR	ALR = 0.6–0.8[g]	> 20	DO, aerobic-anoxic cycle times
DEMON® SBR	SRT, ALR	ALR = 0.7–1.2[h]	40–50 (Anammox granules) 10–15 (floc)	pH interval (0.01–0.02 s.u.); DO (0.3 mg/L); SRT
Rotating biological contactor	Media surface loading rate	loading rate = 2.3–2.8 g N/m^2·d[i]	> 20	DO (1 mg/L)
Single-stage ANAMMOX®	SRT, ALR, air-lift aeration design	ALR = 2.0	>20	DO, SRT, temp.
Terra-N® two-stage with intermediate clarification	Bentonite concentration, ALR, clarifier overflowrate	ALR = 1.2–2.1 (partial nitritation stage)[j] 1.2–2.1 (Anammox stage)[j]	> 20	DO

(*continued*)

Table 15–8 (*Continued*)

Process	Key design parameters	HRT, h Ammonium-N loading rate (ALR), kg N/m^3·d Media loading rate, g N/m^2·d	SRT[a], d	Process control parameters
Terra-N®-single-stage	Bentonite concentration, ALR	ALR = 0.25–0.7 (1.5)[k]	> 20	DO
Two-stage SHARON®-ANAMMOX®	SRT, ALR, upflow liquid velocity	ALR < 0.7 (SHARON); 3–10 (ANAMMOX)	1.5 (SHARON, aerobic) > 20 (ANAMMOX)	Aerobic SRT, temp (SHARON) Upflow liquid velocity, SRT (ANAMMOX)

[a] Notations: SS = sidestream reactor(s); MS = mainstream secondary reactor(s); total = sum of the aerobic and anoxic SRT values.

[b] Aerobic and anoxic hydraulic retention times and RAS reaeration tank volume based on the maximum RAS flow, typically a 100% return rate, at the minimum operating temperature. HRT values shown are typical. Tank geometry is plug flow and the volume is dependent on the desired nitrification performances in the RAS reaeration tank and the mainstream plant at the minimum operating temperature. Modeling is typically used in this assessment and the autotrophic growth rates are adjusted to approximately 0.5–0.6 d^{-1} (20°C) to account for the effect of low pH on the growth rate.

[c] Loading rate based on total system volume with an aerobic/anoxic volume ratio of 2:1 and a maximum OUR of 150 mg/L·h.

[d] Maximum ammonium removal rate based on three 8-h cycles per day with a *react* period of 6 h per cycle, an intermittent aeration cycle of 66 percent aerobic–34 percent anoxic, a maximum total OUR of 150 mg/L·h.

[e] Maximum specific rate based on total system volume with aerobic/anoxic ratio of 2:1 and a maximum OUR of 150 mg/L·h. Aerobic and anoxic SRTs based on influent flowrate, e.g. if dilution water is added, the volume requirements are based on the diluted sidestream flowrate.

[f] Loading rate dependent on the type of plastic media employed and its effective surface area for biofilm growth. A removal rate up to 1.2 kg N/m^3·d with AnoxKaldnes BiofilmChip™M (effective surface area of 1200 m^2/m^3 of media; 40 percent media fill volume) was reported by Christensson et al. (2011) and Lemaire et al. (2011).

[g] AnoxKaldnes K1 media, effective surface area for biofilm = 500 m^2/m^3 of media; deammonification rate = 1.5 to 2 g N/m^2 of effective surface area per day (Plaza et al., 2011).

[h] Demonstrated range of loading rates. Design loading rate is typically 0.7 kg N/m^3·d.

[i] Loading rates correspond to average nitrogen removal rates demonstrated by RBC systems treating landfill leachate. Peak removal rates up to 4 g/m^2·d have been demonstrated (Siegrist et al., 1998; Seyfried, 2002).

[i] Loading rates demonstrated for retrofitted tanks (Clariant/SÜD Chemie, 2012). Partial nitritation and anammox reactor volumes are typically equal. Proprietary clarifier design-clarifier surface overflowrate and typical solids return flowrate not disclosed by vendor.

[k] Range of values demonstrated for retrofitted tanks. Value in parenthesis is considered by the vendor to be the maximum design loading rate for a new tank (Clariant/SÜD Chemie, 2012).

has an effect on reactor volume and blower capacity requirements. For example, a SBR operating at three cycles per day with a combined *settle*, *decant* and *idle* time of 1.5 h/cycle, the total *react* time over the day is 19.5 h. If the reactor is operated with intermittent aeration during the *react* periods with an aerated:anoxic time ratio of 2/1, the total aeration time is 13 h/d. Therefore, the minimum reactor volume and the design of the aeration system are based on the daily oxygen demand being satisfied over the total aerated time period. Allocation of carbonaceous oxygen demand in the aerated and anoxic periods is dependent on if the reactor is fed continuously during the *react* period, fed rapidly at the beginning of each SBR cycle or fed intermittently during the anoxic phases of the aeration cycle. Process modeling is often used in assessing the total oxygen demand for design.

Type of Aeration System. Because the development of advanced biological treatment processes has been driven partially by the desire to reduce aeration energy, fine and ultra-fine bubble air diffusion systems are common in suspended growth reactors. To achieve a more compact reactor design, maximum floor coverage applicable to the type of diffuser is applied. A design oxygen uptake rate (OUR) of 150 mg/L·h is used commonly for fine and ultrafine bubble diffused air systems. Diffuser selection takes into account the material of construction as some manufacturers specify a maximum wastewater temperature limit for their diffusers (e.g., 30°C), which may be lower than the anticipated average operating temperature of the reactor.

Alpha and fouling factors (see Sec. 5–11 in Chap. 5) are developed through testing or provided by the process technology or diffuser vendor based on their experience with similar applications. The utilization of high purity oxygen is uncommon, but is applicable to separate and integrated sidestream-mainstream systems. High purity oxygen would satisfy a considerably higher OUR, which may allow a reduction in the reactor volume, depending on other operating conditions such as SRT, mixed liquor suspended solids concentration and kinetic rates.

In MBBR systems that employ plastic media, medium to coarse bubble stainless steel air diffusers are standard practice to reduce maintenance requirements and the risk of having to remove the media from the reactor to replace diffusers. The dissolved oxygen concentration requirement is specific to the process and typical values are provided in Table 15–8.

Sludge Retention Time and Mixed Liquor Suspended Solids Concentration

The design SRT is specific to each type of sidestream process. Typical SRT ranges employed in the processes described in Sec. 15–8 through 15–10 are presented In Table 15–8. For suspended growth separate reactors where solids-liquid separation is employed, the suspended solids concentration is typically kept below 4000 mg/L (at the maximum liquid level in a SBR), depending on the settling and compaction characteristics of the solids. Consequently, the impact of the sidestream TSS load on the reactor solids concentration should be examined to determine if the process would benefit from a sidestream pretreatment step where the suspended solids concentration is reduced.

Chemical Requirements

Alkalinity and/or organic carbon addition is often required for many of the nitrification-denitrification and nitritation-denitritation processes, especially if a high ammonium or inorganic nitrogen removal efficiency is desired. Deammonification processes generally do not require any chemical addition, but in certain cases alkalinity addition may prove beneficial. Some of the key considerations for each chemical category are summarized below.

Alkalinity. The importance of alkalinity for ammonium oxidation and the stoichiometric requirements are discussed in Sec. 15–8. As described in Sec. 15–1 and 15–8, the alkalinity in high strength sidestream typically provides up to 50 percent of the total alkalinity required for complete ammonium oxidation. Therefore, an external alkalinity source is added or alkalinity is generated through nitrate or nitrite reduction with an external organic carbon source. In the integrated sidestream-mainstream systems where a portion of the mainstream RAS is fed to the sidestream reactor, RAS will provide a fraction of the alkalinity requirement, reducing the external alkalinity demand. For the BAR/R-D-N/ScanDeNi processes where sidestream is diluted into the entire RAS stream in a RAS reaeration tank, the RAS alkalinity is typically sufficient to meet the alkalinity requirement.

Alkalinity Addition. Under the warm, high rate growth conditions in a separate sidestream reactor, inorganic carbon can impact the autotrophic growth rate at concentrations that would not impact their growth rate under mainstream process conditions (see discussion in Sec. 15–8). As shown in Eq. (15–8), as the bicarbonate concentration approaches the saturation coefficient value, which has been estimated at 4 mole/L (200 mg/L as $CaCO_3$). Concomitantly, the AOB growth rate is reduced, resulting in a reduction in the ammonium removal efficiency in systems operated at or near their design sidestream loading rate. External alkalinity addition has been shown to increase the nitrogen removal in deammonification pilot reactors, reducing the residual ammonium concentration (Yang et al., 2011). The improvement in reactor performance through alkalinity addition may be justified, depending on an economic analysis in which the cost of alkalinity addition is compared to the cost associated with treating the residual ammonium in the mainstream plant (e.g., aeration energy, organic carbon requirement).

Sources of Alkalinity. Caustic soda is the source of alkalinity used most commonly, due to ease of handling and availability. Magnesium hydroxide and sodium carbonate can also be used. Lime is generally avoided due to its limited water solubility and the potential formation of insoluble calcium carbonate. The selection of alkalinity source may be dependent on the regional market conditions for these chemicals.

Organic Carbon. The organic carbon requirement for design is based on complete nitrite or nitrate removal and the type of carbon source. A discussion of commercially available carbon sources is presented in Sec. 8–7 in Chap. 8. Although methanol and glycerol are the carbon sources used most commonly in sidestream treatment, any readily biodegradable carbon source can be used so long as nitrification reaction is not inhibited as a consequence of its addition. The COD demand for nitrate and nitrite reduction can be estimated using Eqs. (7–126) and (15–12), respectively. The observed sludge yields required in these two equations can also be estimated or the COD-to-N ratio can be developed through pilot testing.

Due to the cost of purchasing, storing, and handling an external carbon source, particularly if the carbon source is classified as a hazardous compound (e.g., methanol), a source of organic carbon from within the wastewater treatment facility may be preferred. Fermentation of degritted primary and secondary sludges are established methods for producing readily biodegradable COD in the form of volatile fatty acids to enhance nutrient removal in the mainstream process as described in Sec. 8–7 in Chap. 8. However, there are practical limitations to using primary sludge fermentate in separate sidestream reactors, as the rbCOD is dilute and typically separated from the residual primary solids by elutriation.

Primary sludge and combined primary and secondary sludges have been used as the carbon source for nitrite and nitrate reduction (Wett et al., 1998; Bowden et al., 2012).

In both cases, pretreatment of the sludges through hydrolysis and fermentation may enhance the utilization of the carbon for nitrite and nitrate removal. Screened and degritted sludge is also preferred to limit the introduction of inert materials and debris into the sidestream reactor. Diverting a portion of the plant sludge to the sidestream process results in an incremental decrease in anaerobic digester gas production, but such a diversion may be acceptable, if the sludge has greater economic value as a carbon source for nitrogen removal.

Operating Temperature and pH

The operating temperature of the separate sidestream reactor should not exceed 38°C to avoid inhibiting the ammonium oxidation rate. The lower temperature limit is specific to the process and the desired performance of the system. In general, separate sidestream reactors do not operate at temperatures below 20°C due to the sidestream temperature and biological heat generation. Integrated sidestream-mainstream processes where the sidestream is blended with a portion or the entire mainstream RAS will operate over a broad temperature range due to seasonal changes in the plant influent temperature.

Operating pH

The operating pH of separate sidestream reactors is typically above 6.8 to avoid a pH-limited autotrophic growth rate and limit free nitrous acid inhibition, if nitrite is accumulating to a high concentration. In the RAS reaeration tank of integrated sidestream-mainstream processes (BAR/R-D-N/ScanDeNi), the pH typically decreases to or below 6.5. The impact of lower pH on nitrification performance is accounted for typically in the design by reducing the autotrophic maximum specific growth rates by 40 to 50 percent when modeling the process to determine the reaeration tank volume requirement or to predict performance with an existing tank.

Energy Balance to Determine Reactor Cooling Requirements

The biological reactions associated with nitrification-denitrification, nitritation-denitritation and deammonification are exothermic. Due to the high ammonium concentration and temperature of sidestreams derived from anaerobic sludge digestion, biological heat generation may increase the separate sidestream reactor temperature beyond 38°C, impairing process stability and performance. Therefore, a heat balance is required using the following information to determine if heat removal or the addition of dilution water is required to maintain the sidestream reactor temperature within the desired range.

1. Sidestream flow and constituent concentrations
2. Sidestream enthalpy at reactor inlet
3. Biological heat generation rates
4. Heat losses due to evaporative cooling (aeration and induced by air movement across the open reactor surface), radiation and solar heat transfer and conductive heat transfer through reactor floor and walls
5. Treated sidestream enthalpy at reactor temperature
6. Mechanical energy inputs (blower compression energy, mechanical mixers)

Heat of reactions associated with the principal biological reactions are provided in Table 15–9. The values reported in Table 15–9 take into account cell mass growth. The influent and treated sidestream enthalpies are approximated by the enthalpies of pure water at their respective temperatures.

Table 15–9

Heat of reaction at standard conditions for biological reactions

Reaction	Heat of reaction at 25°C and 1 atm[a]
Nitritation[b]: $NH_4HCO_3 + 1.5O_2 + HCO_3^- \rightarrow NO_2^- + 2CO_2 + 3H_2O$	−14.3 MJ/kg-N
Nitrification[b]: $NH_4HCO_3 + 2O_2 + HCO_3^- \rightarrow NO_3^- + 2CO_2 + 3H_2O$	−21.8 MJ/kg-N
Deammonification[b]: $NH_4HCO_3 + 0.85O_2 + 0.11HCO_3^- \rightarrow 0.44N_2 + 0.11NO_3^- + 1.11CO_2 + 2.56H_2O$	−18.6 MJ/kg-N
Denitritation (external rbCOD): $COD + a\ NO_2^- + b\ CO_2 \rightarrow a\ HCO_3^- + 0.5b\ N_2 + c\ C_5H_7NO_2 + d\ H_2O$	$= [-17.0 + (25.5 \times Y_H{}^c)]$ MJ/kg-COD[d]
Denitritation (primary/secondary sludges): $COD_{VSS} + e\ NO_2^- + f\ CO_2 \rightarrow e\ HCO_3^- + 0.5f\ N_2 + g\ NH_4HCO_3 + h\ H_2O$	
Primary: $C_{4.66}H_{7.2}N_{0.21}O_{2.06}$	−23.9 MJ/kg-COD
Secondary: $C_5H_7NO_2$	−21.8 MJ/kg-COD
Denitrification (external rbCOD): $COD + i\ NO_3^- + j\ CO_2 \rightarrow i\ HCO_3^- + 0.5i\ N_2 + k\ C_5H_7NO_2 + k\ H_2O$	$= [-13.6 + (20.7 \times Y_H{}^c)]$ MJ/kg-COD[d]
Denitrification (primary/secondary sludges): $COD_{VSS} + l\ NO_3^- + m\ CO_2 \rightarrow l\ HCO_3^- + 0.5l\ N_2 + n\ NH_4HCO_3 + o\ H_2O$	
Primary: $C_{4.66}H_{7.2}N_{0.21}O_{2.06}$	−14.1 MJ/kg-COD
Secondary: $C_5H_7NO_2$	−14.3 MJ/kg-COD

[a] Heat of reaction values calculated by:

$$\Delta H^\circ = \left(\sum_i \nu_i \overline{H}_{f,i}{}^\circ\right)_{\text{products}} - \left(\sum_i \nu_i \overline{H}_{f,i}{}^\circ\right)_{\text{reactants}}$$

Where ν_i = the stoichiometric coefficient

$\overline{H}_{f,i}{}^\circ$ = standard heat of formation of species *i* at standard conditions of 25°C and 1 atm pressure.

Standard heats of formation for bicarbonate, nitrite and nitrate based on aqueous sodium salts (Green and Perry, 2007; Haynes, 2012). Heats of formation were not adjusted from standard conditions to typical sidestream reactor conditions. Heat of formation for cell mass estimated at −258 kJ/mole based on a calorimetric higher heat value of −24 kJ/g-VSS (−2712 kJ/mole). Heat of formation for primary sludge estimated at −290 kJ/mole based on a calorimetric higher heat value of −26 kJ/g-VSS (−2574 kJ/mole).

[b] Due to the low autotrophic cell mass yield under the typical sidestream reactor operating conditions, cell mass yield is ignored in the stoichiometric equation and calculation of the heat of reaction.

[c] Y_H defined as the net cell mass yield, mg VSS/mg COD.

[d] Equation based on heats of reaction for methanol, ethanol, glycerol and acetic acid.

Separate sidestream reactors are covered or uncovered depending on the climatic conditions and the desired reactor temperature range. If heat removal is a daily requirement, the reactors may be uncovered to promote evaporative cooling to minimize the design heat load or eliminate the need for heat removal. The heat load selected for design is typically based on summer climatic conditions and a low wind velocity, which corresponds to the lowest heat loss rate to the surrounding environment. The heat transfer calculations presented in Sec. 13–9 in Chap. 13 for anaerobic digesters are applicable for covered sidestream reactors constructed of concrete. For smaller reactors constructed of steel, the heat transfer coefficient estimation methods presented by Kumana and Kothari (1982) are recommended. The correlations presented by Al-Shammiri (2002) and

Bansal and Xie (1998) are recommended for estimating evaporation cooling induced by air movement across an open reactor surface.

EXAMPLE 15–3 **Estimating Reactor Volumes and Chemical Requirements for Nitritation-Denitritation and Deammonification Processes** For the facility described in Example 15–2, calculate the reactor volume and chemical requirements for (a) nitritation-denitritation SBR and (b) deammonification SBR processes for separate sidestream treatment. Assume the following design conditions apply:

1. Average equalized sidestream flow = 124 m^3/d
2. Peak equalized sidestream flow = 149 m^3/d
3. Dilution water requirement for reactor cooling during peak summer conditions
   a. Nitritation-denitritation = 30 m^3/d
   b. Deammonification = 15 m^3/d
4. Equalized sidestream ammonium concentration = 1000 g N/m^3 (valid for all flows)
5. Equalized sidestream TSS concentration < 200 g/m^3
6. Design maximum OUR = 150 $g/m^3 \cdot h$
7. Carbonaceous OUR = 3% of the nitrogenous OUR for nitritation-denitritation
8. Carbonaceous OUR = 6% of the nitrogenous OUR for deammonification
9. External organic carbon source: methanol
   a. Concentration = 100%
   b. Specific gravity = 790 kg/m^3
   c. COD/mass = 1.5 g/g
10. Biomass yield on methanol = 0.28 g VSS/g COD
11. Nitritation-denitritation and deammonification SBR basis: Three cycles per day with each cycle consisting of:
    a. 6 h react
    b. 1 h settle
    c. 1 h decant
12. Intermittent aeration during react period: 66% aerobic and 34% anoxic

Solution Part A—Nitritation-denitritation SBR

1. Determine nitritation-denitritation reactor volume.
   a. Determine design oxygen demand.

$$\text{Design oxygen demand} = \text{nitrogenous oxygen demand} + \text{carbonaceous oxygen demand at the maximum load}$$

$$\begin{aligned}\text{Nitrogenous oxygen demand} &= (149\ m^3/d)(1\ kg\ N/m^3)(3.43\ kg\ O_2/kg\ N)\\ &= 511\ kg\ O_2/d\end{aligned}$$

$$\text{Carbonaceous oxygen demand} = (0.03)(511\ kg\ O_2/d) = 15\ kg\ O_2/d$$

$$\text{Total oxygen demand} = 511\ kg\ O_2/d + 15\ kg\ O_2/d = 526\ kg\ O_2/d$$

   b. Determine the aerobic reaction time.

$$\begin{aligned}\text{Total aerobic time/d} &= (3\ \text{cycles/d})(6\text{-h react/cycle})(0.66\text{-h aerobic/h react})\\ &= 12\text{-h aerobic/d}\end{aligned}$$

   c. Determine AOR during aeration period.

$$\text{AOR during each aeration period} = (526\ kg\ O_2/d)/(12\ h/d) = 43.8\ kg\ O_2/h$$

d. Determine the required reactor volume.

Using the oxygen requirement computed above, reactor volume at minimum liquid level is:

$$\text{Reactor volume at minimum liquid level} = \frac{\text{AOR}}{\text{Design OUR}} = \frac{(43.8\text{ kg O}_2/\text{h})}{(150\text{ g O}_2/\text{m}^3\cdot\text{h})} \times \frac{10^3\text{ g}}{1\text{ kg}} = 292\text{ m}^3$$

Maximum reactor volume corresponds to the reactor volume at the minimum liquid level plus the additional volume needed for the maximum hydraulic load per cycle.

$$\text{Maximum hydraulic load/cycle} = \frac{(\text{Maximum hydraulic load/d})}{(\text{Number of cycles/d})}$$

$$= \frac{(\text{maximum sidestream flow}) + (\text{maximum dilution water})}{(\text{Number of cycles/d})}$$

$$= \frac{[(149\text{ m}^3/\text{d}) + (30\text{ m}^3/\text{d})]}{(3\text{ cycles/d})}$$

$$= 60\text{ m}^3/\text{cycle}$$

Reactor volume at maximum liquid level $= 292\text{ m}^3 + 60\text{ m}^3 = 352\text{ m}^3$

2. Determine methanol requirement. Assume 100% oxidation of ammonium to nitrite and 100% reduction of nitrite to N_2.
   a. Determine COD requirement for denitritation.
   Using Eq. (15–12) and assuming a biomass yield = 0.28 g VSS/g COD,

   $$\text{COD/N} = 1.71/(1 - 1.42 \times 0.28) = 2.85\text{ kg COD/kg NO}_2\text{ N}$$

   b. Calculate the annual ammonium loading.

   $$\begin{aligned}\text{Annual ammonium loading} &= (1000\text{ g N/m}^3)(124\text{ m}^3/\text{d})(365\text{ d/y})\\ &= (1\text{ kg N/m}^3)(124\text{ m}^3/\text{d})(365\text{ d/y})\\ &= 45{,}260\text{ kg N/y}\end{aligned}$$

   c. Determine methanol consumption.

   From the problem statement, COD of the methanol is 1.5 kg COD/kg-methanol.

   Average annual methanol consumption

   $$\begin{aligned}&= (45{,}260\text{ kg N/y})[(2.85\text{ kg COD/kg N})/(1.5\text{ kg COD/kg methanol})]\\ &= 85{,}994\text{ kg methanol/y}\end{aligned}$$

   Specific gravity of methanol is 790 kg/m^3, therefore annual methanol consumption is:

   $$\begin{aligned}\text{Annual methanol consumption, m}^3/\text{y} &= (85{,}994\text{ kg methanol/y})(1/790\text{ kg/m}^3)\\ &= 109\text{ m}^3/\text{y}\end{aligned}$$

Solution, Part B—Deammonification SBR

1. Determine deammonification reactor volume.
   a. Determine design oxygen demand.

   From Eq. (15–13), the oxygen requirement for complete deammonification = 1.87 kg O_2/kg NH_4 N.

$$\begin{aligned}\text{Maximum nitrogenous oxygen demand} &= (149\ \text{m}^3/\text{d})(1000\ \text{g N/m}^3)(1.87\ \text{kg O}_2/\text{kg N})\\ &= 279\ \text{kg O}_2/\text{d}\end{aligned}$$

Maximum carbonaceous oxygen demand = 6% of nitrogenous oxygen demand.

$$\text{Maximum carbonaceous oxygen demand} = (0.06)(279\ \text{kg O}_2/\text{d}) = 17\ \text{kg O}_2/\text{d}$$

$$\text{Total maximum oxygen demand} = 273\ \text{kg O}_2/\text{d} + 17\ \text{kg O}_2/\text{d} = 290\ \text{kg O}_2/\text{d}$$

b. Determine the time of aerobic reaction.

$$\begin{aligned}\text{Total aerobic time/d} &= (3\ \text{cycles/d})(6\text{-h react/cycle})(0.66\text{-h aerobic/h react})\\ &= 12\text{-h aerobic/d}\end{aligned}$$

c. Determine AOR during aeration period.

$$\text{AOR during each aeration period} = 290\ \text{kg O}_2/\text{d} \div 12\ \text{h/d} = 24\ \text{kg O}_2/\text{h}$$

d. Determine the reactor volume requirement.
Using the oxygen requirement obtained from Step (c), reactor volume at minimum liquid level is calculated as:

$$\begin{aligned}\text{Reactor volume at minimum liquid level} &= \frac{\text{AOR}}{\text{Design OUR}}\\ &= \frac{(24\ \text{kg O}_2/\text{h})(10^3\ \text{g/1 kg})}{(150\ \text{g O}_2/\text{m}^3{\cdot}\text{h})}\\ &= 160\ \text{m}^3\end{aligned}$$

Maximum reactor volume corresponds to the reactor volume at the minimum liquid level plus the additional volume needed for the maximum hydraulic load per cycle.

$$\begin{aligned}\text{Maximum hydraulic load/cycle} &= \frac{(\text{Maximum hydraulic load/d})}{(\text{Number of cycles/d})}\\ &= \frac{(\text{maximum sidestream flow}) + (\text{maximum dilution water})}{(\text{Number of cycles/d})}\\ &= \frac{[(149\ \text{m}^3/\text{d}) + (15\ \text{m}^3/\text{d})]}{(3\ \text{cycles/d})}\\ &= 55\ \text{m}^3/\text{cycle}\end{aligned}$$

Reactor volume at maximum liquid level = 160 m^3 + 55 m^3 = 215 m^3, or 61% of the volume requirement for nitritation-denitritation.

2. Determine methanol requirement.
The deammonification process, as shown in Eq. (15–14), does not require an external carbon source. Therefore methanol requirement = 0 m^3/y

Comment Although Deammonification does not require an external organic carbon source, the nitrate product from the anammox reaction would have to be reduced with a carbon source to yield an equivalent inorganic nitrogen removal efficiency. In the calculations presented above it was assumed that the maximum OUR of the aeration system controls the design reactor volume, which is typical of a conventional digester sidestream. In the case where sidestream TSS is consistently and considerably higher and no reduction is provided, the accumulation of inert suspended solids will increase the reactor MLSS concentration and may result in a need for a greater reactor volume. For this situation, reduction of the sidestream TSS may be cost effective.

PROBLEMS AND DISCUSSION TOPICS

15–1 Alkaline stabilization of combined primary and waste activated solids is currently practiced at a wastewater treatment facility, but there is a plan to replace this system with a single-stage mesophilic anaerobic digestion process. Centrifugation has been selected for biosolids dewatering. In the absence of pilot study data, a preliminary estimate of the daily sidestream volume and characteristics are required to assess the nutrient and solids loads returned to the mainstream nutrient removal process. Using the following data and assumptions, estimate the future daily sidestream volumes and concentrations of soluble TKN, total TKN, soluble orthophosphate, and total suspended solids at the average and peak thickened sludge loads to the proposed digestion and dewatering processes. In the calculation of the orthophosphate concentration, assume no precipitation of phosphate. The contribution of centrifuge wash-water to the sidestream flow can also be ignored.

Thickened combined raw sludge data

Parameter	Unit	Value
Daily volume, average—maximum two-week	m^3/d	530–700
Total solids concentration (applicable for all flowrates)	%	4.5
Volatile fraction	%	78
Volatile fraction nitrogen content	%	6.5
Volatile fraction phosphorus content	%	1.5
Specific gravity		1.02

Single-stage mesophilic digestion performance criteria

Parameter	Unit	Value
Temperature	°C	35
Volatile solids destruction efficiency at minimum digester SRT	%	45
Volatile solids destruction efficiency at average digester SRT	%	50
Digested volatile solids nitrogen content	%	6.5
Digested volatile solids phosphorus content	%	1.5

Biosolids dewatering performance criteria (applicable for all sludge loading rates)

Parameter	Unit	Value
Cake solids concentration	%	22
Solids capture efficiency	%	95

15–2 Digested primary and waste activated sludge is dewatered six day per week and eight hours per day. The average sidestream flow, ammonium-N concentration and soluble orthophosphate concentration are shown below:

Parameter	Unit	Value
Flowrate during biosolids dewatering,	m^3/h	83
Ammonium-N concentration	mg/L	1050
Orthophosphate-P concentration	mg/L	190
Maximum period without dewatering	d	2

Using the given information, (a) calculate the tank volume required for full equalization of the sidestream so that the equalized flow is returned continuously at constant flowrate to the mainstream plant and (b) the required volume if the equalized sidestream is to be returned to the mainstream plant seven days per week between the hours of 10 p.m. and 6 a.m.

15–3 The sidestream described in Problem 15-2 is discharged to the inlet of the primary clarifiers in the mainstream process. Ferric chloride is applied to the primary clarifiers at an average Fe/P mass ratio of 2 kg/kg to reduce the orthophosphate concentration in the primary tank effluent. Using the given data,

a. Estimate the volume of concentrated ferric chloride solution required to precipitate the orthophosphate-P contributed by sidestream to the primary tank influent. The physical property data for the ferric chloride solution is shown below:

Parameter	Unit	Value
$FeCl_3$ concentration, percent by weight	%	37
Specific gravity of concentrated solution		1.4

b. The implementation of a struvite crystallization process for sidestream pretreatment is being considered. Assuming negligible loss of phosphate during to precipitation in the equalization tank, a target soluble orthophosphate-P concentration of 15 mg/L in the crystallizer effluent and 100 percent recovery of the crystallized product, estimate the average daily mass of struvite that can be potentially harvested from this process. An air-dried product in the form of a hexahydrate salt should be assumed in the calculation.

15–4 For the sidestream described in Problem 15–2, a process consisting of struvite crystallization followed by deammonification in a SBR has been proposed for pretreatment before discharge to the mainstream plant. Using the struvite crystallization criteria provided in Problem 15–3(b),

a. Calculate the ammonium-N concentration in the struvite crystallizer effluent.
b. Estimate the deammonification SBR volume requirement. The following conditions apply:
    i. Sidestream flow will be equalized as calculated in Problem 15–2(a) and this equalized flow will serve as the design basis.
    ii. An energy balance has revealed that sufficient heat losses from the equalization tank, struvite crystallizer and SBR will occur to maintain the SBR temperature below 38°C during the peak summer conditions; thus, no dilution water is required.
    iii. Fine bubble diffusers will be used and can satisfy a maximum OUR of 150 mg/L·h.
    iv. Carbonaceous OUR is estimated to be 8 percent of the nitrogenous OUR.
    v. Intermittent aeration is applied with each aeration cycle time consisting of 66 percent aerobic and 34 percent anoxic.
    vi. Three SBR cycles per day with each cycle consisting of 6-h *react*, 1-h *settle* and 1-h *decant*.
    vii. Assume an ammonia removal efficiency of 100 percent as the design basis.

15–5 A sidestream derived from mesophilic anaerobic digestion of primary and waste activated sludge is produced at a equalized daily volume of 600 m^3/d and contains an ammonium concentration of 900 mg N/L. For the three biological treatment options, nitrification-denitrification, nitritation-denitritation and deammonification,

a. Calculate the daily biological heat generated by the three processes in megajoules/day using the following performance conditions:
    i. Ammonium-N removal efficiency = 95% in all processes
    ii. NOx-N removal efficiency = 95% for denitrification and denitritation.

iii. Denitrification of the nitrate produced by the anammox reaction with sidestream degradable carbon is not significant; thus, this reaction can be excluded from the heat calculation.

iv. Net sludge yield, $Y_H = 0.2$ g VSS/g COD and is applicable to denitrification and denitritation.

b. Determine if the biological heat generated in the three processes is sufficient to increase the reactor temperature beyond a maximum limit of 38°C. If the temperature will exceed 38°C, determine the fraction of the biological heat in each process that must be removed or absorbed via dilution water addition. The equalized sidestream has a peak temperature of 35°C.

15–6 For the sidestream and the process performance criteria described in Problem 15-5, calculate the daily mechanical mixing and aeration energy consumption (kWh/d) for nitrification-denitrification, nitritation-denitritation, deammonification or all three processes (instructor's preference). The following information should be used for the calculations:

Sidestream Characteristics

Parameter	Unit	Value
Equalized flowrate for design	m^3/d	600
Ammonium-N concentration	mg/L	900
Degradable COD concentration[a]	mg/L	200

[a] sum of the readily and complex biodegradable COD.

A sequencing batch reactor is selected for design. The SBR will be fed continuously during the *react* period of each SBR cycle. The following operating and design conditions apply to all three processes:

Parameter	Unit	Value
Number of SBR cycles per day	–	3
Settle period duration	h/cycle	1
Decant period duration	h/cycle	1
Aerobic fraction of react period	%	66
Average reactor temperature	°C	34
Idle period duration	h/cycle	0
Maximum OUR for design	mg/L·h	150
Maximum sidewater depth	m	7
Ammonia and degradable COD removal efficiencies for SBR design	%	100
Actual ammonia removal efficiency	%	90
Actual degradable COD removal efficiency	%	95
Net heterotrophic yield, Y_H	gVSS/gCOD	0.2

Based on a heat loss analysis for open top concrete reactors, the following average daily dilution water requirements were estimated for each process:

Process	Unit	Value
Nitrification-denitrification	m^3/d	200
Nitritation-denitritation	m^3/d	100
Deammonification	m^3/d	0

Fine bubble membrane disk diffusers and submersible mixers are selected for design.

Parameter	Unit	Value
Mech. mixing intensity (nitrification-denitrification)[a]	W/m^3	4
Mech. mixing intensity (nitritation-denitritation)[a]	W/m^3	4
Mech. mixing intensity (deammonification)[a]	W/m^3	6
Mixer total efficiency (electrical + mechanical)	%	84
Operating DO conc. (nitrification-denitrification)	mg/L	2.0
Operating DO conc. (nitritation-denitritation)	mg/L	0.5
Operating DO conc. (deammonification)	mg/L	0.3
Alpha factor, α	—	0.5
Fouling factor, F	—	0.85
Beta factor, β	—	0.95
Temperature correction factor, θ	—	1.024
Site barometric pressure	kPa	99.97
Distance from floor to membrane surface	m	0.25
Pressure drop (blower inlet)	kPa	1.7
Pressure drop (piping, valves, diffusers)	kPa	12
Standard oxygen transfer efficiency, SOTE[b]	%/m	6
Average ambient air temperature	°C	20
Blower mechanical efficiency	%	75
Blower motor electrical efficiency	%	90

[a] Mixing intensity at maximum liquid level. The submersible mixers only operate during the anoxic periods and when they operate, the mixers run at a constant speed regardless of the liquid depth.

[b] SOTE per meter of diffuser submergence. For simplification, assume a linear relationship with depth.

15–7 A wastewater treatment facility requires a capacity expansion to accommodate the projected growth in the service population. The following processes will be added to the facility:

i. Primary sedimentation tanks
ii. Gravity thickening of primary sludge
iii. Dissolved air flotation for thickening of waste activated sludge
iv. Mesophilic anaerobic digestion of combined primary and waste activated sludges
v. Screw press for dewatering digested sludge

Using the plant information given below:

a. Calculate the flow and suspended solids concentrations for the gravity thickener overflow and the dissolved air flotation subnatant.
b. Calculate the pressate flow and concentrations of soluble TKN, total suspended solids and soluble phosphorus.
c. Calculate the percent contribution of the pressate soluble TKN and soluble phosphorus to the primary effluent TKN and TP loads to the secondary process.

Future plant influent flowrate and characteristics:

Parameter	Unit	Value
Average daily flowrate	m^3/d	26,500
COD	mg/L	580
Carbonaceous BOD	mg/L	275
Total suspended solids	mg/L	290
Volatile suspended solids	mg/L	226
TKN	mg/L	40
Ammonium-N	mg/L	23
Total phosphorus	mg/L	7
Ortho-phosphorus	mg/L	3.6
Particulate TKN/VSS ratio	—	0.04
Particulate P/VSS ratio	—	0.015
Particulate COD/VSS ratio	—	1.6

Future solids removal, thickening and digester performance criteria:

Parameter	Unit	Value
Gravity thickener TSS capture efficiency	%	93
Thickened primary sludge percent solids	%	6
DAF TSS capture efficiency	%	95
Thickened waste activated sludge percent solids	%	5
Primary tank TSS removal efficiency	%	60
Primary tank underflow percent solids	%	1
Primary tank cBOD removal efficiency	%	30
Screw press TSS capture efficiency	%	95
Digested sludge cake percent solids	%	25
Digester volatile solids destruction	%	50
Nitrogen content of digested VSS	%	6
Phosphorus content of digested VSS	%	1.8

Future secondary process performance and solids production:

Parameter	Unit	Value
SRT	d	12
cBOD removal efficiency	%	98
Observed yield	gVSS/gBOD	0.55
Volatile content of WAS TSS	%	80
WAS MLSS concentration	mg/L	7500
Nitrogen content of WAS VSS	%	9.5
Phosphorus content of WAS VSS	%	2
Filtered plant effluent TSS concentration	mg/L	< 2

15–8 Using Eqs. (7-96) in Sec. 15-8 and (15-11) in Sec. 15-9, estimate the amount of methanol that can be saved with the conversion of a sidestream treatment process from nitrification-denitrification to nitritation-denitritation. Express the results as kilograms of methanol saved per kilogram of NOx-N-removed.

15–9 For the sidestream described in Problem 15-2, and assuming a sidestream alkalinity of 3750 mg/L as $CaCO_3$, estimate the soda ash (Na_2CO_3) dosing rate required for complete nitrification of the sidestream ammonium-N in a separate reactor performing only nitrification. Describe how the soda ash dosing requirement would change if the sidestream treatment process is modified from nitrification-denitrification to nitritation-denitritation.

Air Emissions from Wastewater Treatment Facilities and Their Control

WORKING TERMINOLOGY

Term	Definition
Absorption	The process by which atoms, ions, molecules, and other constituents are transferred from one phase and are distributed uniformly in another phase (see also adsorption).
Adsorption	The process by which atoms, ions, molecules, and other constituents are transferred from one phase and accumulate on the surface of another phase (see also absorption).
Air stripping	The removal of volatile and semi-volatile contaminants from a liquid by passing air and liquid counter currently through a packed tower.
Buffer zone	An area around a facility which serves to diminish the impact of any odors emitted from the facility. Trees are sometimes planted at the periphery of buffer zones to further reduce the impact of odors.
Catalytic incineration	Controlled process used to oxidize VOCs with the help of a catalyst such as platinum and palladium.
Chemical scrubber	A reactor used to provide contact between air, water, and chemicals, if used, to provide oxidation or entrainment of odorous compounds.
Biofilter	Open or closed packed-bed filters used for the removal of odors biologically. In open biofilters, gases to be treated move upward through the filter bed. In closed biofilters, the gases to be treated are either blown or drawn through the packing lateral.
Biotrickling filter	Similar to biofilters, with the exception that moisture is provided continuously or intermittently over the packing. Liquid is recirculated and nutrients are often added.
Digester gas	Gas produced from anaerobic digestion of sludges. Also often referred to as biogas. Digester gas typically contains 60 percent or higher methane gas by volume and can be used as a fuel source.
Gas stripping	The purposeful introduction of air or other gases to transfer volatile constituents such as VOCs and odors from a liquid phase to a gaseous phase.
Global warming potential (GWP)	A measure of relative effects of a gas to trap heat in the atmosphere in reference to that of carbon dioxide.
Greenhouse gases	Gases that have been identified as contributing to global warming.
Mass transfer	The transfer of material from one homogeneous phase to another; aeration, gas stripping, and adsorption are examples of mass transfer.
Mechanical aerators	Devices used to agitate water to promote mixing with atmospheric air.
Mixing	The agitation of a liquid-solids suspension for the purpose of blending the mixture and keeping solids in suspension, entraining gases, or for accelerating a chemical reaction.
Odor threshold	The concentration at which an odor is detectable by human sense of smell.
Off-gas	The gaseous emission from a process; off-gas may be odorous and/or contain greenhouse gases and VOCs.
Stripping tower	A closed vertical reactor used to bring about the transfer of VOCs from a liquid phase to a gaseous phase.
Thermal oxidation	Controlled process used to oxidize VOCs at high temperatures.
Vapor phase adsorption	Process whereby hydrocarbons and other compounds arc are adsorbed selectively on the surface or such materials as activated carbon, silica gel, or alumina.
Volatile organic compounds (VOCs)	A term often used generically to mean total organic carbon; in the context of air quality the term means total nonmethane hydrocarbons.
Volatilization	The release of VOCs from water surface to the atmosphere.

The treatment of wastewater results in the release of a variety of air emissions, many of which are odorous and/or may contain air pollutants. Activities that result in emissions of air pollutants to the outdoor atmosphere may require approval of the state or regional environmental agency or the U.S. Environmental Protection Agency (U.S. EPA). The extent of the air permitting requirements is based on a number of factors such as the nature of the air pollutant, the quantity of emissions, the air quality in the vicinity of the facility, the existing air emissions and emission sources, the state air permitting requirements, and emissions control regulations mandated by the governing agency and federal regulations. The governing agency may be at the state, region, city, or tribal level. Air permitting is typically at the federal and state level, but authority may vary. As used herein, "state" refers to agencies other than the U.S. EPA that have jurisdiction to implement air permitting under the Clean Air Act (CAA) at the state, regional, city, or tribal level. Topics discussed in this chapter include (1) types of emissions, (2) regulatory requirements, (3) odor management, (4) volatile organic carbon emissions and their control, (5) emissions from combustion of gases and solids, and (6) emission of greenhouse gases.

16–1 TYPES OF EMISSIONS

Typical air emissions from wastewater treatment plants that are subject to regulation under the CAA are provided in Table 16–1. Some states require that additional classes of compounds (e.g., odors and greenhouse gases) be calculated at these facilities. For example, a recently promulgated regulation by the U.S. EPA requires that the total emissions from all sources of greenhouse gases be calculated and compared to regulatory thresholds. Certain processes within wastewater treatment plants have qualified for exemptions to the rule due to the "biogenic" nature of their emissions (i.e., non-fossil fuel origin). Emission of greenhouse gases is discussed further in Sec 16–6. Sources of emissions within odor management is particularly important for the operation of wastewater treatment facilities, and it is discussed in detail in Sec 16–3.

16–2 REGULATORY REQUIREMENTS

The CAA is the basis for federal and state regulations, which are codified in Subchapter C, Air Programs, of Title 40 of the Code of Federal Regulations. The CAA and amendments establish air permitting programs at the federal level and provide a regulatory framework for state and regional regulations. Permit authority may be at the federal, state, or regional level. Emissions of air pollutants fall into three general categories: criteria pollutants, non-criteria pollutants, and hazardous air pollutants (HAPs). Criteria pollutants have an associated air quality standard. The key air quality regulations cover broad categories, as described herein.

Ambient Air Quality and Attainment Status

The U.S. EPA has established National Ambient Air Quality Standards (NAAQS) to protect public health and public welfare. Primary standards are based on observable human health responses and are set at levels that provide an adequate margin of safety for sensitive segments of the population. Secondary standards are intended to protect public welfare interests such as structures, vegetation, and livestock. States may also establish ambient air quality standards that are more stringent than the federal standards and may retain a revoked federal standard.

Table 16–1

Typical air pollutants associated with wastewater treatment plants

Air pollutant	Source(s)
Criteria pollutants	
Carbon monoxide (CO)	Incomplete combustion, partial oxidation of organic material
Nitrogen dioxide (NO_2)	Combustion processes
Sulfur dioxide (SO_2)	Combustion processes
Total suspended particulate matter (TSP)	Combustion processes, material handling, aggregate handling, other process sources
Respirable particulate matter with a diameter of up to 10 microns (PM_{10})	Combustion processes, material handling, aggregate handling, other process sources
Fine particulate matter with a diameter of up to 2.5 microns ($PM_{2.5}$)	Combustion processes, material handling, aggregate handling, other process sources
Ozone (O_3):	Generated at ground level through photochemical oxidation of precursors NOx and VOC
Oxides of nitrogen (NOx)	Combustion processes
Volatile organic compounds (VOC)	Combustion processes, organic material storage and use, other process sources
Lead (Pb)	Combustion processes
Non-criteria pollutants	
Hydrogen sulfide (H_2S)	Process sources, anaerobic reduction of sulfur compounds
Methane (CH_4)	Anaerobic digestion, combustion processes
Carbon dioxide (CO_2)	Combustion processes, anaerobic digestion
Ammonia (NH_3)	Solids processing/polymer breakdown
Nitrous oxide (N_2O)	Biological nitrogen removal systems
Hazardous air pollutants (HAPs)	
Toluene, benzene, xylene, etc	Influent constituents from industrial sources
Methanol	Nutrient removal systems
Trimethylammine and dimehtylammine	Solids processing/polymer breakdown
Carbon disulfide and carbonyl sulfide	Total reduced sulfur compounds from sulfate oxidation
Formaldehyde and hexane	Combustion by-products from combined heat and power/boilers/process heaters/etc.
Chlorine (Cl_2)	Used in chlorination processes
Mercury, other heavy metals and polycyclic organic compounds (POM)	Wastewater sludge incinerators

The CAA requires the U.S. EPA and states to identify by category the ambient air quality compliance status for specific geographic regions (air quality control regions or portions thereof). Areas may be designated “attainment” or “nonattainment” of the NAAQS based on monitoring data, or “unclassifiable” if insufficient ambient monitoring data exists; “unclassifiable” areas are generally considered as “attainment” areas. The attainment status of the existing/new source location determines the applicability of pre-construction permitting programs.

Table 16–2

Permitting programs and control technologies

Requirements	Regulations, rules and technologies
Preconstruction and operating permitting	Nonattainment new source review (NNSR or NANSR)
	Prevention of significant deterioration (PSD)
	Title V operating permits
	Minor source permitting programs
Stationary source control permitting	New Source Performance Standards (NSPS per 40 CFR Part 60)
	National Emission Standards for Hazardous Air Pollutants (NESHAPs per 40 CFR Parts 61 and 63)
	Reasonably Available Control Technology (RACT)

Preconstruction and Operating Permitting Programs

New sources and modifications/reconstructions of existing sources that result in air pollution emissions (above specified thresholds) will be subject to air permitting requirements. Air permitting programs are listed in Table 16–2. The applicability of nonattainment new source review (NNSR) and prevention of significant deterioration (PSD) depends upon the nature of the project, the air quality designation in the vicinity of the project, and the quantity of annual emissions. Both are preconstruction approval programs applicable to major projects, and both prohibit commencement of construction until the preconstruction approval is issued. If major source or major modification criteria are met, NNSR may be applicable to a nonattainment pollutant (and precursor pollutants) while PSD may be applicable to an attainment pollutant. If NNSR is applicable, then the lowest achievable emission rate (LAER) control technology that is technically feasible must be incorporated in the project design, regardless of cost.

If PSD is applicable, then the best available control technology (BACT) must be incorporated into the project design. Factors such as cost, energy requirements, and other environmental consequences/benefits are part of a BACT analysis. The U.S. EPA may delegate authority to approve NNSR and PSD projects to state agencies; alternatively, it may approve state regulations that meet U.S. EPA requirements (e.g., approval of State Implementation Plan). Within the PSD program, more stringent protection of air quality is afforded to "Class I" areas, which include national parks, wildlife areas, and other designated areas. Impacts to visibility and ecology must also be minimized for the project to obtain an air permit to construct.

The CAA Amendments of 1990 added the Title V operating permit program, which established state and federal permitting procedures for major facilities that allow for the consolidation of facility specific requirements into a single, federally-enforceable permit. These requirements include emission limitations, work practice standards, monitoring requirements, recordkeeping requirements, and submittal/notification requirements. Applicable requirements may be based on regulations or preconstruction approval conditions. Title V permitting programs are usually administered at the state level. Minor source permitting programs apply to sources that are not subject to Title V operating permits. These requirements are established by state agencies.

Stationary Source Control Technology Requirements

Stationary source emissions control technology requirements are listed in Table 16–2. Unlike the control technology requirements of the NNSR and PSD preconstruction programs, regulations such as new source performance standards (NSPS) and national emission standards for hazardous air pollutants (NESHAPs) apply to equipment based on the function and category of the equipment. The NSPS apply to new, modified, or reconstructed sources that meet the applicability criteria specific to the source type. The NESHAP requirements apply primarily to major sources of HAPs, but some requirements are applicable to "area sources" (minor sources) of HAPs. Reasonably available control technology (RACT) broadly refers to the control technology requirements specified by state regulations that establish the minimum level of emissions control. RACT requirements can be applied retroactively to a source and are generally more stringent in nonattainment areas than in attainment areas.

16–3 ODOR MANAGEMENT

The potential release of odors is a major concern of the public relative to modifying existing wastewater treatment facilities and constructing new facilities. Thus, the control of odors has become a major consideration in the design and operation of wastewater collection, treatment, and disposal facilities, especially with respect to the public acceptance of these facilities. In many instances, projects have been rejected because of the fear of potential odors. In several states, wastewater management agencies are now subject to fines and other legal action over odor violations. In view of the importance of odors in the field of wastewater management, the following topics are considered in this section: (1) the types of odors encountered, (2) the sources of odors, (3) measurement of odors, (4) the movement of odorous gases, (5) strategies for odor control, (6) odor control methods, and (7) the design of odor control facilities.

Types of Odors

For humans, the importance of odors at low concentrations is related primarily to the psychological stress the odors cause, rather than to the harm they do to the body. The principal types of odors encountered in wastewater management facilities are reported in Table 16–3. With few exceptions, odorous compounds typically contain either sulfur or nitrogen. The characteristic odor of organic compounds containing sulfur is that of decayed organic material. Of the odorous compounds reported in Table 16–3, the rotten egg smell of hydrogen sulfide is the odor encountered most commonly in wastewater management facilities. As noted in Chap. 2, gas chromatography has been used successfully for the identification of specific compounds responsible for odors. Unfortunately, this technique has not proved as successful in the detection and quantification of odors derived from wastewater collection, treatment, and disposal facilities, because of the many compounds that may be involved. It should be noted that at higher concentrations, many of the odorous gases (e.g., hydrogen sulfide) can, depending on exposure, be lethal.

Sources of Odors

The principal sources of odors in wastewater management facilities and the relative potential for release of odor are presented in Table 16–4. Minimization of odors from these sources is the concern of odor management.

Wastewater Collection Systems. The principal sources of odorous compounds in collection systems are from (1) the biological conversion, under anaerobic conditions, of organic matter containing nitrogen and sulfur, and (2) the discharge of industrial wastewater that may contain odorous compounds or compounds that may react with compounds in the wastewater to produce odorous compounds. Odorous gases released to the sewer atmosphere can accumulate and be released at air release valves, cleanouts, access ports (i.e., manholes), and house vents.

Table 16–3

Odor thresholds of odorous compounds and their characteristics associated with wastewater management

Odorous compound	Chemical formula	Molecular weight	Odor threshold, ppm_v[a]	Characteristic odor
Ammonia	NH_3	17.0	46.8	Pungent, irritating
Chlorine	Cl_2	71.0	0.314	Pungent, suffocating
Chlorophenol	ClC_6H_4OH	128.51	0.00018	Medicinal odor
Crotyl mercaptan	$CH_3\text{-}CH{=}CH\text{-}CH_2\text{-}SH$	90.19	0.000029	Skunk like
Dimethyl sulfide	$CH_3\text{-}S\text{-}CH_3$	62	0.0001	Decayed cabbage
Diphenyl sulfide	$(C_6H_5)_2S$	186	0.0047	Unpleasant
Ethyl mercaptan	$CH_3CH_2\text{-}SH$	62	0.00019	Decayed cabbage
Ethyl sulfide	$(C_2H_5)_2SH$	91.9	0.000025	Nauseating odor
Hydrogen sulfide	H_2S	34	0.00047	Rotten eggs
Indole	C_8H_6NH	117	0.0001	Fecal, nauseating
Methyl amine	CH_3NH_2	31	21.0	Putrid, fishy
Methyl mercaptan	CH_3SH	48	0.0021	Decayed cabbage
Skatole	C_9H_9NH	132	0.019	Fecal odor, nauseating
Sulfur dioxide	SO_2	64.07	0.009	Pungent, irritating
Thiocresol	$CH_3\text{-}C_6H_4\text{-}SH$	124	0.000062	Skunk like, irritating
Trimethyl amine	$(CH_3)_3N$	59	0.0004	Pungent, fishy

[a] Parts per million by volume.

Table 16–4

Sources of odor in wastewater management systems[a]

Location	Source/cause	Odor potential
Wastewater collection system		
Air release valves	Accumulation of odorous gases released from wastewater	High
Cleanouts	Accumulation of odorous gases released from wastewater	High
Access ports (manholes)	Accumulation of odorous gases released from wastewater	High
Industrial wastewater discharges	Odorous compounds may be discharged to wastewater collection system	
Raw wastewater pumping station	Wetwell/septic raw wastewater, solids and scum deposits	High
Wastewater treatment facilities		
Headworks	Release odorous gases generated in the wastewater collection system due to turbulence in hydraulic channels and transfer points	High
Screening facilities	Putrescible matter removed by screening	High
Preaeration	Release of odorous compounds generated in wastewater collection system	High

(*continued*)

Table 16–4 (*Continued*)

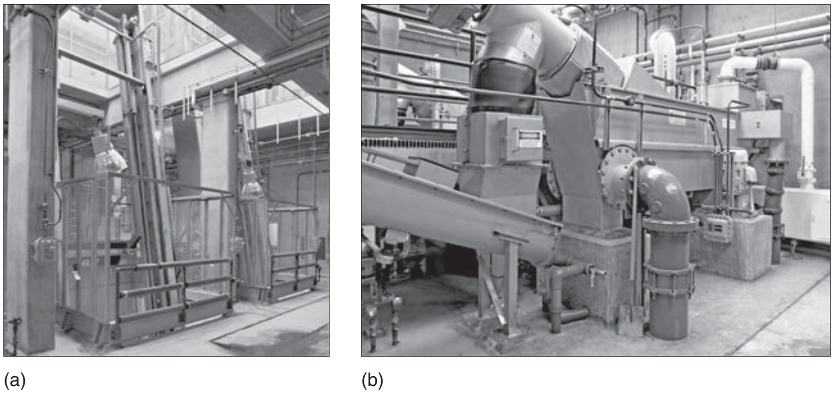
Location	Source/cause	Odor potential
Grit removal	Organic matter removed with grit	High
Flow equalization basins	Basin surfaces/septic conditions due to accumulation of scum and solids deposits	High
Septage receiving and handling facilities	Odorous compounds can be released at septage receiving stations, especially when septage is being transferred	High
Sidestream returns[b]	Return flows from biosolids processing facilities	High
Primary clarifiers	Effluent weirs and troughs/turbulence that releases odorous gases. Scum-either floating or accumulated on weirs and baffles/putrescible matter. Floating sludge/septic conditions	High/moderate
Fixed film processes (trickling filters or RBCs)	Biological film/septicity due to insufficient oxygen, high organic loading, or plugging of trickling filter medium; turbulence causing release of odorous material	Moderate/high
Aeration basins	Mixed liquor/septic return sludge, odorous sidestream flows, high organic loading, poor mixing, inadequate DO, solids deposits	Low/moderate
Secondary clarifiers	Floating solids/excessive solids retention	Low/moderate
Sludge and biosolids facilities		
Thickeners, solids holding tanks	Floating solids; weirs and troughs/scum and solids septicity due to long holding periods, solids deposits, and temperature increases; odor release by turbulence	High/moderate
Aerobic digestion	Incomplete mixing in reactor	Low/moderate
Anaerobic digestion	Leaking hydrogen sulfide gas/upset conditions, high sulfate content in solids	Moderate/high
Sludge storage basins	Lack of mixing, formation of scum layer	Moderate/high
Mechanical dewatering by belt filter press, recessed plate filter press, or centrifuge	Cake solids/putrescible matter; chemical addition, ammonia release	Moderate/high
Sludge loadout facilities	Release of odors during the transfer of biosolids from storage to transfer facilities	High
Composting facilities	Composting solids/insufficient aeration, inadequate ventilation	High
Alkaline stabilization	Stabilized solids/ammonia generation resulting from reaction with lime	Moderate
Incineration	Air emissions/combustion temperature is not high enough to destroy all organic substances	Low
Sludge drying beds	Drying solids/excess putrescible matter due to insufficient stabilization	Moderate/high

[a] Adapted in part from WEF (1996a).

[b] Sidestreams could include digester decant, dewatering return flows, or backwash water (see Chap. 15).

Figure 16–1

Typical examples of odor management for preliminary treatment processes: (a) bar screen in enclosed building with odor control facilities and (b) enclosed grit processing facilities.



Wastewater Treatment Facilities. In considering the potential for the generation and release of odors from treatment plants, it is common practice to consider the liquid and solids processing facilities separately. The headworks and preliminary treatment operations have the highest potential for release of odor, especially for treatment plants that have long collection systems where anaerobic conditions can develop (see Fig. 16–1). Sidestream discharges including return flows from filter backwashing and from sludge and biosolids processing facilities are often a major source of odors, especially where these flows are allowed to discharge freely into a control structure or mixing chamber.

Sludge and Biosolids Handling Facilities. Typically, the most significant sources of odors at wastewater treatment plants are sludge thickening facilities, anaerobic digesters, and sludge loadout facilities. The highest potential for odor release occurs when unstabilized sludge is handled (e.g., turned, spread, or stored).

One of the major contributors to odor in solids processing and an important item to consider in treatment plant design is shear. Shear is the cutting or tearing of solids by shear stress. When solids undergo mixing by either high shear dewatering or conveyance equipment, particle size reduction occurs, and odor production increases. Solids that exit a dewatering facility can be sheared enough to release odors. The major mechanism appears to be the release of proteinaceous biopolymer. Once released, these proteins are degraded, liberating a number of odorous compounds, but mostly mercaptans. The increase in solution protein also makes dewatering more difficult. The solution proteins can be "coagulated" by addition of polymer, but the synthetic polymers are degraded and the protein becomes degradable. The synthetic polymer can also generate methylamines when degraded (Novak, 2001; Murthy, 2001).

Trimethylamine (TMA) is present in the liquid phase in many anaerobically digested sludges. Trimethylamine, like ammonia, is soluble below pH 9, but above this pH level is a gas, which can be released into the air. Adding lime to digested sludge for odor control may, in fact, enhance the release of odors by converting TMA to a gas (Novak, 2001; Murthy, 2001). Some plants may be unable to land apply dewatered sludge because of the increased odor production. Thus, in evaluating processing and disposal options, the ramifications of odor generation and control have to be evaluated carefully.

Measurement of Odors

The sensory (organoleptic) measurement of odors by the human olfactory system is used most often to detect odors emanating from wastewater treatment facilities. Detection of odors by the human olfactory system and instrumental methods is described in Chap. 2.

Although there are several different ways of assessing the impact of odors, the primary method at wastewater treatment facilities is dilution-to-threshold ratio (D/T). The D/T ratio is a measure of the number of dilutions of fresh air needed to render the odorous ambient air nondetectable. The higher the D/T value, the greater amount of fresh air needed to render the odor nondetectable. The D/T values, determined by an odor panel, are used as a regulatory standard for assessing off-site odor impacts. Typical D/T values vary from 1 to 50, with a median value of 5. The location where D/T impacts are measured varies with the governing jurisdiction, but typically is at the location of the receptor of odor, e.g., property fence line, residence, community, park, etc. Modeling, discussed subsequently, is used to predict the D/T values at the receptor location using source-specific D/T values.

There are two challenges with the measurement of odors; one challenge is that the detection threshold varies between individuals, and the second challenge is that odorous compounds tend to be mixed together, such as hydrogen sulfide and methyl mercaptan. The first challenge can be overcome through the use of standard methods for measuring odor, such as ASTM E679–04 where a specialized device presents different D/T mixtures to subjects for testing. The second challenge can only be overcome through the use of an odor panel, as the impact of individual odors cannot be summed. Typical probability distributions of threshold odor levels for different odorous compounds, as reported in the literature, are illustrated on Fig. 16–2. As shown on Fig. 16–2, the range of threshold odor values can vary by as much as seven orders of magnitude.

Odor Dispersion Modeling

Odor dispersion modeling is used to assess the impact from an odor source at the receptor location and the type and the extent of the odor management facilities must be implemented. Typically, the odor dispersion model is run over a set time period, and a probability of exceeding a given D/T value at the receptor location is estimated. Input to the model must be obtained from the emission source, and usually these samples must be sent for analysis by an odor panel. The model run time corresponds to the amount of time a receptor can be exposed to an odor. Average expose times range between 3 and 60 min. Depending on the governing jurisdiction or agency, the odor D/T value at the receptor location must be lower than the established regulatory D/T value (e.g., 5), 98 to 100 percent of the time.

Movement of Odors from Wastewater Treatment Facilities

Under quiescent meteorological conditions (i.e., calm winds and low atmospheric mixing), odorous gases that develop at treatment facilities tend to hover over the point of generation (e.g., sludge thickening facilities, sludge storage lagoons), because the odorous gases are more dense than air. Depending on the local meteorological conditions, it has been observed that odors may be measured at undiluted concentrations at great distances from the point of generation. The following events appear to happen: (1) in the evening or early morning hours, under quiescent meteorological conditions, a cloud of odors will develop over the wastewater treatment unit prone to the release of odors; and (2) the concentrated cloud of odors can then be transported (i.e., pushed along), without breaking up, over great distances by the weak evening or early morning breezes, as they develop. In some cases, odors have been detected at distances of up to 25 km from their source. This transport phenomenon has been termed the puff movement of odors (Tchobanoglous and Schroeder, 1985). The puff movement of odors was first described by Wilson (1975). Air dispersion modeling can be used to predict whether quiescent conditions will tend to persist over prolonged periods of time. The most common method used to mitigate the effects of the

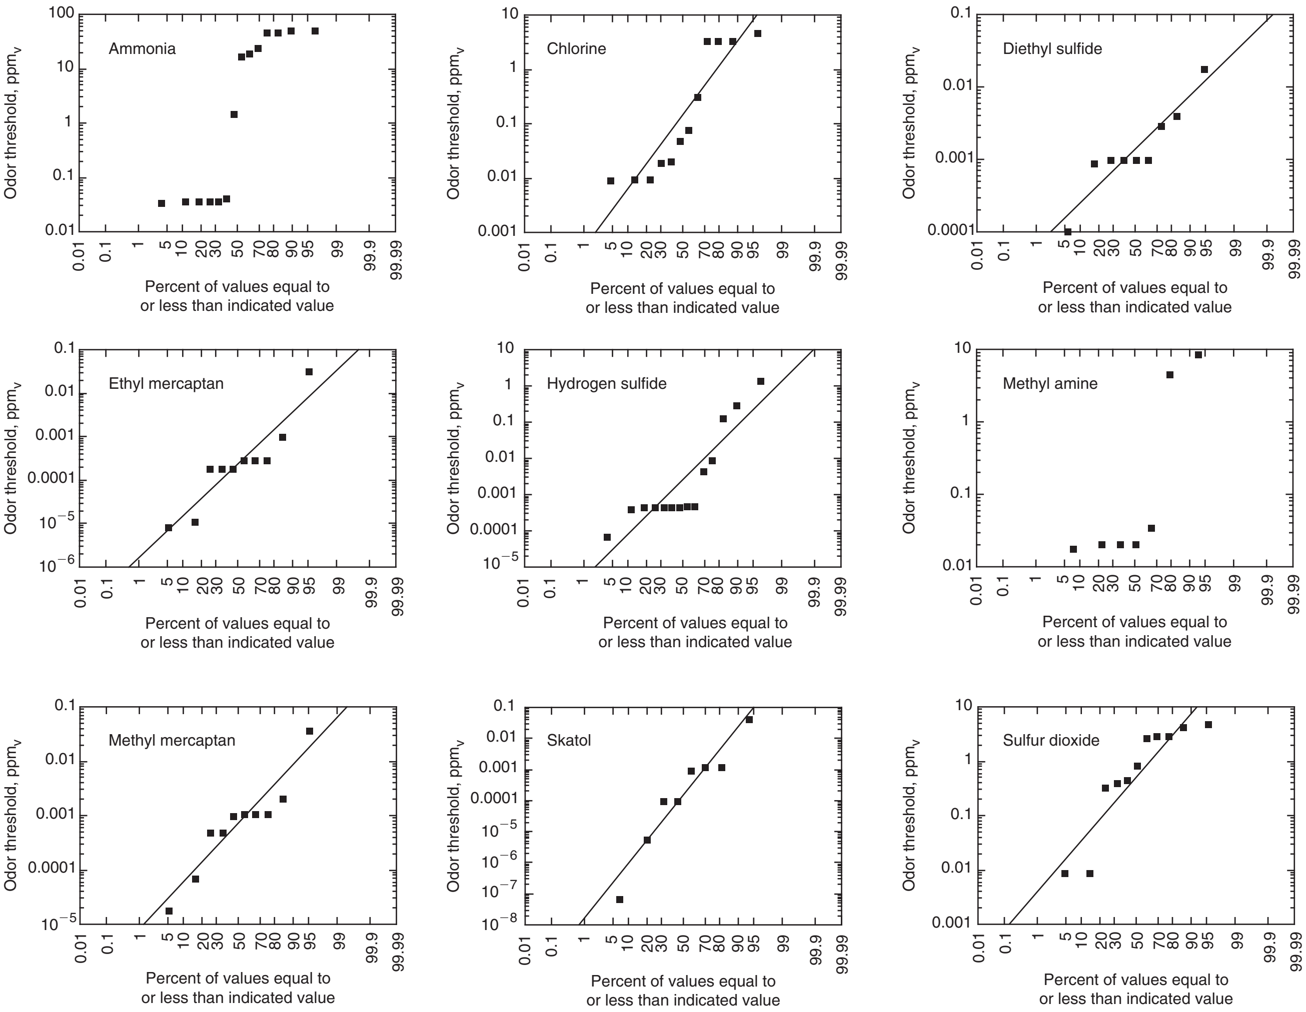


Figure 16–2

Log probability plots of odor threshhold odor values reported in the literature for a variety of odorous compounds.

odor puff is to install barriers to induce turbulence, thus breaking up and dispersing the cloud of concentrated odors, and/or to use wind generators to maintain a minimum velocity across the source.

Strategies for Odor Management

Strategies for the management and control of odors are presented and discussed below. An overview of some of the methods used to control and treat odorous gases is presented in the following section. Where chronic odor problems occur at treatment facilities, approaches to solving these problems may include (1) control of odor-causing wastewaters discharged to the collection system and treatment plant that creates odor problems, (2) control of odors generated in the wastewater collection system, (3) control of odors generated in wastewater treatment facilities, (4) installation of odor containment and treatment facilities, (5) application of chemicals to the liquid (wastewater) phase, (6) use of odor masking and neutralizing agents, (7) use of gas-phase turbulence-inducing structures and facilities, and (8) establishment of buffer zones.

Control of Discharges to Wastewater Collection System. The elimination and/or control of wastewater discharges containing odorous compounds to the collection system can be accomplished by (1) adopting more stringent waste discharge ordinances and enforcement of their requirements, (2) requiring pretreatment of industrial wastewater, and (3) providing flow equalization at the source to eliminate slug discharges of wastewater.

Odor Control in Wastewater Collection Systems. The release of odors from the liquid phase in wastewater collection systems can be limited by (1) maintaining aerobic conditions through the addition of hydrogen peroxide, pure oxygen, or air at critical locations in the collection system and to long force mains (see Fig. 16–3), (2) controlling anaerobic microbial growth by disinfection or pH control, (3) oxidizing or precipitating odorous compounds by chemical addition, (4) design of the wastewater collection system to minimize the release of odors due to turbulence, and (5) off-gas treatment at selected locations.

Odor Control in Wastewater Treatment Facilities. With the proper attention to design details, such as the use of submerged inlets and weirs, the elimination of hydraulic jumps in influent piping and channels, the elimination of physical conditions leading to the formation of turbulence, proper process loadings, containment of odor sources, off-gas treatment, and good housekeeping, the routine release of odors at treatment plants can be minimized. It must also be recognized, however, that odors will develop occasionally. When they do, it is important that immediate steps be taken to control them. Some steps that can be taken include operational changes or the addition of chemicals, such as chlorine, sodium hypochlorite, hydrogen peroxide, lime, or ozone.

Design and operational changes that can be instituted can include (1) minimizing free-fall turbulence by controlling water levels, (2) reducing of overloading of plant processes, (3) increasing the aeration rate in biological treatment processes, (4) increasing the plant treatment capacity by operating standby process units, (5) reducing solids inventory and sludge backlog, (6) increasing the frequency of pumping of sludge and scum, (7) adding chlorinated dilution water to sludge thickeners, (8) controlling the release of aerosols, (9) increasing the frequency of disposal of grit and screenings, (10) cleaning odorous accumulations more frequently, and (11) containment, ventilation, and treatment of odorous gases.

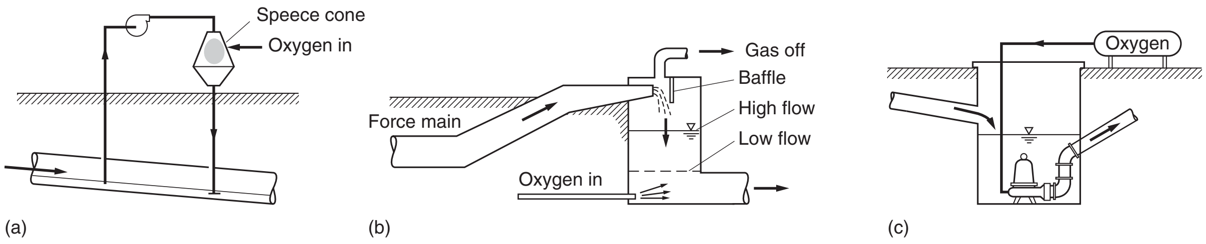

Figure 16–3

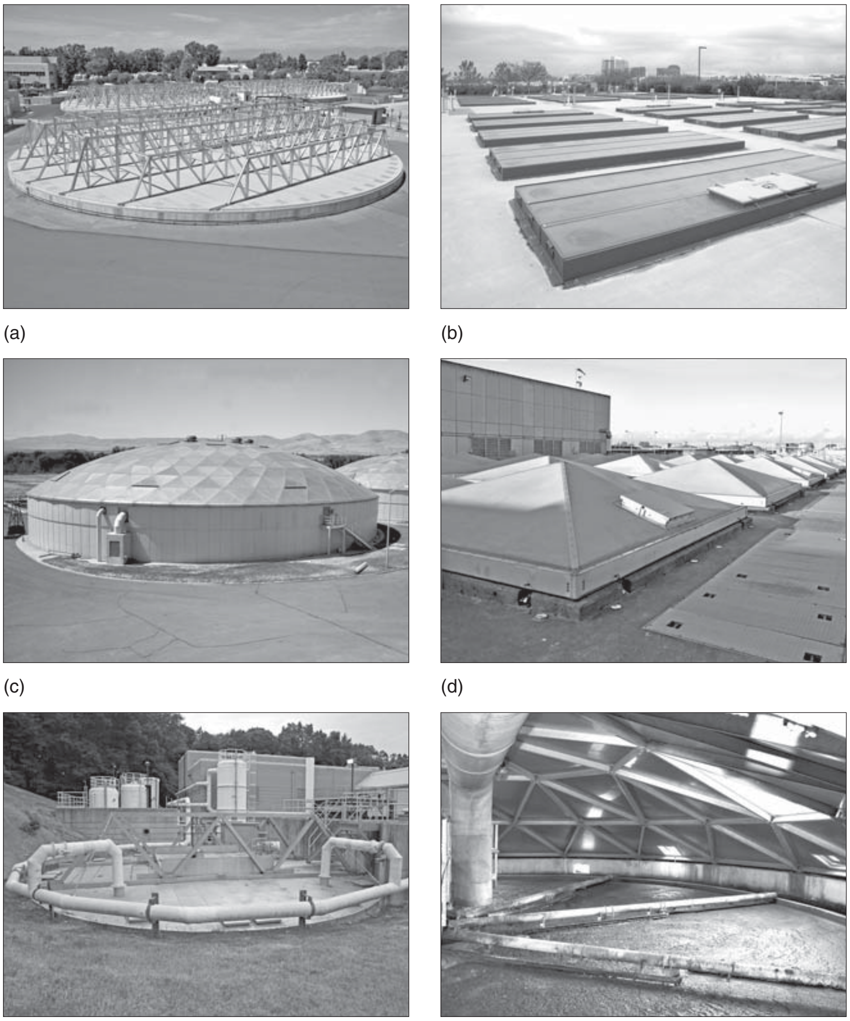
Typical uses of commercial oxygen in wastewater collection systems for odor control: (a) sidestream oxygenation and reinjection of wastewater into a gravity sewer, (b) Injection of oxygen into a hydraulic fall and (c) Injection of oxygen into two-phase flow in force main. (From Speece et al., 1990.)



(a) (b) (c) (d) (e) (f)

Figure 16–4

Typical odor containment facilities at wastewater treatment plants: (a) and (b) covered primary sedimentation tanks, (c) covered trickling filter, (d) cover over the solids contact portion of a trickling filter solids contact biological treatment process, (e) covered primary sludge fermentor, and (f) view inside of an enclosed sludge thickener.

Odor Containment. Odor containment includes the installation of covers, collection hoods, and air handling equipment for containing and directing odorous gases to disposal or treatment systems. In cases where the treatment facilities are close to developed areas, it has become common practice to enclose or cover treatment units such as the bar screens and grit processing units [see Fig. 16–1(a) and (b)], primary clarifiers [see Figs. 16–4(a) and (b)], trickling filters [see Fig. 16–4(c)], (d) biological treatment processes [see Fig. 16–4(d)], (e) sludge fermentors [see Fig. 16–4(e)], sludge thickeners [see Fig. 16–4(f)], sludge-processing facilities, and sludge-loadout facilities. Where covers are used, the trapped gases must be collected and treated. The specific method of treatment will depend on the characteristics of the odorous compounds. Typical containment alternatives for the control of odor emissions from wastewater management facilities are reported in Table 16–5.

Chemical Additions to Wastewater for Odor Control. Odors can be eliminated in the liquid phase through the addition of a variety of chemicals to achieve (1) chemical oxidation, (2) chemical precipitation, and (3) pH control. The most common oxidizing chemicals that can be added to wastewater include oxygen, air, chlorine, sodium

Table 16–5

Odor containment and process alternatives for the control of odors the emission from wastewater management facilities

Source	Suggested control strategies
Wastewater sewers	Seal existing access ports (i.e., manholes). Eliminate the use of structures that create turbulence and enhance volatilization.
Sewer appurtenances	Isolate and cover existing appurtenances.
Pump stations	Vent odorous gases from wet-well to treatment unit. Use variable-speed pumps to reduce the size of the wet-well.
Bar racks	Cover existing units. Reduce headloss through bar racks.
Comminutors	Cover existing units. Use inline enclosed comminutors.
Parshall flume	Cover existing units. Use alternative measuring device.
Grit chamber	Cover existing aerated grit chambers. Reduce turbulence in conventional horizontal-flow grit chambers; cover if necessary. Avoid the use of aerated grit chambers.
Equalization basins	Cover existing units. Use submerged mixers, and reduce air flow.
Primary and secondary sedimentation tanks	Cover existing units [see Figs. 16–4(a) and (b)]. Replace conventional overflow weirs with submerged weirs.
Biological treatment	Cover existing units. Use submerged mixers and reduce aeration rate.
Transfer channels	Use enclosed transfer channels.

hypochlorite, potassium permanganate, hydrogen peroxide, and ozone. While all of these compounds will oxidize hydrogen sulfide (H_2S) and other odorous compounds, their use is complicated by the chemical matrix in which the odorous gases exist. The only way to establish the required chemical dosages for the removal of chemical compounds is through bench- or pilot-scale testing.

Odorous compounds can also be reduced by precipitation. For example, ferrous chloride and ferrous sulfate can be used for the control of H_2S odors by precipitation of the sulfide ion as ferrous sulfide. As with the oxidation reactions, the required chemical dosage can be determined only through bench- or pilot-scale testing. The release of H_2S can also be controlled by increasing the pH value of the wastewater. Increasing the pH of the wastewater results in reduced bacterial activity and also shifts the equilibrium so that the sulfide ion is present as HS^-. With most of the odor control methods involving the addition of chemicals to wastewater, some residual product is formed that must ultimately be dealt with. Shock treatment involving the addition of sodium hydroxide (NaOH) can be used to reduce microbial slimes in sewers. The high pH also reduces sulfide (S^{2-}) formation. Additional details on chemical addition may be found in Rafson (1998).

Use of Odor Masking and Neutralization. On occasion, chemicals have been added to wastewater or offgases to mask an offensive odor with a less offensive odor. Masking chemicals are based on essential oils with the most common aromas being vanilla, citrus, pine, or floral (Williams, 1996). Typically, enough masking chemical is added to wastewater to overpower the offensive odor. Masking chemicals, however, do not modify or neutralize the offensive odors. Neutralization involves finding chemical compounds that can be combined with the odorous gases in the vapor state so that the

Figure 16–5

High barrier fence placed around sludge holding lagoons to induce air turbulence and mixing, and thus limit the release of odors off the treatment plant site (a) aerial view of sludge storage basins (coordinates N 38.439, W121,480) and (b) view of high barrier fence.

combined gases cancel each other's odor, produce an odor of lower intensity, or eliminate the odorous compounds. Although odor masking and neutralization are viable options for short-term management of odor problems, the key to long-term odor management is to identify the source of the odors and implement corrective measures.

Use of Turbulence-Inducing Structures and Facilities for Odor Dispersion. In a number of wastewater treatment plants, physical facilities used to induce atmospheric turbulence have been constructed specifically for the purpose of gas-phase odor reduction. The high barrier fence [3.7 m (12 ft)] shown on Fig. 16–5 surrounds sludge-storage lagoons. Operationally, any odorous gases that develop under quiescent conditions over the lagoons are diluted as they move away from the storage lagoons, due to the local turbulence induced by the barrier. Trees are also used commonly to dilute odorous gases by inducing turbulence (i.e., the formation of eddies) and mixing. Trees are also known to help purify the air as a result of respirometric activity.

Use of Buffer Zones. The use of buffer zones can also help in reducing the impact of odors on developed areas. Typical buffer zone distances used by regulatory agencies are presented in Table 16–6. If buffer zones are used, odor studies should be conducted that identify the type and magnitude of the odor source, meteorological conditions, dispersion characteristics, and type of adjacent development. Trees that grow rapidly are often planted at the periphery of the buffer zones to further reduce the impact of odors.

Odor Treatment Methods

The general classification of odor treatment methods is presented in Table 16–7, along with typical applications in wastewater management. Odor treatment methods are designed either to treat the odor producing compounds in the wastewater stream or to treat the foul air. Most of the methods in Table 16–7 are meant to be used to treat the foul air (i.e., the gas phase). As noted above, to control the release of odorous gases from treatment facilities, it has become more common to cover wastewater treatment processes (see Fig. 16–4).

The principal methods used to treat odorous gases include the use of (1) chemical scrubbers, (2) activated-carbon absorbers, (3) vapor-phase biological treatment processes (i.e., compost filters), (4) treatment in conventional biological treatment processes, and (5) thermal processes. Each of these methods is discussed below. The specific method of odor control and treatment that should be applied will vary with local conditions. However, because odor control measures are expensive, the cost of making process changes or

Table 16–6

Methods to control and treat odorous gases found in wastewater management systems[a]

Method	Description and/or application
Physical methods	
Adsorption on activated carbon	Odorous gases can be passed through beds of activated carbon to remove odors. Carbon regeneration can be used to reduce costs. Additional details may be found in Chap. 11.
Adsorption on sand, soil, or compost beds	Odorous gases can be passed through sand, soil, or compost beds. Odorous gases from pumping stations may be vented to the surrounding soils or to specially designed beds containing sand or soils. Odorous gases collected from treatment units may be passed through compost beds.
Combustion	Gaseous odors can be eliminated by combustion at temperatures varying from 650 to 815°C (1200 to 1500°F). Gases can be combusted in conjunction with treatment plant solids or separately in a fume incinerator.
Containment	Installation of covers, collection hoods, and air handling equipment for containing and directing odorous gases to disposal or treatment systems.
Dilution with odor-free air	Gases can be mixed with fresh air sources to reduce the odor unit values. Alternatively, gases can be discharged through tall stacks to achieve atmospheric dilution and dispersion.
Masking agents	Perfume scents can be sprayed in fine mists near offending process units to overpower or mask objectionable odors. In some cases, the odor of the masking agent is worse than the original odor. Effectiveness of masking agents is limited.
Oxygen injection	The injection of oxygen (either air or pure oxygen) into the wastewater to control the development of anaerobic conditions has proven to be effective.
Scrubbing towers	Odorous gases can be passed through specially designed scrubbing towers to remove odors. Some type of chemical or biological agent is usually used in conjunction with the tower.
Thermal oxidation	Combustion of off-gases at temperatures from 800 to 1400°C will eliminate odors. Lower temperatures (400 to 800°C) are used with catalytic incineration.
Turbulence inducing facilities	Use of wind breaks, such as high fences and trees, and propeller fans.
Chemical oxidation	Oxidizing the odor compounds in wastewater is one of the most common methods used to achieve odor control. Chlorine, ozone, hydrogen peroxide, and potassium permanganate are among the oxidants that have been used. Chlorine also limits the development of a slime layer.
Chemical precipitation	Chemical precipitation refers to the precipitation of sulfide with metallic salts, especially iron.
Scrubbing with various alkalies	Odorous gases can be passed through specially designed scrubbing towers to remove odors. If the level of carbon dioxide is high, costs may be prohibitive.
Biological methods	
Activated sludge aeration tanks	Odorous gases can be combined with the process air for activated sludge aeration tanks to remove odorous compounds.
Biological conversion	Biological processes in the wastewater can reduce odors by converting malodorous constituents through oxidation.
Biological stripping towers	Specially designed towers can be used to strip odorous compounds. Typically, the towers are filled with plastic packing of various types on which biological growths can be maintained.
Compost filters	Gases can be passed through biologically active beds of compost to remove odors.
Sand and soil filters	Gases can be passed through biologically active beds of compost to remove odors.
Trickling filters	Odorous gases can be passed through existing trickling filters to remove odorous compounds.

[b] Actual buffer distance requirements will depend on local conditions.

modifications to the facilities to eliminate odor development should always be evaluated and compared to the cost of various alternative odor control measures before their adoption is suggested.

Chemical Scrubbers. The basic design objective of a chemical scrubber is to provide contact between air, water, and chemicals (if used) to provide oxidation or entrainment of the odorous compounds. The principal wet scrubber types, as shown on Fig. 16–6, include single-stage countercurrent packed towers, countercurrent spray chamber absorbers, and cross-flow scrubbers. In most single-stage scrubbers, such as shown on Fig. 16–7, the scrubbing fluid (usually sodium hypochlorite) is recirculated. The commonly used oxidizing scrubbing liquids are sodium hypochlorite, potassium permanganate, and hydrogen peroxide solutions. Because of safety and handling issues, chlorine gas is not used commonly in scrubbing applications at wastewater treatment facilities. Sodium hydroxide is also used in scrubbers where H_2S concentrations in the gas phase are high.

Figure 16–6

Typical wet scrubbers systems for odor control: (a) countercurrent packed tower, (b) spray chamber absorber, and (c) cross-flow scrubber.

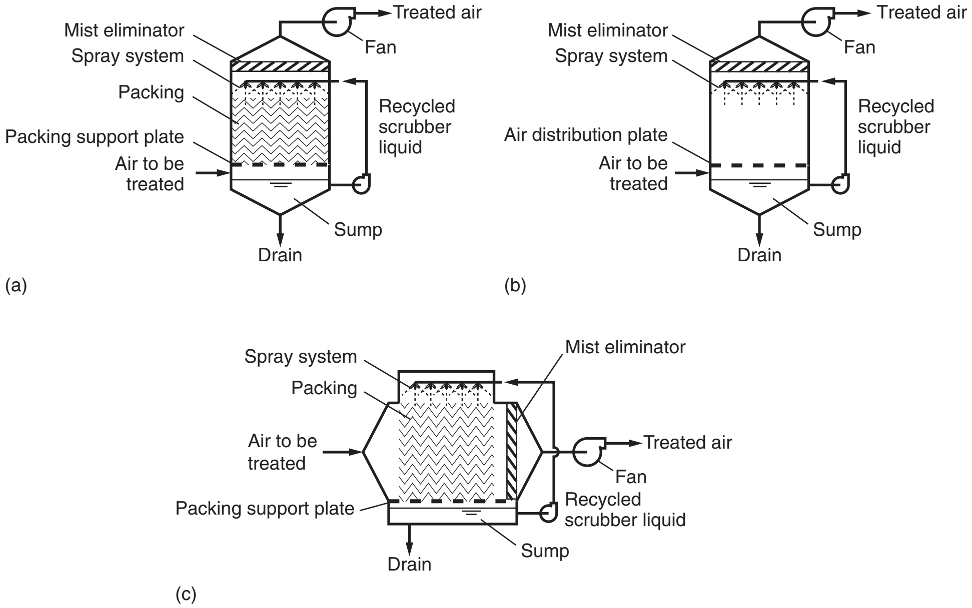

Figure 16–7

Typical sodium hypochlorite scrubber used to treat the odors from the trickling filters shown on Fig. 16–4(c).

Chemical Scrubbing Reactions for Hydrogen Sulfide. Typical simplified scrubbing reactions for H_2S with chlorine, sodium hypochlorite, potassium permanganate, and hydrogen peroxide are as follows:

With chlorine

$$\underset{(34.06)}{\mathrm{H_2S}} + \underset{(4\times 70.91)}{\mathrm{4Cl_2}} + \mathrm{4H_2O} \rightarrow \mathrm{H_2SO_4} + \mathrm{8HCl} \tag{16–1}$$

$$\underset{(34.06)}{\mathrm{H_2S}} + \underset{(70.91)}{\mathrm{Cl_2}} \rightarrow \mathrm{S^\circ}\downarrow + \mathrm{2HCl} \tag{16–2}$$

With sodium hypochlorite

$$\underset{(34.06)}{\mathrm{H_2S}} + \underset{(4\times 74.45)}{\mathrm{4NaOCl}} + \mathrm{2NaOH} \rightarrow \mathrm{Na_2SO_4} + \mathrm{2H_2O} + \mathrm{4NaCl} \tag{16–3}$$

$$\underset{(34.06)}{\mathrm{H_2S}} + \underset{(74.45)}{\mathrm{NaOCl}} \rightarrow \mathrm{S^\circ}\downarrow + \mathrm{NaCl} + \mathrm{H_2O} \tag{16–4}$$

With potassium permanganate

$$\underset{(3\times 34.06)}{\mathrm{3H_2S}} + \underset{(2\times 142.04)}{\mathrm{2KMnO_4}} \rightarrow \mathrm{3S} + \mathrm{2KOH} + \mathrm{2MnO_2} + \mathrm{2H_2O}\ \text{(acidic pH)} \tag{16–5}$$

$$\underset{(3\times 34.06)}{\mathrm{3H_2S}} + \underset{(8\times 142.04)}{\mathrm{8KMnO_4}} \rightarrow \mathrm{3K_2SO_4} + \mathrm{2KOH} + \mathrm{8MnO_2} + \mathrm{2H_2O}\ \text{(basic pH)} \tag{16–6}$$

With hydrogen peroxide

$$\underset{(34.06)}{\mathrm{H_2S}} + \underset{(34.0)}{\mathrm{H_2O_2}} \rightarrow \mathrm{S^\circ}\downarrow + \mathrm{2H_2O}\ (\mathrm{pH} < 8.5) \tag{16–7}$$

In the reaction given by Eq. (16–3), 8.74 mg/L of sodium hypochlorite is required per mg/L of hydrogen sulfide, or 9.29 mg/L if the hydrogen sulfide is expressed as sulfide. In addition, in the reaction given by Eq. (16–3), 2.35 mg/L of sodium hydroxide (caustic) will be required per mg/L of hydrogen sulfide to make up for alkalinity consumed in the reaction. In practice, the required sodium hypochlorite dosage for the reaction given by Eq. (16–3) will vary from 8 to 10 mg/L per mg/L of H_2S. For the reaction given by Eq. (16–4), 2.19 mg/L of sodium hypochlorite is required per mg/L of hydrogen sulfide.

When potassium permanganate is used, the reactions that occur are typically various combinations of the reactions given by Eqs. (16–5) and (16–6). Reaction products that can occur, depending on the local wastewater chemistry, include elemental sulfur, sulfate, thionates, dithionates, and manganese sulfide. Stoichiometrically, about 2.8 and 11.1 mg/L of $KMnO_4$ are required for each mg/L of H_2S oxidized as given by Eqs. (16–5) and (16–6), respectively. However, based on operating data from actual field installations, about 6 to 7 mg/L $KMnO_4$ are required for each mg/L of H_2S oxidized. Potassium permanganate is generally used in smaller installations because of the cost (U.S. EPA, 1985; WEF, 1995).

In the reaction given in Eq. (16–7), 1.0 mg/L of hydrogen peroxide is required for each mg/L of sulfide expressed as hydrogen sulfide. In practice, the required dosage can vary from 1 to 4 mg/L per mg/L of H_2S. Because the systems used to carry out the reactions defined by Eqs. (16–1) through (16–7) are complex, especially where competing reactions may occur, the proper dosage should be established by site-specific testing.

Hypochlorite scrubbers can be expected to remove oxidizable odorous gases when other gas concentrations are minimal. Typical removal efficiencies for single-stage scrubbers are reported in Table 16–8. In cases where the concentrations of odorous components in the exhaust gas from the scrubbers are above desirable levels, multistage scrubbers (see Fig. 16–8) are often used. In the three-stage scrubber shown on Fig. 16–8, the first stage is a pretreatment stage used to raise the pH so that a portion of the odorous gases (e.g., hydrogen sulfide) is reduced before treatment with chlorine in the second and third stages. The reaction that occurs in the first stage of a three-stage unit can be represented as follows.

$$H_2S + 2NaOH \rightarrow Na_2S + 2H_2O \qquad (16\text{–}8)$$

To reduce maintenance problems due to precipitation, it is recommended that a low hardness (less than 50 mg/L as $CaCO_3$) be used for the makeup water.

Chemical Scrubbing of Ammonia and/or Ammine Compounds. In situations where there is a potential for the release of high concentrations of ammonia or ammine compounds, such as from solids handling and lime stabilization processes, an additional tower may be needed. The removal of ammonia or ammine compounds is accomplished with an

Table 16–8

Effectiveness of hypochlorite wet scrubbers for removal of several odorous gases[a]

Gas	Expected removal efficiency, %	
	Range	Typical
Hydrogen sulfide	90–99	98
Ammonia	90–99	98
Sulfur dioxide	90–96	95
Mercaptans	85–92	90
Other oxidizable compounds	70–90	85

[a] Adapted in part from U.S. EPA (1985).

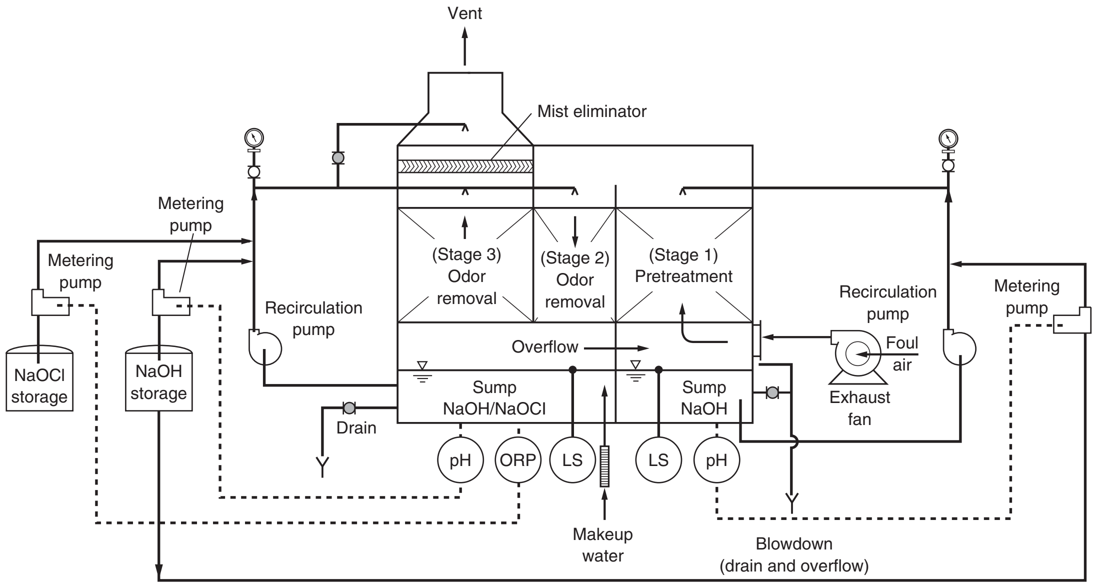

Figure 16–8

Three-stage odor control process flow diagram. (From Lo/Pro Systems, Inc.)

acid/base reaction with sulfuric acid. Typically, the pH of recirculating sulfuric acid solutions is around 4.0 to 6.0 and the following reaction occurs:

$$2NH_3 + H_2SO_4 \rightarrow (NH_4)_2SO_4 \tag{16–9}$$

Some of the spent scrubbing liquid that contains the solid ammonium sulfate is discharged from the scrubber. The waste spent scrubbing fluid is typically returned to the treatment plant headworks. The remaining scrubbing liquid is recirculated back into the tower with additional sulfuric acid added to maintain the proper pH of the scrubbing liquid.

Activated Carbon Adsorbers. Activated carbon adsorbers are used commonly for odor control (see Fig. 16–9). The rate of adsorption for different constituents or compounds will depend on the nature of the constituents or compounds being adsorbed (nonpolar versus polar). It has also been found that the removal of odors depends on the

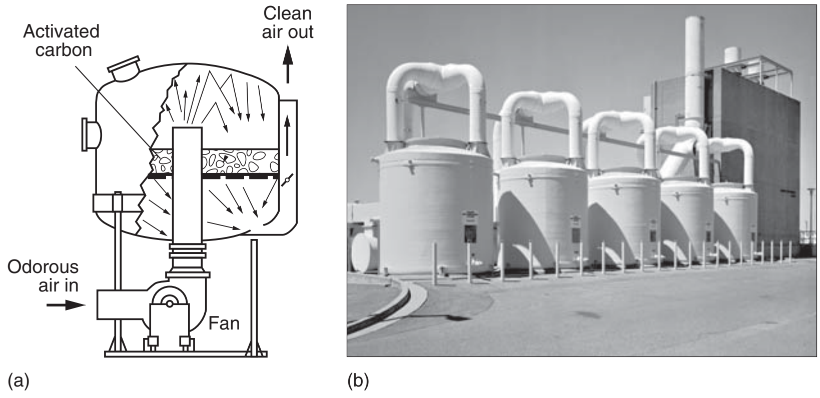

Figure 16–9

Use of activated carbon for odor control: (a) schematic of typical downflow activated carbon reactor and (b) view of multiple activated carbon odor control reactors.

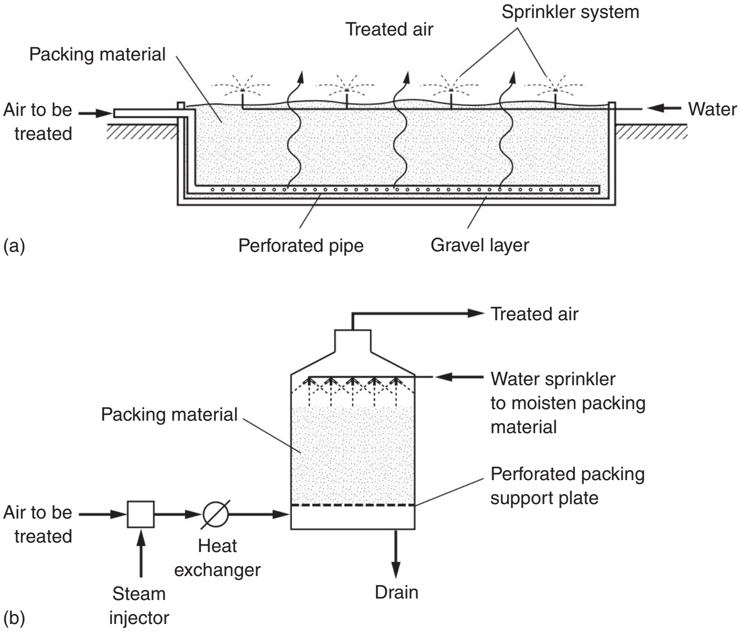
concentration of the hydrocarbons in the odorous gas. Typically, hydrocarbons are adsorbed preferentially before polar compounds such as H_2S are removed (note activated carbon is nonpolar). Thus, the composition of the odorous gases to be treated must be known if activated carbon is to be used effectively. Because the life of a carbon bed is limited, carbon must be regenerated (see Sec. 11–7 in Chap. 11) or replaced regularly for continued odor removal. To prolong the life of the carbon, two-stage systems have been used, with the first stage being a wet scrubber followed by activated-carbon adsorption.

Vapor-Phase Biological Treatment Processes. The two principal biological processes used for the treatment of odorous gases present in the vapor phase are (1) biofilters and (2) biotrickling filters (Eweis et al., 1998). The use of microbial growths for the treatment of odors was the subject of an early patent by Pomeroy (1957), one of the important early researchers in the area of odor management in wastewater collection and treatment facilities.

Biofilters. Biofilters are packed-bed filters. In open biofilters [see Fig. 16–10(a)], the gases to be treated move upward through the filter bed. In closed biofilters [see Fig. 16–10(b)], the gases to be treated are either blown or drawn through the packing material. As the odorous gases move through the packing in the biofilter, two processes occur simultaneously: sorption (i.e., absorption/adsorption) and bioconversion. Odorous gases are absorbed into the moist surface biofilm layer and the surfaces of the biofilter packing material. Microorganisms, principally bacteria, actinomycetes, and fungi, attached to the packing material, oxidize the absorbed/adsorbed gases and renew the treatment capacity of the packing material. Moisture content and temperature are important environmental conditions that must be maintained to optimize microorganism activity (Williams and Miller, 1992a, 1992b; Yang and Allen, 1994; Eweis et al., 1998). Although compost biofilters are used commonly, one drawback is the large surface area (footprint) required for these units.

Figure 16–10

Typical packed bed biofilters: (a) open bed type and (b) enclosed reactor type.



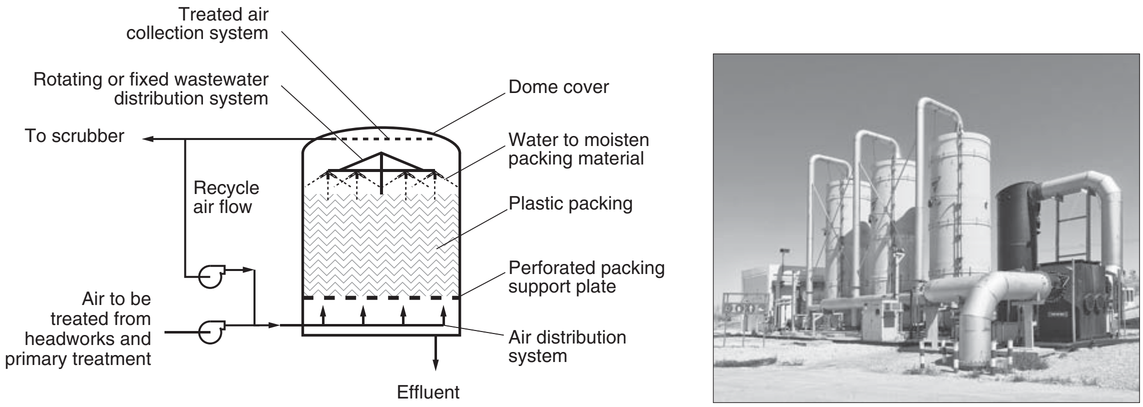


Figure 16–11

Typical covered biological stripping tower used for odor control (a) schematic and (b) view of multiple biological stripping towers.

Biotrickling Filters. Biotrickling filters are essentially the same as biofilters with the exception that moisture is provided continuously or intermittently by applying (typically spraying) a liquid (e.g., treated effluent) over the packing (see Fig. 16–11). The liquid is recirculated and nutrients are often added. Because water is lost in the gas leaving the filter, makeup water must be provided. Similarly, because of the accumulation of salts in the recycled water, a blowdown stream is required. Compost is not a suitable packing material for biotrickling filters because water will accumulate within the compost, thereby limiting the free movement of air within the filter. Typical packing materials include Pall rings, Raschig rings, lava rock, and granular activated carbon (Eweis et al., 1998; see also Sec. 11–8, Gas Stripping, in Chap. 11).

Conventional Biological Treatment Processes. The ability of microorganisms to oxidize hydrogen sulfide and other similar odorous compounds dissolved in the liquid under aerobic conditions is the basic concept used for the treatment of odors in liquid-based systems. The two principal types of conventional liquid-based systems used in wastewater treatment plants are the activated sludge process and the trickling filter process. In the activated sludge process, the odorous compounds are introduced into the aeration basin either with the existing air supply or injected separately through a manifold system. A major concern with this method of odor management is the high rate of corrosion in the air piping and blowers that occurs due to the presence of moist air containing hydrogen sulfide. The ability to transfer the odorous gaseous compounds to the liquid phase is also of concern.

With conventional uncovered trickling filters the major issues are how to transfer the air containing the odorous compounds to the trickling filter and how to avoid the release of untreated odorous compounds to the atmosphere. To control the release of odorous compounds, existing trickling filters that are to be used for odor control are almost always covered [see Fig. 16–4(c)].

Thermal Processing. Three thermal processing techniques have been used: (1) thermal oxidation, (2) catalytic oxidation, and (3) recuperative and regenerative thermal oxidation.

The Oxidation Process. The oxidation of CH_4 (methane) and H_2S can be used to illustrate the basic principle of all three thermal processes.

$$CH_4(\text{gas}) + 2O_2(\text{gas}) \rightarrow CO_2(\text{gas}) + 2H_2O(\text{vapor}) + \text{heat} \tag{16–10}$$

$$H_2S(\text{gas}) + 2O_2(\text{gas}) \rightarrow H_2SO_4(\text{vapor}) \tag{16–11}$$

If the gas to be combusted does not liberate enough heat to sustain the combustion process, it is usually necessary to use an external fuel source such as fuel oil, natural gas, or propane. Unfortunately, because of the low concentrations of odorous combustible gases in most waste streams, sustainable thermal oxidation is seldom possible, and large amounts of fuel are typically required to maintain the combustion temperatures needed to eliminate odors.

Thermal Oxidation. Thermal oxidation is used, more commonly, for concentrated waste streams. The flaring of odorous gases is a relatively crude form of thermal combustion [see Fig. 16–12(a)]. Depending on the design of the combustion facility, incomplete combustion can occur due to variations in gas flow. For this method of odor control to be sustainable, the waste gas must typically contain 50 percent of the fuel value of the gas stream to be combusted.

Catalytic oxidation. A flameless oxidation that occurs in the range from 310 to 425°C (600 to 800°F) in the presence of a catalyst is defined as catalytic oxidation [see Fig. 16–12(b)]. Common catalysts include platinum, palladium, and rubidium. The decrease in temperature as compared to complete thermal oxidation reduces the energy requirements significantly. However, because the catalysts can become fouled, the gas to be

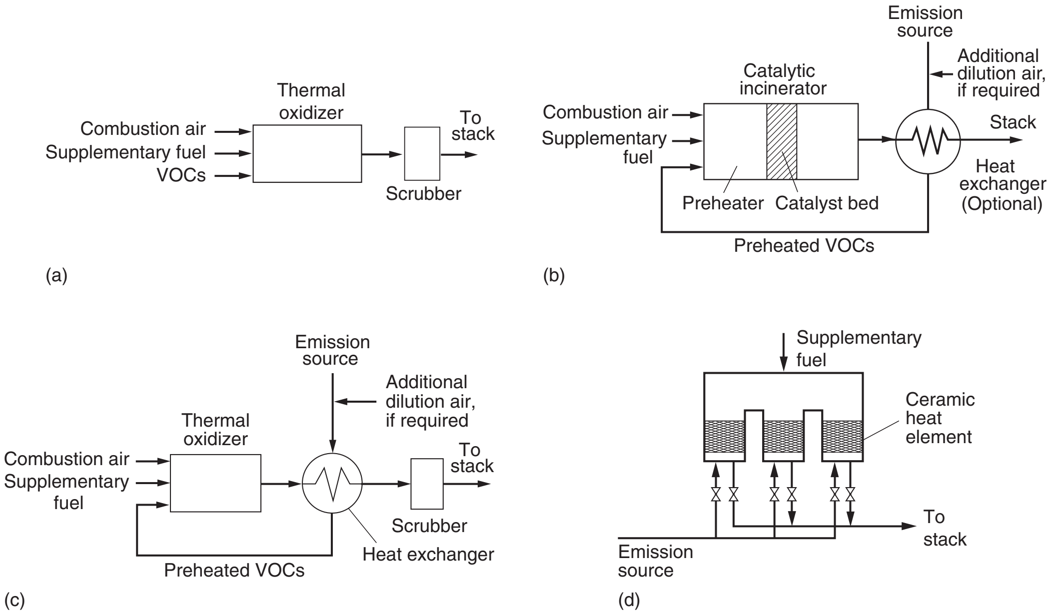

Figure 16–12

Schematic diagrams of thermal processes for treatment of VOCs: (a) thermal oxidation, (b) catalytical oxidizer, (c) recuperative thermal oxidizer, and (d) regenerating thermal oxidizer.

oxidized must not contain particulate material or constituents that will result in a residue. Additional information on the physical facilities used for thermal processing of VOCs may be found in Sec. 16–4.

Recuperative and Regenerative Thermal Oxidation. This process involves preheating the odorous gases before passing them into the combustion chamber so that complete oxidation can be achieved. Combustion occurs at temperatures in the range from 425 to 760°C (800 to 1400°F). Recuperative and regenerative thermal oxidation processes are used to reduce fuel consumption by preheating the incoming air, especially in large installations. In recuperative oxidizers, thin wall tubes are used to transfer heat recovered from exhaust air to the incoming air [see Fig. 16–12(c)]. In regenerative oxidizers, ceramic packing material is used to capture the heat from the hot exhaust gas and subsequently to release it to the incoming air. To maintain optimal heat recovery, the exhaust and incoming air are cycled through the packing material so that the incoming air is always passed through the hottest packing material. Typically, three stages of packing material are used in regenerative oxidizers [see Fig. 16–12(d)].

Selection and Design of Odor Control Facilities

The following steps are involved in the selection and design of odor control and treatment facilities:

1. Determine the characteristics and volumes of the gas to be treated.
2. Define the exhaust requirements for the treated gas.
3. Evaluate climatic and atmospheric conditions.
4. Select one or more odor control and treatment technologies to be evaluated.
5. Conduct pilot tests to determine design criteria and performance.
6. Perform life cycle economic analysis.

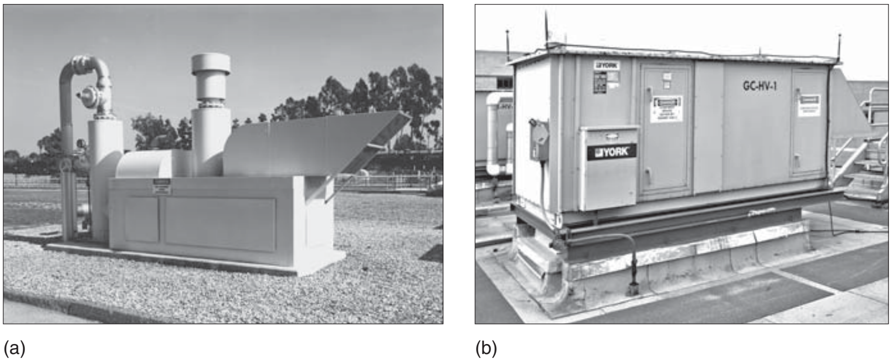
Many of the chemical odor control technologies are supplied as complete packages, designed to meet a given performance specification. The analysis of chemical scrubbers and the design of biofilters is considered in the following discussion.

Design Considerations for Chemical Scrubbers

Most chemical scrubbers are supplied as a complete unit (see Fig. 16–13). Typical design factors for chemical scrubbers are presented in Table 16–9. Determination of the chemical requirements for odor scrubbing is illustrated in Example 16–1.

Figure 16–13

Typical self contained chemical odor stripping unit.



(a) (b)

Table 16–9

Typical design factors for chemical scrubbers[a]

Item	Unit	Value
Packing depth	m	1.8–3
Gas residence time in packing	s	1.3–2.0
Scrubbant flowrate	kg H_2O/kg air flow	1.5–2.5
	L/s per m^3/s air flow	2–3
Makeup water flow	L/s per kg sulfide at pH 11	0.075
	L/s per kg sulfide at pH 12.5	0.004
pH	unitless	11–12.5
Temperature	°C	15–40
Caustic usage	kg NaOH/kg sulfide	2–3

[a] Adapted in part from from WEF (1995), Devinny et al. (1999).

EXAMPLE 16–1 **Chemical Requirements for Odor Scrubbing** Hydrogen sulfide is to be scrubbed from a waste airstream using sodium hypochlorite. Determine the chemical (i.e., sodium hypochlorite and caustic) and water requirements for the following conditions.

1. Waste airstream flowrate = 1000 m^3/min
2. H_2S concentration in waste stream = 20 ppm_v at 20°C
3. Specific weight of air = 0.0118 kN/m^3 at 20°C
4. Density of air = 1.204 kg/m^3 at 20°C (see Sec. B-3 in Appendix B)
5. Assume liquid to gas ratio for scrubber = 1.75
6. Density of 50 percent NaOH solution = 1.52 kg/L

Solution

1. Determine the volume occupied by one mole of a gas at a temperature of 20°C and a pressure of 1.0 atm using Eq. (2–44).

$$V = \frac{nRT}{P}$$

$$V = \frac{(1\text{ mole})(0.082057\text{ atm}\cdot\text{L/mole}\cdot\text{K})[(273.15 + 20)\text{K}]}{1.0\text{ atm}}$$

$$= 24.055\text{L} \qquad \text{use } 24.1\text{L}$$

2. Estimate the sodium hypochlorite requirement.
   a. Using Eq. (2–45), convert the H_2S concentration from ppm_v to g/m^3.

$$20\text{ ppm}_v = \left(\frac{20\text{ m}^3}{10^6\text{ m}^3}\right)\left[\frac{(34.8\text{ g/mole H}_2\text{S})}{(24.1 \times 10^{-3}\text{ m}^3\text{/mole of H}_2\text{S})}\right]$$

$$\text{H}_2\text{S concentration} = 28.3 \times 10^{-3}\text{ g/m}^3$$

   b. Determine the amount of H_2S that must be treated per day.

$$(1000\text{ m}^3\text{/min}) \times (28.3 \times 10^{-3}\text{ g/m}^3)(1440\text{ min/d})(1\text{ kg}/10^3\text{ g}) = 40.8\text{ kg/d}$$

c. Estimate the sodium hypochlorite dose. From Eq. (16–3), 8.74 mg/L of sodium hypochlorite are required per mg/L of sulfide, expressed as hydrogen sulfide.

$NaOCl_2$ required per day = (40.8 kg/d)(8.74) = 356.6 kg/d

3. Estimate the water requirement for the scrubbing tower.
   a. Determine the mass air flowrate.

   $(1000 \text{ m}^3/\text{min})(1.204 \text{ kg/m}^3) = 1204 \text{ kg/min}$

   b. Determine the water flowrate.

   $(1204 \text{ kg/min})(1.75) = 2107 \text{ kg/min} = 2.1 \text{ m}^3/\text{min}$

4. Determine the amount of sodium hydroxide (caustic) that must be added to replace the alkalinity consumed in the reaction.
   a. From the reaction given by Eq. (16–3), 2.35 mg/L of NaOH is required for each mg/L of H_2S removed.
   b. Determine the amount of NaOH required.

   NaOH = (40.8 kg/d)(2.35) = 95.9 kg/d

   c. Determine the volume of NaOH required. The amount of caustic per liter at 50% NaOH is

   NaOH = (1.52 kg/L)(0.50) = 0.76 kg/L

$$\text{Volume of NaOH} = \frac{(95.9 \text{ kg/d})}{(0.76 \text{ kg/L})} = 126.2 \text{ L/d}$$

Comment The water requirement for the scrubbing tower will be specified initially by the scrubber supplier and field adjusted based on the results of pilot-plant studies and past operating experience. If the wastewater has sufficient alkalinity, it may not be necessary to add sodium hydroxide.

Design Considerations for Odor Control Biofilters

Important design considerations for biofilters include (1) the type and composition of the packing material, (2) facilities for gas distribution, (3) maintenance of moisture within the biofilter, and (4) temperature control. Each of these topics is considered below. Design and operational parameters are presented and discussed following the discussion of the above topics. Additional details on biofilters may be found in van Lith (1989), Allen and Yang (1991, 1992), WEF (1995), Eweis et al., (1998), Devinny et al. (1999), and WEF (2004).

Packing Material. The requirements for the packing used in biofilters are (1) sufficient porosity and near-uniform particle size, (2) particles with large surface areas and significant pH-buffering capacities, and (3) the ability to support a large population of microflora (WEF, 1995). Packing materials used in biofilters include compost, peat, and a variety of synthetic mediums. Although soil and sand have been used in the past, they are less used today because of excessive headloss and clogging problems (Bohn and Bohn, 1988). Bulking materials used to maintain the porosity of compost and peat biofilters include perlite, Styrofoam™ pellets, wood chips, bark, and a variety of ceramic and plastic materials. A typical recipe for a compost biofilter is as follows (Schroeder, 2001):

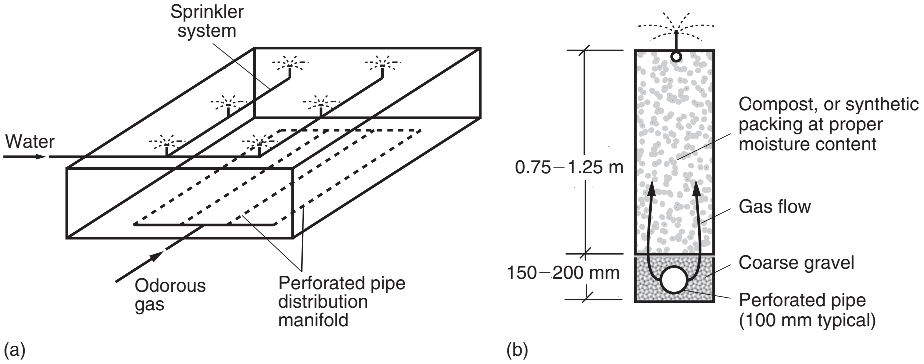
Compost = 50 percent by volume

Bulking agent = 50 percent by volume

1 meq $CaCO_3$/g of packing material by weight

Figure 16–14

Definition sketch for packed bed biofilters: (a) open bed and (b) trench type.



Optimal physical characteristics of a packing material include a pH between 7 and 8, air-filled pore space between 40 and 80 percent, and organic matter content of 35 to 55 percent (Williams and Miller, 1992a, 1992b). When compost is used, additional compost must be added periodically to account for the loss due to biological conversion. Bed depths of up to 1.8 m (6.0 ft) have been used. However, because most of the removal takes place in the first 20 percent of the bed, the use of deeper beds is not recommended.

Gas Distribution. An important design feature of a biofilter is the method used to introduce the gas to be treated. The most commonly used gas distribution systems include (1) perforated pipes, (2) prefabricated underdrain systems, and (3) plenums. Perforated pipes are usually placed in a gravel layer below the compost (see Fig. 16–14). Where perforated pipes are used, it is important to size the pipe so that it performs as a reservoir and not a manifold to assure uniform distribution (Crites and Tchobanoglous, 1998). A variety of prefabricated underdrain systems are available that allow for the movement of gas upward through the compost bed and allow for the collection of drainage. Air plenums are used to equalize the air pressure to achieve uniform flow upward through the compost bed. The height of air plenums will typically vary from 200 to 500 mm.

Moisture Control. Perhaps the most critical item in the successful operation of a biofilter is to maintain the proper moisture within the filter bed. If the moisture content is too low, biological activity will be reduced. If the moisture content is too high, the flow of air will be restricted and anaerobic conditions may develop within the bed. Also, biofilters tend to dry out unless moisture or humidity is added. The optimal moisture content is between about 50 and 65 percent, defined as follows:

$$\text{Moisture content, \%} = \left(\frac{\text{mass of water}}{\text{mass of water} + \text{mass of dry packing}}\right) \times 100 \qquad (16\text{–}12)$$

Moisture can be supplied by adding water to the top of the bed (usually by spraying) or by humidifying the incoming gas in a humidification chamber. The relative humidity of the gas entering the biofilter should be 100 percent at the operating temperature of the biofilter (Eweis et al., 1998). The liquid application rate for biotrickling filters is typically about 0.75 to 1.25 $m^3/m^2 \cdot d$.

Temperature Control. The operating temperature range for biofilters is between 15 and 45°C, with the optimal range being between 25 and 35°C. In cold climates, biofilters must be insulated, and the incoming gas must be heated. Where the incoming gas is warmer, it may have to be cooled before being introduced to the biofilter. Operation at higher temperatures (e.g., 45 to 60°C) is often possible, as long as the temperature remains relatively constant.

Design and Operating Parameters for Biofilters. The sizing of biofilters is typically based on a consideration of the gas residence time in the bed, the unit air loading rate, and the constituent elimination capacity. Terms that will be encountered in the literature and the relationships commonly used to describe the performance of bulk media filters are summarized in Table 16–10. The empty bed residence time (EBRT) [see Eq. (16–13)], used to define the relationship between the volume of the contactor and the volumetric gas flowrate, is similar to Eq. (11–62) used for the analysis of activated-carbon systems. The true residence time is determined by incorporating the porosity, a [see Eq. (16–14)]. Surface and volumetric mass loading rates are often used to define the operation of bulk media filters. The elimination capacity, as given by Eq. (16–20), is used to compare the performance of different odor control systems.

The residence time for foul air from wastewater treatment facilities is typically between 15 and 60 s, and surface loading rates have ranged up to 120 $m^3/m^2 \cdot min$ for H_2S concentrations up to 20 mg/L. Constituent elimination rates are determined experimentally and are usually reported as a function of the constituent loading rate (e.g., mg $H_2S/m^3 \cdot h$). An essentially linear, 1 to 1, constituent elimination rate up to a critical loading rate has been observed for hydrogen sulfide and other odorous compounds

Table 16–10

Parameters used for the design and analysis of bulk media filters[a]

Parameter	Definition
Empty bed residence time $\text{EBRT} = \frac{V_f}{Q}$ (16–13) Actual residence time in filter $\text{RT} = \frac{V_f \times \alpha}{Q}$ (16–14) Surface loading rate $\text{SLR} = \frac{Q}{A_f}$ (16–15) Surface mass loading rate $\text{SLR}_m = \frac{Q \times C_o}{A_f}$ (16–16) Volume loading rate $\text{VLR} = \frac{Q}{V_f}$ (16–17) Volume mass loading rate $\text{VLR}_m = \frac{Q \times C_o}{V_f}$ (16–18) Removal efficiency $\text{RE} = \frac{C_o - C_e}{C_o} \times 100$ (16–19) Elimination capacity $\text{EC} = \frac{Q(C_o - C_e)}{V_f}$ (16–20)	EBRT = empty bed residence time, h V_f = total volume of filter bed contactor, m^3 Q = volumetric flowrate, m^3/h RT = residence time, h, min, s a = porosity of filter bed contactor SLR = surface loading rate, $m^3/m^2 \cdot h$ A_f = surface area of filter bed contactor, m^2 VLR = volumetric loading rate, $m^3/m^3 \cdot h$ RE = removal efficiency, % C_o = influent gas concentration, mg/L EC = elimination capacity, $g/m^3 \cdot h$ C_e = effluent gas concentration, mg/L

---

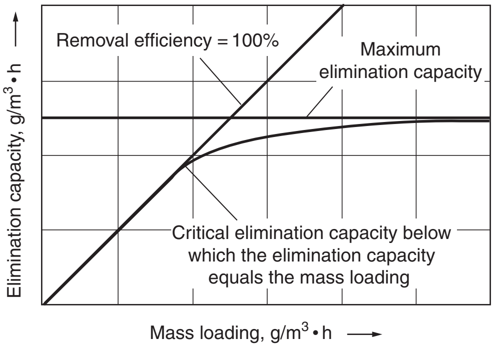
Figure 16–15

Typical odor elimination capacity versus applied load.



(see Fig. 16–15). Yang and Allen (1994) have reported a linear 1 to 1 elimination rate for H_2S, with loading rates for compost filters up to a maximum value of about 130 g $S/m^3 \cdot h$, beyond which the elimination rate becomes essentially constant at a rate of 130 g $S/m^3 \cdot h$ with increased loading. It should be noted that H_2S is eliminated easily as it passes through a biofilter.

Typical design criteria for biofilters are presented in Table 16–11. Typical biofilters are shown on Fig. 16–16. Some states regulate the design of compost biofilters including

Table 16–11

Typical design factors for biofilters[a]

		Type of biofilter	
Item	**Units**	**Biofilter**	**Biotrickling filter**
Oxygen concentration	Parts oxygen/ parts oxidizable gas	100	100
Moisture			
Compost filter	%	50–65	50–65
Synthetic media	%	55–65	55–65
Temperature, optimum	°C	15–35	15–35
pH	unitless	6–8	6–8
Porosity	%	35–50	35–50
Gas residence time	s	30–60	30–60
Depth of medium	m	1–1.25	1–1.25
Inlet odorous gas concentration	g/m^3	0.01–0.5	0.01–0.5
Surface loading rate	$m^3/m^2 \cdot h$	10–100[b]	10–100[b]
Volume loading rate	$m^3/m^3 \cdot h$	10–100	10–100
Liquid application rate	$m^3/m^2 \cdot d$		0.75 to 1.25
Elimination capacity			
H_2S (in compost filter)	$mg/m^3 \cdot h$	80–130	80–130
Other odorous gases	$mg/m^3 \cdot h$	20–100	20–100
Back pressure, maximum	mm of water	50–100	50–100

[a] Adapted in part from van Lith (1989), Yang and Allen (1994), WEF (1995), and Devinny et al. (1999).

[b] Loading rates as high as 500 $m^3/m^2 \cdot h$ have been reported, depending on the compound and its concentration.

Figure 16–16

(a) (b)

loading rates, biofilter emission rates, odor-sampling procedures, and setbacks from property lines. A typical odor-emission limit at the surface of the biofilter is 50 dilutions to threshold [see Eq. (2–52) in Chap. 2)] (Finn and Spencer, 1997). The design of a compost biofilter for the elimination of hydrogen sulfide is illustrated in Example 16–2.

EXAMPLE 16–2 **Design of a Compost Biofilter for Odor Control** Determine the size of compost biofilter needed to scrub the air from a 100 m^3 enclosed volume using the design criteria given in Table 16–11. Also estimate the mass of the buffer compound needed to neutralize the acid formed as a result of treatment within the filter. Assume 12 air changes per hour are needed. Assume a bed porosity of 40 percent. Will the volume selected be adequate if the air contains 40 ppm_v of H_2S in addition to other odorous constituents? Assume an elimination rate of 65 g $S/m^3{\cdot}h$, which incorporates a factor of safety of 2 as compared to the maximum rate given in Table 16–11. The temperature of the air is 20°C.

Solution

1. Estimate the airflow to be scrubbed.
   Flow = volume/time
   Flow = $(100\ m^3)(12\ \text{changes per h}) = 1200\ m^3/h$
2. Select a loading rate from Table 16–11; use 90 $m^3/m^2{\cdot}h$.
3. Select a filter-bed depth from Table 16–11; use 1.0 m.
4. Calculate the area needed for the filter bed.
   Area = gas flow/loading rate
   Area = $(11200\ m^3/h)/(90\ m^3/m^2{\cdot}h)$
   Area = $13.3\ m^2$
5. Check the empty bed residence time using Eq. (16–13).

$$\text{EBRT} = \frac{V_f}{Q} = \frac{(13.3\ m^2)(1\ m)}{(1200\ m^3/h)}$$
$$= 0.011\ h = 39.9\ s\ (\text{OK } 39.9\ s > 30\ s)$$

6. Determine if the volume of the biofilter determined in Step 5 is adequate to treat the H_2S.

a. Determine the concentration of H_2S in g/m^3 using Eq. (2–45). From Example 16–1 the volume of gas occupied by one mole of a gas at a temperature of 20°C and a pressure of 1.0 atm is 24.1 L. Thus, the concentration of H_2S is

$$\text{g/m}^3 = \left(\frac{40\ \text{L}^3}{10^6\ \text{L}^3}\right)\left[\frac{(34.08\ \text{g/mole H}_2\text{S})}{(24.1 \times 10^{-3}\ \text{m}^3\text{/mole of H}_2\text{S})}\right]$$

$$= 0.057\ \text{g/m}^3$$

b. Determine the mass loading rate of S^{2-} in g S/h.

$$M_s = \left(\frac{1200\ \text{m}^3}{\text{h}}\right)\left(\frac{0.057\ \text{g H}_2\text{S}}{\text{m}^3}\right)\left(\frac{32\ \text{g S}^{2-}}{34.08\ \text{g H}_2\text{S}}\right)$$

$$= 64.2\ \text{g S}^{2-}\text{/h}$$

c. Determine the required volume assuming an elimination rate of 65 g S/m^3·h.

$$V = \frac{(64.2\ \text{g S/h})}{(65\ \text{g S/m}^3\cdot\text{h})} = 0.99\ \text{m}^3$$

Because the volume of the bed (13.3 m^3) is significantly greater than the required volume, the removal of H_2S will not be an issue.

7. Determine the mass of the buffer compound needed to neutralize the acid formed as a result of treatment within the filter.

a. Determine the mass of H_2S in kg applied per year.

$$\text{H}_2\text{S, kg/year} = \frac{(1200\ \text{m}^3\text{/h})(0.057\ \text{g/m}^3)(24\ \text{h/d})(365\ \text{d/y})}{(10^3\ \text{g/1 kg})}$$

$$= 599.2\ \text{kg/y}$$

b. Determine the mass of buffer compound required. Assume the following equation applies:

$$\underset{34.06}{\text{H}_2\text{S}} + \underset{74.08}{\text{Ca(OH)}_2} + 2\text{O}_2 \rightarrow \text{Ca}_2\text{SO}_4 + 2\text{H}_2\text{O}$$

Thus, about 2.18 kg of $Ca(OH)_2$ (74.08/34.06) will be required per kg of H_2S. If the compost biofilter has a useful life of 2 y, then a total of 2457 kg of $Ca(OH)_2$ equivalent will be required to be added to the bed. Typically, 1.25 to 1.5 times as much are added. The buffer compound is mixed in with the compost and the bulking agent.

Comment Based on the results of the computation carried out in Step 6, it is clear why compost and soil filters are so effective in the elimination of H_2S.

16–4 CONTROL OF VOLATILE ORGANIC CARBON EMISSIONS

Many of the organic priority pollutants of concern in wastewater treatment are, as noted in Chap. 2, also classified as volatile organic compounds (VOCs). At some wastewater-treatment facilities, volatile organic compounds (VOCs) such as trichloroethylene (TCE) and 1,2-dibromo-3-chloropropane (DBCP) have been detected in wastewater.

The uncontrolled release of such compounds that now occurs in wastewater collection systems and wastewater-treatment plants is of concern because (1) once such compounds are in the vapor state they are much more mobile and, therefore, more likely to be released to the environment, (2) the presence of some of these compounds in the atmosphere may pose a significant public health risk, and (3) they contribute to a general increase in reactive hydrocarbons in the atmosphere, which can lead to the formation of ground-level ozone. The physical properties of selected VOCs, the mechanisms governing the release of these compounds, the locations where the release of these compounds is most prevalent, and the methods of controlling the discharge of these compounds to the atmosphere are discussed in this section.

Physical Properties of Selected VOCs

The physical properties of selected VOCs are presented in Table 16–12. Organic compounds that have a boiling point less than or equal to 100°C and/or a vapor pressure greater than 1 mm Hg at 25°C are generally considered to be volatile organic compounds (VOCs). For example, chloroethene (vinyl chloride), which has a boiling point of −13.9°C and a vapor pressure of 2548 mm Hg at 20°C, is an example of an extremely volatile organic compound.

Emission of VOCs

The release of VOCs in collection systems and at treatment plants, especially at the headworks, is of particular concern with respect to the health of the collection system and treatment plant workers. The principal mechanisms governing the release of VOCs in wastewater collection and treatment facilities are (1) volatilization and (2) gas stripping. These mechanisms and the principal locations where VOCs are released are considered in the following discussion.

Volatilization. The release of VOCs from wastewater surfaces to the atmosphere is termed volatilization. Volatile organic compounds are released because they partition between the gas and water phase until equilibrium concentrations are reached (Roberts et al., 1984). The mass transfer (movement) of a constituent between these two phases is a function of the constituent concentration in each phase relative to the equilibrium concentration. Thus, the transfer of a constituent between phases is greatest when the concentration in one of the phases is far from equilibrium. Because the concentration of VOCs in the atmosphere is extremely low, the transfer of VOCs usually occurs from wastewater to the atmosphere. However, because of the dynamic nature of the flows found within a wastewater treatment plant equilibrium conditions rarely exist, VOCs are either volatilized and/or degraded biologically.

Gas Stripping. Gas stripping of VOCs occurs when a gas (usually air) is entrained temporarily in wastewater or is introduced purposefully to achieve a treatment objective. When gas is introduced into a wastewater, VOCs are transferred from the wastewater to the gas. The forces governing the transfer between phases are the same as described above. For this reason, gas (air) stripping is most effective when contaminated wastewater is exposed to contaminant-free air. In wastewater treatment, air stripping occurs most commonly in aerated grit chambers, aerated biological treatment processes, and aerated transfer channels. Specially designed facilities (e.g., stripping towers) for gas stripping are considered in Sec. 11–10 in Chap 11 and Sec 15–5 in Chap. 15.

Table 16–12

Physical properties of selected volatile and semi-volatile organic compounds[a,b]

Compounds	mw	mp, °C	bp, °C	vp, mm Hg	vd	sg	Sol., mg/L	Cs, g/m³	H, m³·atm/mol	log K_{ow}

[a] Data were adapted from Lang (1987).

[b] All values are reported at 20°C.

Note: mw = molecular weight, mp = melting point, bp = boiling point, vd = vapor density relative to air, s_g = specific gravity relative to water, Sol = solubility, C_s = saturation concentration in air, H = Henry's Law Constant, log K_{ow} = logarithm of the octanol-water partition coefficient.

Locations Where VOCs Are Emitted. The principal locations where VOCs are emitted from wastewater collection and treatment facilities are summarized in Table 16–13. The degree of VOC removal at a given location will depend on local conditions. Mass transfer is considered in the following section.

Table 16–13

Sources, methods of release, and control of VOCs from wastewater facilities

Source	Method of release	Suggested control strategies
Domestic, commercial, and industrial discharges	Discharge of small amounts of VOCs in liquid wastes	Institute active source control program to limit the discharge of VOCs to municipal sewers
Wastewater sewers	Volatilization from the surface enhanced by flow induced turbulence	Seal existing manholes. Eliminate the use of structures that create turbulence and enhance volatilization
Sewer appurtenances	Volatilization due to turbulence at junctions, etc., volatilization and air stripping at drop manholes and junction chambers	Isolate and cover existing appurtenances
Pump stations	Volatilization and air stripping at influent wet-well inlets	Vent gases from wet-well to VOC treatment unit Use variable-speed pumps to reduce size of wet-well
Bar racks	Volatilization due to turbulence	Cover units, reduce headloss through bar racks
Comminutors	Volatilization due to turbulence	Cover units, use inline enclosed comminutors
Parshall flume	Volatilization due to turbulence	Cover units, use alternative measuring device
Grit chamber	Volatilization due to turbulence in horizontal-flow grit chambers Volatilization and air stripping in aerated grit chambers Volatilization in vortex-type grit chambers	Cover aerated and vortex-type grit chambers Reduce turbulence in horizontal-flow grit chambers; cover if necessary
Equalization basins	Volatilization from surface enhanced by local turbulence Air stripping where diffused air is used	Cover units, use submerged mixers. Reduce air flow
Primary and secondary sedimentation tanks	Volatilization from surface. Volatilization and air stripping at overflow weirs, in effluent channel, and at other discharge points	Cover tanks, replace overflow weirs with drops with submerged launders
Biological treatment	Air stripping in diffused-air activated sludge. Volatilization in activated sludge processes with surface aerators. Volatilization from surface enhanced by local turbulence. Volatilization from trickling filters	Cover units, in activated sludge systems, use submerged mixers and reduce aeration rate
Transfer channels	Volatilization from surface enhanced by local turbulence. Volatilization and air stripping in aerated transfer channels	Use enclosed transfer channels
Digester gas	Uncontrolled release of digester gas. Discharge of incompletely combusted or incinerated digester gas	Controlled thermal incineration, combustion, or flaring of digester gas

Mass Transfer Rates for VOCs

The mass transfer of VOCs can, for practical purposes, be modeled using the following equation (Roberts et al., 1984, and Thibodeaux, 1979):

$$r_{\mathrm{VOC}} = -(K_La)_{\mathrm{VOC}}(C - C_s) \tag{16–21}$$

where r_{VOC} = rate of VOC mass transfer, mg/m^3·h
$(K_La)_{\mathrm{VOC}}$ = overall VOC mass transfer coefficient, 1/h
C = concentration of VOC in liquid, mg/m^3
C_s = saturation concentration of VOC in liquid, mg/m^3

Due to chemical handling and analytical requirements, measuring $K_L\mathrm{a}_{\mathrm{VOC}}$ is much more difficult than measuring $K_La_{O_2}$. Therefore, a practical approach is to relate the K_La_{VOC} to the $K_La_{\mathrm{O_2}}$. The following equation is used to relate the mass transfer coefficients as a function of the VOC and O_2 diffusion coefficients in water:

$$(K_La)_{\mathrm{VOC}} = (K_La)_{\mathrm{O_2}}\left(\frac{D_{\mathrm{VOC}}}{D_{\mathrm{O_2}}}\right)^n \tag{16–22}$$

where $(K_La)_{\mathrm{VOC}}$ = system mass transfer coefficient, T^{-1} (1/h)
$(K_La)_{\mathrm{O_2}}$ = system oxygen mass transfer coefficient, T^{-1} (1/h)
D_{VOC} = diffusion coefficient of VOC in water, $\mathrm{L^2T^{-1}}$ (cm^2/s)
$D_{\mathrm{O_2}}$ = diffusion coefficient of oxygen in water, $\mathrm{L^2T^{-1}}$ (cm^2/s)
n = coefficient

Diffusion coefficient values for different compounds can be obtained from Schwarzenbach et al. (1993) or in other handbooks. It should be noted that there is often considerable variation in the values reported in the literature. However, based on the results a variety of experimental investigations of the relationship between K_La_{VOC} and $K_La_{\mathrm{O_2}}$ it has been found that Eq. (16–22) is generally applicable, and that the value for n varies depending on whether the gas/liquid transfer is accomplished by surface aeration, diffused aeration, or a packed column air stripper, and the power intensity of the gas transfer device (Roberts and Dandliker, 1983; Matter-Muller et al., 1981; Hsieh et al., 1993; Libra, 1993; and Bielefeldt and Stensel, 1999). For practical power intensities of less than 100 W/m^3 a reasonable value of n is 0.50 for packed columns and mechanical aeration and 1.0 for diffused aeration. For higher power intensities the work of Hsieh et al. (1993) should be consulted. The K_La_{VOC} value has also been found to be essentially the same in wastewater as in tap water (Bielefeldt and Stensel, 1999).

Mass Transfer of VOCs from Surface and Diffused-Air Aeration Processes

The amount of VOCs released from a complete-mix reactor used for the activated-sludge process will depend on the method of aeration (e.g., surface aeration or diffused aeration).

Complete-Mix Reactor with Surface Aeration. A materials balance for the stripping of a VOC written around a complete-mix reactor is as follows, assuming no other removal mechanisms for the VOC compound such as biodegradation or solids sorption are applicable.

1. General word statement:

$$\begin{array}{c}\text{Rate of accumulation}\\\text{of VOC within}\\\text{the system boundary}\end{array} = \begin{array}{c}\text{rate of flow of}\\\text{VOC into the}\\\text{system boundary}\end{array} - \begin{array}{c}\text{rate of flow of}\\\text{VOC out of the}\\\text{system boundary}\end{array} + \begin{array}{c}\text{amount of VOC}\\\text{removed through}\\\text{system boundary}\\\text{by stripping}\end{array} \tag{16–23}$$

2. Simplified word statement:

Accumulation = inflow-outflow + decrease due to stripping (16–24)

3. Symbolic representation:

$$\frac{dC}{dt}V = QC_i - QC_e + r_{\text{VOC}}V \tag{16–25}$$

where dC/dt = rate of change in VOC concentration in reactor
V = volume of complete mix reactor, L^3 (m^3)
Q = liquid flowrate, L^3T^{-1} (m^3/s)
C_i = concentration of VOC in influent to reactor, ML^{-3} (mg/m^3)
C_e = concentration of VOC in effluent from reactor, ML^{-3} (mg/m^3)
rVOC = rate of VOC mass transfer, $ML^{-3}T^{-1}$ ($mg/m^3 \cdot h$)

Substituting for rVOC from Eq. (16–21) and τ for V/Q yields

$$\frac{dC}{dt} = \frac{C_i - C_e}{\tau} + [-(K_La)_{\text{VOC}}(C_e - C_s)] \tag{16–26}$$

If steady-state conditions are assumed and it is further assumed that C_s is equal to zero, then the amount of VOC that can be removed by surface aeration is given by the following expression:

$$1 - \frac{C_e}{C_i} = 1 - [1 + (K_La)\tau]^{-1} \tag{16–27}$$

If a significant amount of the VOC is adsorbed or biodegraded, the results obtained with the above equation will be overestimated. The above analysis can also be used to estimate the release of VOCs at weirs and drops by assuming the time period is about 30s.

Complete Mix Reactor with Diffused-Air Aeration. The corresponding expression to Eq. (16–24) for a complete-mix reactor with diffused-air aeration is developed by a mass balance on the VOC compound. At steady state the VOC in equals the VOC out, and the corresponding mass balance is

$$\begin{matrix}\text{Inflow in} \\ \text{liquid stream}\end{matrix} = \begin{matrix}\text{outflow} \\ \text{liquid stream}\end{matrix} + \begin{matrix}\text{outflow} \\ \text{in exit gas}\end{matrix}$$

$$QC_i = QC_e + Q_gC_{g,e} \tag{16–28}$$

where Q = liquid flowrate, L^3T^{-1} (m^3/s)
C_i = VOC concentration in influent, ML^{-3} (mg/m^3)
C_e = VOC concentration in effluent, ML^{-3} (mg/m^3)
Q_g = gas flowrate, L^3T^{-1} (m^3/s)
$C_{g,e}$ = VOC concentration in exit gas, ML^{-3} (mg/m^3)

The general expression for the removal of VOC by gas sparging through a liquid is (Bielefeldt and Stensel, 1999)

$$Q_gC_{g,e} = Q_gH_uC_e(1 - e^{-\phi}) \tag{16–29}$$

where H_u = Henry's law constant, dimensionless
ϕ = VOC saturation parameter defined as

$$\phi = \frac{(K_La)_{\text{VOC}}V}{H_uQ_g} \tag{16–30}$$

Eq. (16–29) can be rearranged as follows:

$$Q(C_i - C_e) = H_u C_e (1 - e^{-\phi}) \tag{16–31}$$

Solving Eq. (16–31) for C_e/C_i yields

$$\frac{C_e}{C_i} = \left[1 + \frac{Q_g}{Q} H_u (1 - e^{-\phi})\right]^{-1} \tag{16–32}$$

and the fraction removed is given by

$$1 - \frac{C_e}{C_i} = 1 - \left[1 + \frac{Q_g}{Q} H_u (1 - e^{-\phi})\right]^{-1} \tag{16–33}$$

The application of the above equations is illustrated in Example 16–3.

EXAMPLE 16–3 **Stripping of Trichloroethene in the Activated Sludge Process** Determine the amount of trichloroethene (TCE) that can be stripped in a complete-mix activated sludge reactor equipped with a diffused-air aeration system. Assume the following conditions apply:

1. Wastewater flowrate = 4000 m^3/d
2. Aeration tank volume = 1000 m^3
3. Depth of aeration tank = 6 m
4. Air flowrate = 50 m^3/min at standard conditions
5. Oxygen mass transfer rate, $(K_L a)_{O_2} = 6.2/h$
6. $H_{TCE} = 1.17 \times 10^{-2}\ m^3 \cdot atm/mol$ (see Table 16–10)
7. $n = 1.0$
8. Temperature = 20°C
9. Oxygen diffusivity = $2.11 \times 10^{-5}\ cm^2/s$
10. Trichloroethene diffusivity ~ $1.0 \times 10^{-5}\ cm^2/s$

Solution

1. Determine the quantity of air referenced to the mid-depth of the aeration tank, which represents the depth for an average bubble size. Using the universal gas law, the air flowrate at mid-depth (3 m) is:

$$Q_g = (50\ m^3/min)\frac{(10.33\ m)}{(10.33\ m + 3\ m)} = 38.7\ m^3/min$$

Note: 10.33 = standard atmospheric pressure expressed in m of H_2O.

2. Determine the air/liquid ratio.

$$Q = \frac{(4000\ m^3/d)}{(1440\ min/d)} = 2.78\ m^3/min$$

$$\frac{Q_g}{Q} = \frac{(38.7\ m^3/min)}{(2.78\ m^3/min)} = 13.9$$

3. Estimate the mass transfer coefficient for TCE using Eq. (16–22).

$$(K_L a)_{VOC} = (K_L a)_{O_2}\left(\frac{D_{VOC}}{D_{O_2}}\right)^n = (6.2/h)\left[\frac{(1.0 \times 10^{-5}\ cm^2/s)}{(2.11 \times 10^{-5}\ cm^2/s)}\right]^{1.0}$$

$$(K_L a)_{VOC} = 2.94\ /h = 0.049/min$$

4. Determine the dimensionless value of the Henry's law constant for TCE using Eq. (2–51).

$$H_u = \frac{H}{RT}$$

$$H_u = \frac{0.0117}{0.000082057 \times (273 + 20)} = 0.487$$

5. Determine the saturation parameter ϕ using Eq (16–30).

$$\phi = \frac{(K_La)_{\text{VOC}}V}{H_uQ_g}$$

$$\phi = \frac{(0.049/\text{min})(1000\ \text{m}^3)}{(0.228 \times 38.7\ \text{m}^3/\text{min})} = 5.55$$

6. Determine the fraction of TCE removed from the liquid phase using Eq. (16–33).

$$1 - \frac{C_e}{C_i} = 1 - \left[1 + \frac{Q_g}{Q}(H_u)(1 - e^{-\phi})\right]^{-1}$$

$$1 - \frac{C_e}{C_i} = 1 - [1 + 13.9(0.487)(1 - e^{-5.55})]^{-1}$$

$$1 - \frac{C_e}{C_i} = 1 - 0.13 = 0.87 \text{ or } 87\%$$

Comment The computations presented in this example are based on the assumption that the concentration of TCE in the influent is not being reduced by diffusion and turbulence in the headworks, primary sedimentation tank or by adsorption or biological degradation in the aeration tank.

Control Strategies for VOCs

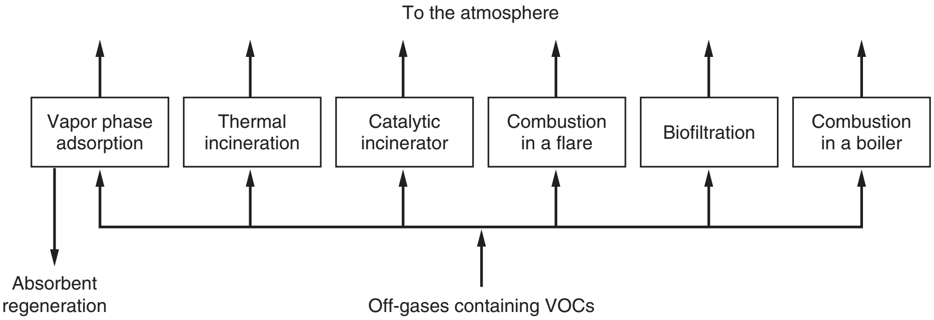
Volatilization and gas stripping are, as noted previously, the principal means by which VOCs are released from wastewater-treatment facilities. In general, it can be shown that the release of VOCs from open surfaces is quite low compared to the release of VOCs at points of liquid turbulence and by gas stripping. Thus, the principal strategies for controlling the release of VOCs, as reported in Table 16–13, are (1) source control, (2) elimination of points of turbulence, and (3) the covering of various treatment facilities. Three serious problems associated with the covering of treatment facilities are (1) treatment of the off-gases containing VOCs, (2) corrosion of mechanical parts, and (3) provision for confined space entry for personnel for equipment maintenance.

Treatment of Off-Gases

The off-gases containing VOCs from covered treatment facilities will have to be treated before they can be discharged to the atmosphere. Options for the off-gas treatment include (see Fig. 16–17) (1) vapor-phase adsorption on granular activated carbon or other VOC selective resins, (2) thermal incineration, (3) catalytic oxidation, (4) combustion in a flare, (5) biofiltration, and (6) combustion in a boiler or process heater (U.S. EPA, 1986; WEF, 1997). The application of these processes will depend primarily on the volume of air to be treated and the types and concentrations of the VOCs contained in the airstream. The first four of these off-gas treatment processes are considered in greater detail in the

Figure 16–17

Options for treating off-gases containing VOCs. (Adapted from Eckenfelder, 2000.)



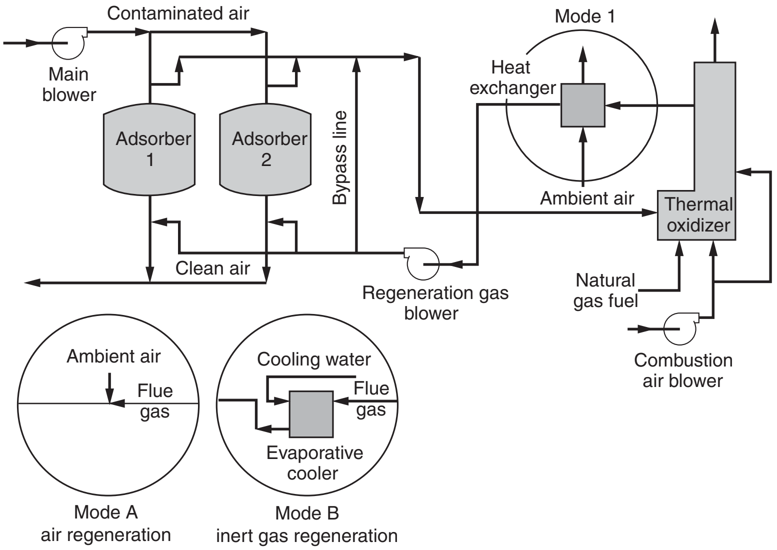
following discussion. Biofiltration was discussed previously in Sec. 16–3. A boiler or process heater is used only where a combustion process is included as part of the plant facilities.

Vapor-Phase Adsorption. Adsorption is the process whereby hydrocarbons and other compounds are adsorbed selectively on the surface of materials such as activated carbon, silica gel, or alumina. Of the available adsorbents, activated carbon is used most widely. The adsorption capacity of an adsorbent for a given VOC is often represented by adsorption isotherms that relate the amount of VOC adsorbed (adsorbate) to the equilibrium pressure (or concentration) at constant temperature. Typically, the adsorption capacity increases with the molecular weight of the VOC being adsorbed. In addition, unsaturated compounds are generally adsorbed more completely than saturated compounds, and cyclical compounds are adsorbed more easily than linearly structured materials. It should be noted that careful evaluation of the adsorption media should be undertaken to be assured that the compound being adsorbed does not react with the adsorbent. Also, the adsorption capacity is enhanced by lower operating temperatures and higher concentrations. VOCs characterized by low vapor pressures are more easily adsorbed than those with high vapor pressures (U.S. EPA, 1986).

Steps in VOC Adsorption Process. The two main steps involved in the VOC adsorption process are (1) the continuous adsorption in multiple beds (see Fig. 16–18) and (2) batch regeneration of the adsorbent. For control of continuous emission streams, at least one bed

Figure 16–18

Gas phase carbon adsorption and regeneration system for the treatment of VOCs in off-gas.



remains online in the adsorption mode while the other is being regenerated. In a typical batch operation, the off-gas containing VOCs is passed through the carbon bed where the VOCs are adsorbed on the bed surface. As the adsorption capacity of the bed is approached, traces of VOCs appear in the exit stream, up to the level where the breakthrough point of the bed has been attained. The off-gas is then directed to a parallel bed containing regenerated adsorbent, and the process continues. Concurrently, the saturated bed is regenerated by the passage of hot air (see Fig. 16–18, Mode A), hot inert gases (see Fig. 16–18, Mode B), low-pressure steam, or a combination of vacuum and hot gas. Because adsorption is a reversible process, the VOCs adsorbed on the bed can be desorbed by supplying heat (equivalent to the amount of heat released during adsorption). Small residual amounts of VOCs are always left on the carbon bed, because complete desorption is technically difficult to achieve and economically impractical. Regeneration with hot air and a hot inert gas is considered in the following discussion.

Hot Air Regeneration. When the VOCs are either nonflammable or have a high ignition temperature and thus do not pose a risk of carbon fires, hot air regeneration is used. A portion of the hot flue gas in the oxidizer is mixed with ambient air to cool the gas to below 180°C (350°F). The regeneration gas is driven upflow (or countercurrent to adsorption flow) through the GAC adsorber. As the temperature of the carbon bed rises, the desorbed organics are transferred to the regeneration gas stream. The regeneration gas containing the desorbed VOCs is sent directly to the thermal oxidizer where the VOCs are oxidized. After the bed has been maintained at the desired regeneration temperature for a sufficient period of time, regeneration is ended. The bed is then cooled to approximately ambient temperature by shutting off the hot regeneration gas and continuing to pass ambient air through the carbon bed. The regeneration and cooling times are predetermined based on the amount of carbon in the adsorber and the expected loading on the carbon (U.S. EPA, 1986).

Inlet Gas Regeneration. Where the VOCs contained in the off-gas include compounds such as ketones and aldehydes that may pose fire risks at elevated temperatures in the presence of oxygen, inert gas regeneration is used. A relatively inert gas can be obtained by passing a portion of the hot flue gas from the thermal oxidizer through an evaporative cooler. It is possible, therefore, to keep the oxygen concentration in the regeneration gas at 2 to 5 percent by volume. The desorbed VOCs are transferred along with the regeneration gas to the thermal oxidizer. A controlled amount of secondary air is added to the oxidizer. The addition of air ensures complete combustion of the VOCs but limits the excess oxygen level in the oxidizer to an acceptable range (e.g., 2 to 5 percent by volume). Regeneration is complete when the carbon bed has reached the necessary temperature for a given period of time, and VOCs are no longer being desorbed from the bed. Cooling of the bed is accomplished by increasing the water flowrate to the evaporative cooler and reducing the regeneration gas temperature to between 105 and 120°C (220 and 250°F).

Thermal Incineration. Thermal incineration [see Fig. 16–12(a)] is used to oxidize VOCs at high temperatures. The most important variables to consider in thermal incinerator design are the combustion temperature and residence time because these design variables determine the VOC destruction efficiency of the incinerator. Further, at a given combustion temperature and residence time, destruction efficiency is also affected by the degree of turbulence, or mixing of the emission stream and hot combustion gases, in the incinerator. In addition, halogenated organics are more difficult to oxidize than unsubstituted organics; hence, the presence of halogenated compounds in the emission stream requires higher temperature and longer residence times for complete oxidation. When emission streams treated by thermal incineration are dilute (i.e., low heat content), supplementary fuel is required to maintain the desired combustion temperatures. Supplementary fuel requirements may be reduced by recovering the energy contained in the hot flue gases from the incinerator. Also, depending on the byproducts of incineration (e.g., HCl, H_2SO_4, HF), it may be necessary to provide an acid gas scrubber.

Catalytic Oxidation. In catalytic oxidation [see Fig. 16–12(b)], VOCs in an emission stream are oxidized with the help of a catalyst. A catalyst is a substance that accelerates the rate of a reaction at a given temperature without being appreciably changed during the reaction. Catalysts typically used for VOC oxidation include platinum and palladium; other formulations are also used, including metal oxides for emission streams containing chlorinated compounds. The catalyst bed (or matrix) in the oxidizer is generally a metal mesh-mat, ceramic honeycomb, or other ceramic matrix structure designed to maximize catalyst surface area. The catalysts may also be in the form of spheres or pellets. Before passing through the catalyst bed, the emission stream is preheated, if necessary, in a natural gas-fired preheater (U.S. EPA, 1986).

The performance of a catalytic oxidizer is affected by several factors including (1) operating temperature, (2) space velocity (reciprocal of residence time), (3) VOC composition and concentration, (4) catalyst properties, and (5) presence of catalyst poisons or inhibitors in the emission stream. In catalytic incinerator design, the important variables are the operating temperature at the catalyst bed inlet and the space velocity. The operating temperature for a particular destruction efficiency is dependent on the concentration and composition of the VOC in the emission stream and the type of catalyst used (U.S. EPA, 1986). As with incineration, it may be necessary to provide an acid gas scrubber.

Combustion in a Flare. Flares, another type of thermal incineration commonly used for disposal of waste digester gas, can be used to destroy most VOCs found in off-gas streams. Flares can be designed and operated to handle fluctuations in emission VOC content, inerts content, and flowrate. Several different types of flares are available, including steam-assisted, air-assisted, and pressure-head flares. Steam-assisted flares are employed in cases where large volumes of waste gases are released. Air-assisted flares are generally used for moderate off-gas gas flows. Pressure-head flares are used for small gas flows.

16–5 EMISSIONS FROM THE COMBUSTION OF GASES AND SOLIDS

Various types of fuels are used at wastewater treatment facilities to generate heat and electricity onsite to supplement energy supplied from outside sources and to operate equipment. As discussed in Chaps. 13 and 14, part or all of gases and solids generated at wastewater treatment facilities can also be used as fuels within the wastewater treatment facility. Fuel sources, combustion systems used at wastewater treatment plants and their emissions, and flaring of excess digester gas are discussed in this section.

Sources of Fuels

Fuels used for the operation of a wastewater treatment plant include various grades of fuel oils, natural gas, and digester gas. The types of fuels used will depend on the types of combustion systems used at a treatment facility. Emissions of certain pollutants will vary with the quality of the fuel and the type and condition of the combustion system. Typical fuels used at a wastewater treatment plant are listed in Table 16–14.

Table 16–14

Fuels used commonly at wastewater treatment plants

Fuel type	Characteristics
No. 2 fuel oil[a]	A distillate fuel oil that has a distillation temperature of 640 degrees Fahrenheit at the 90-percent recovery point. It is used in atomizing type burners for domestic heating or for moderate capacity commercial/industrial burner units.
No. 4 fuel oil[a]	A distillate fuel oil made by blending distillate fuel oil and residual fuel oil stocks. It is used extensively in industrial plants and in commercial burner installations that are not equipped with preheating facilities. It also includes No. 4 diesel fuel used for low- and medium-speed diesel engines.
Natural gas[b]	Typical composition of natural gas before refining is 70 to 90 percent methane, up to 20 percent of ethane, propane, and butane, and up to 8 percent carbon dioxide. Sulfur content is typically low but unprocessed natural gas may have higher sulfur content.
Digester gas	Typically contains 50 to 65 percent methane. Siloxanes in the digester gas can be detrimental to the combustion system. The level of cleaning required for use depends on the types of the combustion system. Emission of sulfur oxides depends on the sulfur contents in the digester gas.

[a] From U.S. Energy Information Administration.

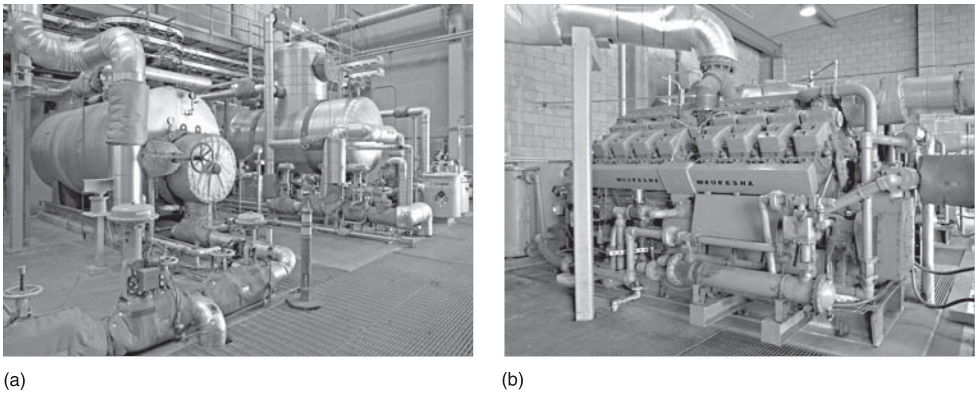
[b] Typical composition from Natural Gas Supply Association (naturalgas.org).

Combustion Systems Used at Wastewater Treatment Plants

Major combustion systems used at wastewater treatment plants include boilers and power generators. In some cases, solids are incinerated within the treatment facility (see Sec. 14–4 in Chap. 14). Flares are used to combust excess digester gas.

Boiler. Boilers used at wastewater treatment facilities use fuel oil, natural gas, digester gas, or a combination of these fuels to produce hot water or steam [see Fig. 16–19(a)]. The main purposes of using boilers are to provide heat for maintaining temperature of anaerobic digesters and to provide heat and hot water in the buildings. In addition, boilers are used to produce process steam for use in sludge drying and to treat biosolids thermally in various processes. The use of steam boilers is less common, especially at smaller wastewater treatment facilities, as additional treatment of the boiler feed water may be required. Combustion of a fuel is controlled to heat water to a desired temperature, and hot water or steam is circulated for various purposes.

Reciprocating Engine. Internal combustion reciprocating engines are used most commonly for the generation of electricity [see Fig. 16–19(b)]. Reciprocating engines can also be used to operate pumps, gas compression, or chillers. Reciprocating engines are categorized as spark ignition or compression ignition. Diesel fuel is used for compression ignition engines, or the engines can be set up to use natural gas with a small amount of diesel to ignite with compression. Emission of nitrogen oxides (NOx) is correlated with the combustion temperature as well as nitrogen in the fuel (typically a concern with liquid fuels), and NOx removal may be necessary if the emission exceeds the permit level. Emission of particulate matters and carbon monoxide (CO) are generally correlated with incomplete combustion of fuels.



(a) (b)

Figure 16–19

Combustion systems used commonly at wastewater treatment facilities: (a) view of heat recovery boiler and (b) view of internal combustion engine.

Gas Turbine. In gas turbines, compressed fuel and air is combusted in a combustion chamber, and the expanded hot exhaust gas is used to spin the power turbine. Because gas turbines generally operate at a significantly higher temperature than reciprocating engines, the emission of NOx has to be controlled. The use of gas turbines is increasing with the use of combined heat and power (CHP) system at wastewater treatment facilities [see Fig. 17–8(d) in Chap. 17]. Steam is generated using a heat exchanger that removes excess energy from turbine exhaust gases. The steam produced in this manner can be used to replace boiler-produced steam for heating or used in a steam turbine to produce additional electricity.

Emissions of Concern from Combustion Sources

The major emissions of concern from combustion sources are NOx, CO, particulate matter (PM) and sulfur dioxide (SO_2). VOCs are generally emitted in small quantities from the incomplete combustion of fuel and are only a concern when a significant combustion equipment is being used. In addition, combustion emissions may contain hazardous air pollutants (HAPs) in small quantities such as formaldehyde, and any metals contained in the fuel.

Fuel gas such as natural gas and digester gas is oxidized completely to carbon dioxide (CO_2) when a combustion temperature is at or above 850°C (1560°F) and the combustion time is 0.3 s or longer. Lower combustion temperatures, shorter combustion times, and incomplete mixing of fuel and air can cause the incomplete oxidation of the fuel resulting in the production of CO. Carbon monoxide emission is controlled by adjusting the operating conditions, or by the use of a post-combustion catalytic oxidation system. Emission of VOC is essentially the emission of unburned hydrocarbons in the fuel as a result of incomplete combustion.

At combustion temperatures above 1200°C, oxidation of the nitrogen gas contained in the combustion air will occur, and NOx will be formed. Particulate matter emissions from fuel combustion include both organic and inorganic fractions. The organic fractions of particulate matter include by-products of incomplete combustion, such as polycyclic organic matter. Inorganic fractions include metals as well as acid mists. Emissions of sulfur dioxide occur as a result of the oxidation of sulfur contained in the fuel. Both liquid and gaseous fuels contain sulfur both in elemental as well as in organic fractions.

Emission Factor. An emission factor is a representative value that is used to relate the quantity of a pollutant released to the atmosphere by a specific activity associated with the release of that pollutant (U.S. EPA, 1995). Pollutant emissions are estimated using Eq. (16–34):

$$E = (A)(EF)(1 - ER/100) \tag{16–34}$$

where, E = emissions
A = activity rate, e.g., rate of the fuel consumption
EF = emission factor for given activity
ER = overall emission reduction efficiency for given activity, %

Activity rate is a general term for the rate of the fuel consumption when emissions from a combustion system are being considered. For example, if there is no device to destroy or capture the pollutant, the overall emission reduction efficiency (*ER*) is zero. Thus, without emission reduction Eq. (16–34) is simply the product of the rate of fuel consumption and the emission factor. As noted above, emission factors are available for specific emission generating activities. The U.S. EPA has been compiling the emission factors in AP 42, Compilation of Air Pollutant Emission Factors (U.S. EPA, 1995). Emission factors for criteria pollutants from fuel oil and natural gas combustion are reported in Table 16–15. The overall emission reduction is a product of destruction or removal efficiency and the capture efficiency of the control system such as cyclones, scrubbers, and catalytic reduction systems. It should be noted that the estimate based on the emission factor from AP42 is usually conservative. For more accurate estimate, emission data from the equipment supplier should be referenced.

Control of Nitrogen Oxides. Methods to control the emission of NOx include control of combustion temperature and residence time, and the use of catalytic reduction systems. Combustion temperature and residence time may be controlled by adjusting air to fuel ratio or by injecting water or steam. The latter is used mainly for the gas turbine systems. It should be noted that the use of dilution air could result in the emission of CO, and the operating conditions must be controlled to minimize the emission of both NOx and CO. Catalytic reduction systems include selective catalytic reduction with the use of ammonia or urea, and non-selective catalytic reduction. Non-selective catalytic reduction is applicable only for the combustion system with exhaust oxygen levels of 4 percent or less. In selective catalytic reduction, nitrogen oxides, ammonia (or urea) and oxygen react in presence of the catalyst to form nitrogen gas (N_2) and water (H_2O). Selective catalytic reduction is used for both reciprocating engines and gas turbines.

Flaring of Digester Gas

Digester gas, a gas generated from anaerobic digestion of sludges, typically contains 55 to 65 percent methane and can be used as a fuel source to generate heat and electricity. When a wastewater treatment facility does not utilize all digester gas, the excess gas must be fared (see Fig. 16–20).

Combustion of methane gas can be expressed as

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O \tag{16–35}$$

Air contains approximately 21 percent oxygen and requiring 2 moles of oxygen to completely oxidize 1 mole of methane. Therefore, a theoretical ratio of methane to air to achieve complete combustion of methane is approximately 9.5. If digester gas contains 60 percent methane, the theoretical digester gas to air ratio is 5.7. Practically, excess air with a well controlled flaring system is necessary to achieve effective combustion of digester gas. Flaring of digester gas will result in emissions described previously in Table 16–1.

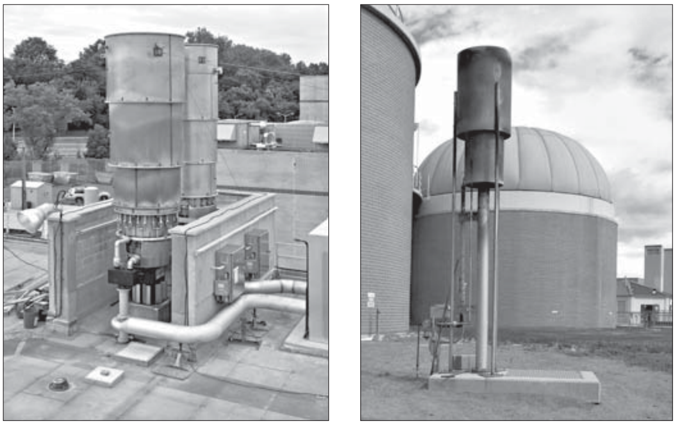

Figure 16–20

Flares for the combustion of excess digester gas: (a) ground effect flare and (b) open air flare.

Similar to the internal combustion systems, the emissions from flaring of digester gas will depend on the completeness of the combustion and the combustion temperature. Digester gas to air ratio should be adjusted according to the quality of the digester gas, but typically 150 to 200 percent of excess air in addition to the stoichiometric air requirement is necessary to achieve sufficient oxidation of methane while minimizing the generation of NOx (IEA Bioenergy, 2000). To minimize emission of CO or NOx, the flare temperature should be controlled between 850 to 1200°C. Technical specification of flaring systems must also meet the Code of Federal Regulations, CFR 40, 60.18, and 60.31.

EXAMPLE 16–4 **Calculation of NO_x Emissions from a Natural Gas-Fired Boiler** Using U.S. EPA's AP42 compilation of air emission factors, estimate NOx emissions from a natural-gas fired boiler. Use the following data to calculate the emissions.

Item	Unit	Basis
Boiler heat input rating	52,753 MJ/h (50.0 MMBtu/h)	Vendor or Manufacturer
Boiler fuel	Natural Gas	
Natural gas heat content	39.1 MJ/m^3 (1050 MMBtu/MMscf)	U.S. EPA AP42[a], Appendix A
Boiler operation	8760 h/y	
Emission factor	1600 kg/m^3 (100 lb/MMscf)	U.S. EPA AP42[a], 1.4–5, Small Boilers, Uncontrolled

[a] Latest version of AP42 sections can be found in: http://www.epa.gov/ttnchie1/ap42/.

Solution

1. Determine the amount of fuel that is combusted over a a period of a year. The amount of fuel is given by

$$\text{Amount of fuel} = (\text{Boiler heat input rating / fuel heat content}) \times \text{h of operation/y}$$

$$(52{,}753 \text{ MJ/h}) / (39.1 \text{ MJ/m}^3) \times 8760 \text{ h/y}$$

$$= 11.82 \times 10^6 \text{ m}^3\text{/y of natural gas consumed}$$

2. Using the emission factor found in U.S. EPA AP42 (see Table 16–15), estimate the anticipated emissions:

Emissions = fuel consumed × emission factor

$$\text{Emissions} = (11.82 \times 10^6 \text{ m}^3/\text{y}) \times (1600 \text{ kg/m}^3) \times (1 \text{ tonne}/10^3 \text{ kg})$$

$$= 18.9 \text{ tonne of NOx emissions/y}$$

Comment As reported in Table 16–15, the emission factor for low NOx burner is 800 kg/10^3 m^3 (50 lb/10^6 ft^3), which is half of uncontrolled small natural gas boilers, and the emission factor is 512 kg/10^3 m^3 (32 lb/10^6 ft^3), less than one-third, with a flue gas recirculation.

16–6 EMISSION OF GREENHOUSE GASES

Recognizing the evidence and projected impacts of the emission of greenhouse gases (GHG), their reduction and/or elimination has become an important element of wastewater management. Assessment of GHG emissions is important in establishing priorities for future capital investments. In planning wastewater treatment facilities, reduction of GHG emissions is often considered in the environmental assessment of the triple bottom line (TBL) approach (see Chap. 18). Because there was no standard protocol for the measurement of GHG emissions until recently and the methodology can affect the outcome of the assessment, it is useful to first review the GHG measurement framework and protocols. After the review of the framework and protocols, opportunities for the reduction of GHG emissions from wastewater treatment plant are discussed.

Framework for Greenhouse Gases Reduction

The United Nations Framework Convention on Climate Change (UNFCCC), first signed in Rio de Janeiro in June 1992, was the first major world-wide recognition of the challenges posed by climate change. The Kyoto Protocol, adopted in 1997, is the first international agreement that set binding targets for industrialized countries towards actions to reduce greenhouse gas emissions. Following the Kyoto Protocol, Intergovernmental Panel on Climate Change (IPCC) issued National Greenhouse Gas Inventories Guidelines (updated most recently in 2006). Protocols developed thereafter to measure the GHG emissions in smaller scales generally follow the greenhouse gases specified in the Kyoto Protocol. In the United States, US EPA issued the Mandatory Reporting of Greenhouse Gases Rule (74 FR 56260) in 2008.

Assessment Protocols

The protocol entitled “GHG Protocol Corporate Accounting and Reporting Standard,” often referred simply as the *GHG Protocol*, developed by the World Resources Institute (WRI) and the World Business Council for Sustainable Development (WBCSD) is consistent with the IPCC Guidelines and accepted widely as the standard protocol to quantify GHG emissions from a specific business(WRI and WBCSD, 2004). In the United States, the Local Government Operations (LGO) protocol was developed based on the *GHG Protocol* in partnership with the California Air Resources Board (ARB), California Climate Action Registry (CCAR), ICLEI-Local Government for Sustainability, in collaboration with the Climate Registry and dozens of stakeholders (ARB et al., 2010). In the LGO protocol, procedures to calculate GHG emissions from government-owned facilities including water and wastewater treatment facilities are identified. The procedure to calculate GHG emissions from a wastewater treatment plant is illustrated in Example 16–4. It should be noted that these protocols are being updated to reflect the latest scientific findings, and latest publications of relevant protocols should be consulted.

Greenhouse Gases. Based on the Kyoto Protocol, the following six greenhouse gases are usually considered in the assessment: carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6). Because each greenhouse gas has a different level of impact on retaining heat in the atmosphere, the amount of GHG is usually reported as carbon dioxide equivalent, using global warming potentials (GWPs) determined for each greenhouse gas (see Table 16–16). For wastewater treatment facilities, only CO_2, CH_4 and N_2O are usually assessed because emissions of HFCs, PFCs, and SF_6 are generally negligible.

GHG Emissions Categories. Generally, GHG emissions are categorized in three categories:

Scope 1: All direct GHG emissions
Scope 2: Indirect emissions associated with the consumption of purchased or acquired electricity, steam, heating, or cooling
Scope 3: All other indirect emissions not covered in Scope 2

In the LGO protocol, Scopes 1 and 2 are considered mandatory for reporting, while Scope 3 is stated as optional. In the LGO protocol it is also recommended that CO_2 emissions from the combustion of biomass (or biomass-based fuels including digester gas) be quantified, but not included in the Scope 1 emissions, and reported separately (LGOP, 2008) as “biogenic” emissions.

The protocol, PAS 2050, prepared by the British Standards Institution (BSI), is another approach that can be used for the assessment of greenhouse gas emissions (BSI, 2011). The PAS 2050 protocol is based on the life cycle assessment, and encompasses the boundary to the Scope 3 in the WRI/WBSCD protocol.

Nitrous Oxide Emission. Because of its global warming potential (about 310 times the effect of carbon dioxide), emission of nitrous oxide from wastewater treatment facilities could potentially be significant relative to the emission of other greenhouse gases.

Table 16–16

Fuels used commonly at wastewater treatment plants[a]

Greenhouse gas	Global warming potential (GWP)
Carbon dioxide (CO_2)	1
Methane (CH_4)	21
Nitrous oxide (N_2O)	310
Hydrofluorocarbons (HFCs)	12–11,700
Perfluorocarbons (PFCs)	6500–9200
Sulfur hexafluoride (SF_6)	23,900

[a] From LGO Protocol (2010). GWP values vary for HFCs and PFCs depending on the specific chemical compounds.

Currently, the protocols described above use an approximate estimate of nitrous oxide emission from wastewater treatment facilities based on the nitrogen loading to the plant or population served, types of treatment, and types of receiving waters. The emission is considered as a direct emission from the facility and included in the Scope 1 item. As discussed in Chap. 7, the mechanism of nitrous oxide emission from wastewater treatment facility is highly dependent on the operating conditions, making it difficult to make accurate estimates. Based on the protocol, nitrous oxide emission could make up almost one third, or more, of the total GHG emissions from a wastewater treatment facility.

EXAMPLE 16–5 **Calculation of GHG Emissions from a Wastewater Treatment Plant** Calculate the GHG emissions from the wastewater treatment plant. The treatment plant is designed for BOD removal and nitrification/denitrification, and effluent is discharged to an estuary. The treatment plant serves a combination of residential and industrial/commercial customers. The data required to complete the calculations for the treatment plant were collected and summarized as below. Report Scope 1 and Scope 2 emissions, and report biogenic emissions separately.

Item	Unit	Value
Energy use		
Electricity	kWh/y	14,100,000
Natural gas	m^3/y	17,300
Fuel oil #2	m^3/y	390
Digester gas production	m^3/y	1,047,900
Digester gas used	m^3/y	755,000
Digester gas flared	m^3/y	290,500
Digester gas vented	m^3/y	2400
Plant performance		
Annual average flowrate	m^3/d	100,000
Average influent ammonium concentration	mg/L	18
Average influent total nitrogen concentration	mg/L	32
Average effluent ammonium concentration	mg/L	1.5
Average effluent total nitrogen concentration	mg/L	8.3
Other required information		
Population served	persons	430,000
Methane content in digester gas	%	60
Carbon dioxide in digester gas	%	35
Energy content in natural gas	GJ/m^3	0.0383
Energy content in fuel oil #2	GJ/m^3	38.47
Energy content in digester gas	GJ/m^3	0.0224

(*continued*)

(*Continued*)

Item	Unit	Value
Emission factors		
Electricity	g CO_2e/kWh	720
Natural gas		
CO_2	g/GJ	50,253
CH_4	g/GJ	0.948
N_2O	g/GJ	0.0948
Fuel oil #2		
CO_2	g/GJ	70,100
CH_4	g/GJ	2.844
N_2O	g/GJ	0.569
Digester gas		
CO_2	g/GJ	49,353
CH_4	g/GJ	3.033
N_2O	g/GJ	0.597

Solution

1. Calculate Scope 1 emissions which Include emissions from stationary combustion of natural gas, fuel oil, fugitive emission of digester gas, and emissions associated with wastewater treatment process:
   a. Emissions from natural gas

$$\begin{aligned}\text{CO}_2\text{ emission} &= (\text{Natural gas use, m}^3/\text{y})(\text{energy content, GJ/m}^3)(\text{emission factor})\\ &= (17{,}300\text{ m}^3/\text{y})(0.0383\text{ GJ/m}^3)(50{,}253\text{ g/GJ})(1\text{ tonne}/10^6\text{ g})\\ &= (33{,}297{,}135\text{ g/y})(1\text{ tonne}/10^6\text{ g})\\ &= 33.3\text{ tonne/y}\end{aligned}$$

$$\begin{aligned}\text{CH}_4\text{ emission} &= (\text{Natural gas use, m}^3/\text{y})(\text{energy content, GJ/m}^3)(\text{emission factor})\\ &= (17{,}300\text{ m}^3/\text{y})(0.0383\text{ GJ/m}^3)(0.948\text{ g/CH}_4\text{/GJ})(1\text{ tonne}/10^6\text{ g})\\ &= (628.1\text{g CH}_4/\text{y})(1\text{ tonne}/10^6\text{ g})\\ &= 0.000628\text{ tonne CH}_4/\text{y}\end{aligned}$$

$$\begin{aligned}\text{N}_2\text{O emission} &= (\text{Natural gas use, m}^3/\text{y})(\text{energy content, GJ/m}^3)(\text{emission factor})\\ &= (17{,}300\text{ m}^3/\text{y})(0.0383\text{ GJ/m}^3)(0.095\text{ g N}_2\text{ O/y})(1\text{ tonne}/10^6\text{ g})\\ &= (628.1\text{g N}_2\text{ O/y})(1\text{ tonne}/10^6\text{ g})\\ &= 0.0000628\text{ tonne N}_2\text{O/y}\end{aligned}$$

$$\begin{aligned}\text{Total emissions} &= (\text{CO}_2\text{ emission})\ \text{GWP}_{\text{CO}_2}\\ &\quad + (\text{CH}_4\text{ emission})\ \text{GWP}_{\text{CH}_4}\\ &\quad + (\text{N}_2\text{O emission})\ \text{GWP}_{\text{N}_2\text{O}}\\ &= 33.3 \times 1.0 + 0.000628 \times 21 + 0.0000628 \times 310\\ &= 33.3\text{ tonne CO}_2\text{ e/y}\end{aligned}$$

b. Emissions from fuel oil #2

$$\begin{aligned}\text{CO}_2\text{ emission} &= (\text{Fuel oil use, m}^3\text{/y})(\text{energy content, GJ/m}^3)(\text{emission factor})\\ &= (390\text{ m}^3\text{/y})(38.47\text{ GJ/m}^3)(70{,}100\text{ g CO}_2\text{/GJ})(1\text{ tonne}/10^6\text{ g})\\ &= (1{,}051{,}731{,}330\text{ g/y})(1\text{ tonne}/10^6\text{ g})\\ &= 1051.7\text{ tonne/y}\end{aligned}$$

$$\begin{aligned}\text{CH}_4\text{ emission} &= (\text{Fuel oil use, m}^3\text{/y})(\text{energy content, GJ/m}^3)(\text{emission factor})\\ &= (390\text{ m}^3\text{/y})(38.47\text{ GJ/m}^3)(2.844\text{ kg CH}_4\text{/GJ})(1\text{ tonne}/10^6\text{ g})\\ &= (42{,}669.4\text{ g CH}_4\text{/y})(1\text{ tonne}/10^6\text{ g})\\ &= 0.0427\text{ tonne CH}_4\text{/y}\end{aligned}$$

$$\begin{aligned}\text{N}_2\text{O emission} &= (\text{Fuel oil use, m}^3\text{/y})(\text{energy content, GJ/m}^3)(\text{emission factor,}\\ &\qquad \text{kg-N}_2\text{ O/GJ})\\ &= (390\text{ m}^3\text{/y})(38.47\text{ GJ/m}^3)(0.569\text{ kg N}_2\text{ O/GJ})(1\text{ tonne}/10^6\text{ g})\\ &= (8536.9\text{ g N}_2\text{O/y})(1\text{ tonne}/10^6\text{ g})\\ &= 0.00854\text{ tonne N}_2\text{O/y}\end{aligned}$$

$$\begin{aligned}\text{Total emissions} &= (\text{CO}_2\text{ emission})\,\text{GWP}_{\text{CO}_2}\\ &\quad + (\text{CH}_4\text{ emission})\,\text{GWP}_{\text{CH}_4}\\ &\quad + (\text{N}_2\text{O emission})\,\text{GWP}_{\text{N}_2\text{O}}\\ &= 1050.7 \times 1.0 + 0.0427 \times 21 + 0.00854 \times 310\\ &= 1054.2\text{ tonne CO}_2\text{ e/y}\end{aligned}$$

c. Emissions from digester gas used. Note CO_2 emission from digester gas combustion is considered "biogenic." Biogenic emissions are often not required to be reported as part of the GHG emission but to be reported separately.

$$\begin{aligned}\text{CO}_2\text{ emission} &= (\text{Digester gas use, m}^3\text{/y})(\text{energy content, GJ/m}^3)(\text{emission factor})\\ &= (755{,}000\text{ m}^3\text{/y})(0.0224\text{ GJ/m}^3)(49{,}353\text{ kg-CO}_2\text{/GJ})(1\text{ tonne}/10^6\text{ g})\\ &= (834{,}657{,}936\text{ g/y})(1\text{ tonne}/10^6\text{ g})\\ &= 834.7\text{ tonne/y (biogenic)}\end{aligned}$$

$$\begin{aligned}\text{CH}_4\text{ emission} &= (\text{Digester gas use, m}^3\text{/y})(\text{energy content, GJ/m}^3)(\text{emission factor})\\ &= (755{,}000\text{ m}^3\text{/y})(0.0224\text{ GJ/m}^3)(3.033\text{ kg CH}_4\text{/GJ})(1\text{ tonne}/10^6\text{ g})\\ &= (51{,}294\text{ g CH}_4\text{/y})(1\text{ tonne}/10^6\text{ g})\\ &= 0.0513\text{ tonne-CH}_4\text{/y}\end{aligned}$$

$$\begin{aligned}\text{N}_2\text{O emission} &= (\text{Digester gas use, m}^3\text{/y})(\text{energy content, GJ/m}^3)(\text{emission factor})\\ &= (755{,}000\text{ m}^3\text{/y})(0.0224\text{ GJ/m}^3)(0.597\text{ kg N}_2\text{ O/GJ})(1\text{ tonne}/10^6\text{ g})\\ &= (10{,}096\text{ g N}_2\text{ O/y})(1\text{ tonne}/10^6\text{ g})\\ &= 0.0101\text{ tonne N}_2\text{O/y}\end{aligned}$$

$$\begin{aligned}\text{Total emissions} &= (\text{CO}_4\text{ emission})\ \text{GWP}_{\text{CH}_4}\\ &\quad + (\text{N}_2\text{O emission})\ \text{GWP}_{\text{N}_2\text{O}}\\ &= 0.0513 \times 21 + 0.0101 \times 310\\ &= 4.21\text{ tonne CO}_2\text{ e/y}\end{aligned}$$

$$\begin{aligned}\text{Biogenic emissions} &= (\text{CO}_2\text{ emission})\ \text{GWP}_{\text{CO}_2}\\ &= 834.7 \times 1.0\\ &= 834.7\text{ tonne CO}_2\text{ e/y}\end{aligned}$$

d. Emissions from digester gas flared. In the LOG Protocol, digester gas flaring is assumed to leave 1 percent of the methane gas within the digester gas due to incomplete combustion, and no nitrous oxide emission is assumed from the digester gas flaring. The approach taken by the LOG protocol is followed in this example. Similarly to combusted digester gas, CO_2 emission is considered "biogenic."

$$\begin{aligned}\text{CO}_2\text{ emission} &= (\text{Digester gas flared, m}^3\text{/y})(\text{energy content, GJ/m}^3)(\text{emission factor})\\ &= (290{,}500\text{ m}^3\text{/y})(0.0224\text{ GJ/m}^3)(49{,}353\text{ kg CO}_2\text{/GJ})(1\text{ tonne}/10^6\text{ g})\\ &= (834{,}657{,}936\text{ g/y})(1\text{ tonne}/10^6\text{ g})\\ &= 321.15\text{ tonne/y (biogenic)}\end{aligned}$$

$$\begin{aligned}\text{CH}_4\text{ emission} &= (\text{Digester gas flared, m}^3\text{/y})(\text{methane content})\\ &\quad \times (\text{incomplete combustion})(\text{mass of methane, g/m}^3)\\ &= (290{,}500\text{ m}^3\text{/y})(0.60)(0.01)(656\text{ g/m}^3)(1\text{ tonne}/10^6\text{ g})\\ &= (1{,}143{,}408\text{ g CH}_4\text{/y})(1\text{ tonne}/10^6\text{ g})\\ &= 1.143\text{ tonne CH}_4\text{/y}\end{aligned}$$

$$\begin{aligned}\text{Total emissions} &= (\text{CH}_4\text{ emission})\ \text{GWP}_{\text{CH}_4}\\ &= 1.143 \times 21\\ &= 24.0\text{ tonne CO}_2\text{ e/y}\end{aligned}$$

$$\begin{aligned}\text{Biogenic emissions} &= (\text{CO}_2\text{ emission})\ \text{GWP}_{\text{CO}_2}\\ &= 321.15 \times 1.0\\ &= 321.2\text{ tonne CO}_2\text{ e/y}\end{aligned}$$

e. Emissions from digester gas vented. Of the digester gas vented to the atmosphere, 60 percent is methane, to be reported as Scope 1 emission. Carbon dioxide (35 percent) is not counted in the GHG inventory.

$$\begin{aligned}\text{CH}_4\text{ emission} &= (\text{Digester gas vented, m}^3\text{/y})(\text{methane content})\\ &\quad (\text{mass of methane, g/m}^3)\\ &= (2400\text{ m}^3\text{/y})(0.60)(656\text{ g/m}^3)(1\text{ tonne}/10^6\text{ g})\\ &= (944{,}640\text{ g-CH}_4\text{/y})(1\text{ tonne}/10^6\text{ g})\\ &= 0.945\text{ tonne-CH}_4\text{/y}\end{aligned}$$

$$\begin{aligned}\text{Total emissions} &= (\text{CH}_4\text{ emission})\,\text{GWP}_{\text{CH}_4}\\ &= 0.945 \times 21\\ &= 19.8\text{ tonne CO}_2\text{ e/y}\end{aligned}$$

f. Determine process N_2O emissions from WWTP with nitrification/denitrification. In the LGO Protocol, process N_2O emission from WWTP with nitrification/denitrification is estimated using an emission factor of 7 g-N_2O/person/y. Using the given data, the emission is estimated as

$$\begin{aligned}\text{Process N}_2\text{O emission} &= [(P_{\text{total}} \times F_{\text{ind-com}})EF_{\text{nit/denit}}(1\text{ tonne}/10^6\text{ g})]\text{GWP}_{\text{N}_2\text{O}}\\ &= [(430{,}000 \times 1.25) \times 7 \times 10^{-6}] \times 310\\ &= 1166.4\text{ tonne CO}_2\text{ e/y}\end{aligned}$$

where, P_{total} = total population served by the treatment plant
$F_{\text{ind-com}}$ = factor for industrial and commercial co-discharge waste into the sewer system = 1.25 for WWTPs
$EF_{\text{nit/denit}}$ = emission factor = 7 g-N_2O/person·y
GWP_{N_2O} = global warming potential for N_2O = 310

g. Determine process N_2O emissions from effluent discharge. In the LGO Protocol, process N_2O emission from wastewater discharge is estimated based on the measured average total nitrogen discharge. The emission factor for N_2O from effluent discharge is 0.005 kg N_2O-N/kg-N discharged in the effluent. Using the given data, the N_2O emission is estimated as follows.

$$\begin{aligned}\text{Process N}_2\text{O emission} &= (\text{N load})(EF_{\text{effluent}})(365.25)(44/28)(10^{-6})\text{CWP}_{\text{N}_2\text{O}}\\ &= [(8.3\text{ g-N/m}^3)(100{,}000\text{ m}^3\text{/d})](0.005\text{ kg N}_2\text{O-N/kg-N})\\ &\quad (365.25\text{ d/y})(44\text{ g-CO}_2/28\text{ g-N})(1\text{ tonne}/10^6\text{ g})(310)\\ &= (2{,}381{,}952\text{ g/y})(1\text{ tonne}/10^6\text{ g})(310)\\ &= 738.4\text{ tonne CO}_2\text{e/y}\end{aligned}$$

h. Prepare a summary of Scope 1 emissions.

$$\begin{aligned}\text{Total Scope 1 emissions} &= 33.3 + 1054.2 + 4.21 + 24.0 + 19.8 + 1166.4\\ &\quad + 738.4 = 3040\text{ tonne CO}_2\text{e/y}\end{aligned}$$

$$\text{Biogenic emissions} = 834.7 + 321.2 = 1156\text{ tonne CO}_2\text{e/y}$$

2. Calculate Scope 2 emissions.
Emissions associated with electricity:

$$\begin{aligned}\text{CO}_2\text{ emission} &= (\text{Electricity use, kWh/y})(\text{emission factor, g CO}_2\text{e/kWh})\\ &= 14{,}100{,}000 \times 720\text{ g/y}\\ &= (10{,}152{,}000{,}000\text{ g/y})(1\text{ tonne}/10^6\text{ g})\\ &= 10{,}152\text{ tonne/y}\end{aligned}$$

3. Prepare a summary of the total and biogenic emissions.

$$\text{Total emissions} = \text{Scope 1 emissions} + \text{Scope 2 emissions}$$

$$= 3040 + 10{,}152 = 13192 \text{ tonne } CO_2e/y$$

$$\text{Total biogenic emissions} = 1156 \text{ tonne } CO_2e/y$$

Comment The calculations shown in this example are based on the LGO Protocol, presented in SI units. It should be noted that nearly two-thirds of Scope 1 emissions is attributed to nitrous oxide emissions, and it constitutes about 14 percent of the total emissions.

Opportunities for GHG Reduction at Wastewater Treatment Facilities

Opportunities typically investigated for the reduction of GHG emissions from wastewater treatment facilities are summarized in Table 16–17. Many of the GHG reduction opportunities are related directly to reduction of energy use, discussed further in Chap. 17. Other opportunities are related to shifting the energy sources to those with lower GHG emissions. Examples of opportunities for GHG reductions are discussed briefly in the following subsections. It should be noted that there are numerous options, most of them site-specific, to achieve energy conservation and GHG emission reduction. It is also important to note that a thorough evaluation of existing conditions must be made before options for GHG reduction are evaluated. In conducting the evaluation of existing conditions and opportunities for GHG reduction, latest publications from U.S. EPA, WEF and other sources should be consulted.

Control of Dissolved Oxygen. Aeration of activated sludge reactors is the most significant process element when evaluating energy use as it takes nearly half of the total process-related energy at a typical conventional secondary treatment facility (see Chaps. 4 and 17). Control of dissolved oxygen not only helps reduce energy use, it also helps improve the treatment performance. The use of automated DO control with online DO analyzers has become a common practice. Other process upgrades to improve DO control and associated energy efficiencies include the improvements in blowers and diffusers (see Chap. 5).

Treatment Process Modification. In selecting a treatment process, or planning a process upgrade and modifications, considerations should be given to the treatment processes that require less energy to achieve the treatment objective. For example, by controlling the nitrogen removal process to nitritation and denitritation (see Chap. 7, 8 and 15), oxygen requirements for nitrogen removal could be reduced by 25 percent. Generation and recovery of energy from wastewater and waste energy within the treatment facility is also a significant consideration in GHG reduction as energy recovered from wastewater constituents (e.g., in the form of digester gas) is considered as biogenic and not counted in the Scope 1 and Scope 2 emissions. Greenhouse gas emissions associated with the use of chemicals of fossil fuel sources are usually counted as a Scope 3 emission. However, CO_2 emissions from the use of fossil fuel-origin methanol for denitrification may be counted as process-oriented Scope 1 emission (ICLEI, 2012).

Management of Nitrous Oxide Emission. Emission of nitrous oxide is estimated with assumptions that may not reflect actual emissions from the treatment processes and receiving waters, and it constitutes a significant fraction of total GHG emissions from wastewater treatment facilities. Depending on the mode of operation and

Table 16–17

Considerations in greenhouse gas reduction options for wastewater treatment facilities

Unit process	Description
General	• Selection of lower GHG emission energy sources (e.g., digester gas or natural gas vs. fuel oil) • Waste energy recovery within wastewater treatment plant (see Chap. 17)
Inlet/preliminary treatment	• Pump efficiency improvement • Flow equalization
Primary treatment	• Improvements in solids removal
Secondary treatment and sidestream treatment	• Use of diffusers with high oxygen transfer efficiencies • Use of blowers with high energy efficiencies • Selection of blowers or combination of blowers sized to allow operation in high efficiency range over full range of possible air requirements • Use of energy efficient mixing system for activated sludge anoxic/anaerobic zones • Control of aeration with DO monitoring • Control of aeration with NH_4-N monitoring • Selection of biological process requiring less oxygen (e.g., nitritation/denitritation, partial nitritation/deammonification) (see Chaps. 7, 8, 9 and 15) • Process configuration and control to minimize generation of N_2O (see Chap. 7)
Sludge processing and biosolids utilization/disposal	• Optimization of sludge thickening and dewatering • Elimination of unaccounted and un-combusted methane emissions • Complete utilization of digester gas • Enhancement in digester gas production (see Chap. 13) • Use of waste heat for pre-heating of sludge drying (see Chap. 14) • Heat recovery from sludge incineration systems (see Chap. 14) • Onsite energy and heat production from digester gas and biosolids (see Chaps. 14 and 17)
Disinfection	• Use of high-output lamps for UV disinfection
Advanced treatment	• Use of membrane systems with lower energy requirements • Energy recovery from residual pressure in the membrane treatment system

control, emission of nitrous oxide from biological treatment process could increase significantly. Generation of nitrous oxide during biological treatment is discussed in Sec. 7–12 in Chap. 7.

Use of Digester Gas. Even though the use of digester gas for boilers and power generation has been a common practice at many wastewater treatment facilities, not all facilities with anaerobic sludge digestion utilize all of the digester gas. Because methane has 21 times higher global warming potential than carbon dioxide, one of the major GHG emission sources can be the release of uncombusted digester gas into the atmosphere. By simply flaring the digester gas, the GHG emission is reduced by 21 fold, and because the CO_2 released from the flare is originated from biological sources, it is counted as a "biogenic" emission, which is reported separately, but not included in the GHG emissions inventory. By maximizing the use of digester gas as a fuel source, part of the GHG emissions associated with the use of electricity and fuels from other sources could be avoided. The use of digester gas and management of energy use are discussed further in Chap. 17.

PROBLEMS AND DISCUSSION TOPICS

16–1 Verify that for each mg/L of H_2S removed with chlorine 10.87 mg/L of alkalinity as $CaCO_3$ will be required.

16–2 Determine the amount of hydrogen peroxide (H_2O_2) required for the oxidation of hydrogen sulfide H_2S.

16–3 Using the following half reaction for permanganate (MnO_4^-), estimate the amount of permanganate that would be required per day to oxidize 100 ppm_v of H_2S from an foul air stream with a flowrate of 1500, 2000, 1800 or 2200 m^3/min (flowrate to be selected by instructor).

$$MnO_4^- + 4H^+ + 3e^- \rightarrow MnO_2(s) + 2H_2O$$

16–4 Determine the amount of ferrous sulfate ($FeSO_4$) that would be required to remove 150 mg/L of H_2S from digester supernatant. Assume the sulfide ion in H_2S will be converted to ferrous sulfide in an exchange reaction.

16–5 Four different waste air streams have been sampled and the results are summarized below. For one of these waste air streams (to be selected by instructor), determine the chemical requirements. Sodium hypochlorite and sodium hydroxide are to be used in the chemical scrubber.

		Plant			
Item	Unit	1	2	3	4
Air waste stream flowrate	m^3/min	1000	2500	3200	1800
H_2S concentration	ppm_v	75	45	65	35
Liquid to gas ratio	kg/kg	1.85	2.0	2.1	1.9
Temperature	°C	28	33	30	25
Density of 50 percent NaOH solution	kg/L	1.52	1.52	1.52	1.52

16–6 Using the design criteria given in Table 16–11, determine the size of compost filter needed to scrub 65 ppm_v H_2S from foul air at a flowrate of 1500, 1880, 2100 or 2300 m^3/min (value to be selected by instructor). Also estimate the mass of the buffer compound needed to neutralize the acid formed as a result of treatment within the filter. Assume a packed bed porosity of 43 percent. The temperature of the foul air is 20°C.

16–7 Using U.S. EPA's AP42 compilation of air emission factors, estimate (CO, NOx or SO_2 emissions, to be selected by instructor) from a dual-fuel reciprocating engine. The data used to calculate the emissions are summarized below and emission factors are reported in Table 16–15.

Item	Unit
Engine power rating	2386 kW (3200 bhp)
Fuel	Fuel oil #2, natural gas
Fuel oil #2 heat content	38.47 GJ/m^3
Natural gas heat content	0.0383 GJ/m^3
Average load by fuel oil	35 percent
Engine operation	8640 h/y

16–8 In Example 16–4, part of the digester gas was flared and vented. Consider the situation where all unutilized digester gas in Example 16–4 is utilized to reduce natural gas consumption, assuming the equipment at the treatment plant is capable to switch the use between natural gas and digester gas. Calculate: (a) the amount of natural gas consumption saved per year, and (b) reduction in the total GHG emissions.

Energy Considerations in Wastewater Management

WORKING TERMINOLOGY

Term	**Definition**
Biogas	A generic term used for the gas produced during anaerobic treatment of organic compounds. Typical composition of biogas generated by anaerobic digestion of sludges is 60 to 65 percent methane, and approximately 30 percent carbon dioxide. The term is used interexchangeably with digester gas.
Bomb calorimeter	A device in which a known mass of sample is combusted and the released energy is measured.
Carnot cycle	A reversible power cycle consisting of two isothermal processes and two isentropic processes without internal heat transfer.
Coefficient of performance (COP)	A ratio of the energy extracted from an energy recovery process to the energy input to the energy recovery process such as heat pump.
Convection	Heat transferred by the movement of gas or liquid.
Combined heat and power (CHP)	A system used to generate both electricity and heat. Also called cogeneration.
Electrical efficiency	The percentage of energy that is converted into electricity relative to the total energy input.
Enthalpy	A thermodynamic property of a system expressed as the sum of the internal energy and the product of pressure and volume.
Exothermic reaction	A chemical reaction resulting in a release of energy from the molecules.
Fuel cell	A device used to generate electricity from the reaction of hydrogen and oxygen gas. In wastewater treatment facilities, methane in biogas can be used to generate hydrogen. Recoverable thermal energy can also be generated with a fuel cell.
Heat exchanger	A device that allows the extraction of heat through a refrigerant with external power input.
Heat pump	A device used to transfer heat from one body to another using a refrigerant and energy from an external power source.
Higher heating value (HHV)	The total amount of energy released by complete combustion of a unit mass of a substance. Latent heat of vaporization is counted in HHV.
Integrated resource recovery (IRR)	A management approach in which the recovery of energy, water, and other resources is achieved by integrating the management of various waste streams such as wastewater, solid waste, and others.
Latent heat	Heat released or absorbed during the change in phases of a chemical substance (e.g., from liquid to gas).
Lower heating value (LHV)	The total amount of energy released by complete combustion of a unit mass of a substance, less the latent heat of vaporization of the water vapor formed by the combustion.

Term	Definition
Organic Rankine process	A process to generate electricity using low grade heat such as waste heat from a stationary combustion system and with an organic fluid that changes phases at a lower temperature than water.
Sensible heat	Energy transferred to a substance that results in a change in temperature of the substance.
Specific heat	The amount of heat necessary for the temperature of a unit mass of a material to increase by one unit.
Syngas	Syngas, or synthesis gas, is a mix of hydrogen, carbon monoxide, and other gaseous compounds generated as a result of the incomplete oxidation of organic materials under restricted oxygen environment. Syngas can be used as a fuel gas or to generate liquid fuel through the Fischer-Tropsch process.
Thermal efficiency	The ratio of net usable thermal output to the energy input, expressed in percentage. Also known as total system efficiency.

In the past, due to the relatively low and stable cost of fossil fuels and electricity, the use, recovery, and management of energy was not typically emphasized in the design and operation of wastewater management facilities. With increasing energy costs, uncertainties about future fossil fuel supplies, and increasing awareness of the impacts of greenhouse gas emissions, the efficient management of energy is now of greater concern with both private and public entities. Recognizing the importance of energy in the implementation of wastewater treatment facilities, and opportunities to recover and utilize energy from various sources within the treatment facilities, the focus of this chapter is on the subject of energy recovery and utilization. Topics considered in this chapter include: (1) need for energy management, (2) energy in wastewater, (3) fundamentals of heat balance, (4) energy usage in treatment plants, (5) recovery and utilization of chemical energy (6) recovery and utilization of heat energy, (7) recovery and utilization of hydraulic potential energy, (8) energy management, and (9) future opportunities for alternative wastewater treatment processes. The recovery of nutrients is considered in Chaps. 14 and 15.

17–1 FACTORS DRIVING ENERGY MANAGEMENT

The principal driving forces for achieving more efficient management of energy in wastewater treatment are

1. Potential for energy cost savings, including opportunity to become a net energy supplier
2. Potential for improved energy supply reliability
3. Considerations for sustainability, including the greenhouse gas reduction goals put forth by local, state, and federal governmental agencies

Potential for Energy Cost Savings

The operation of wastewater treatment facilities, as discussed in Chap. 4, depends largely on the use of energy resources to bring about various reactions. Therefore it is important to appraise energy requirements to better manage the energy usage, which constitutes the second largest expenditure in the operation of wastewater treatment facilities after labor costs. Examples of energy cost saving opportunities include the use of energy efficient equipment, process control for optimized energy use, and selection of energy sources including pricing negotiation.

Energy Supply Reliability

Reliability of energy supply for wastewater treatment facilities is an important consideration because of the potential for unforeseeable events such as an area-wide blackout of electrical power supply and disruption in energy supply after natural disasters. Generally, wastewater treatment facilities are equipped with emergency generators to operate critical elements of the treatment facility during disruption of energy supply, but few treatment plants are able to operate the entire treatment process with the emergency power supply. In recent years, it has been recognized that wastewater theoretically contains more energy than that required for treatment. It is also recognized that wastewater treatment plants could become net exporters of energy if the energy contained in incoming wastewater could be recovered effectively. Becoming self sufficient in the production and utilization of energy would significantly improve treatment plant reliability, even during power outages. As discussed in this chapter, however, inherent inefficiencies with energy recovery process are significant challenges. The use of anaerobic digestion and combustion of biogas, for example, usually achieves one third or less of typical energy requirements for the conventional wastewater treatment facility. Some of the technologies for energy recovery and utilization considered in this chapter are relatively new to the wastewater field, but many of them have been used in various industrial and commercial applications.

Considerations for Sustainability

In addition to the need to reduce costs for purchasing energy from outside sources, the reduction of greenhouse gas (GHG) emissions has become one of key factors affecting decisions on wastewater treatment processes and equipment selection. As discussed in Sec. 4–1, many existing treatment plants built during the 1970s and 1980s will need to be upgraded to meet increasingly stringent discharge limits. In planning treatment plant upgrades, reduction of GHG emissions (see Chap. 16) is often highlighted in the objectives of the project. Even though justifications for funding tend to focus on the immediate cost savings, when similar alternatives are compared, the options which address GHG reduction goals and other environmental impacts are considered favorably. As wastewater treatment facilities are considered more frequently to be an integral part of a regional energy management scheme, various alternative organic wastes such as food waste and grease, could be brought to the treatment plant to enhance energy production (Chap. 14).

17–2 ENERGY IN WASTEWATER

The energy contained in wastewater is comprised of (1) chemical energy, (2) thermal energy, and (3) hydraulic energy. Chemical energy is the energy contained in organic molecules which can be released by chemical reactions. Thermal energy is the heat retained in wastewater. Hydraulic energy of wastewater fluid is the sum of the gravitational potential energy due to elevation head, energy associated with pressure head, and kinetic energy embodied in the wastewater flows as velocity head. Each of the three forms of energy in wastewater is considered in the following discussion.

Chemical Energy

Wastewater contains organic and inorganic molecules, and exothermic reactions of these constituents will result in a release of chemical energy retained in the molecules. A majority of the chemical energy in wastewater is contained in organic compounds measured as COD, even though some inorganic constituents including ammonia also contain chemical energy that could be extracted. In wastewater treatment, part of the chemical energy is removed from the liquid stream in the form of sludge during preliminary and primary treatment. During the biological treatment process, some of the chemical energy is transformed into biomass and reaction products such as carbon dioxide and methane, or released as heat through metabolism of microorganisms. In sludge processing, part of the chemical energy may be recovered in the form of methane gas and utilized as an energy source.

Energy Contents of Wastewater Constituents. The energy content of wastewater, as described in Chaps. 2 and 14, can be estimated from an elemental analysis of the organic constituents in wastewater using the following empirical expression, which is a modified form of the DuLong formula developed by Channiwala (1992), repeated here from Chap. 2 for convenience.

$$\text{HHV (MJ/kg)} = 34.91\,\text{C} + 117.83\,\text{H} - 10.34\,\text{O} - 1.51\,\text{N} + 10.05\,\text{S} - 2.11\text{A} \tag{2–66}$$

Where C, H, O, N, S, and A are the weight fraction of carbon, hydrogen, oxygen, nitrogen, sulfur, and ash, respectively. Note that higher heating value (HHV) is the total amount of energy released by complete combustion of a unit mass of a substance when water remains as liquid. In actual combustion systems, the combustion temperature is well above 100ºC and water will be vaporized, absorbing the latent heat of vaporization. The total amount of energy released from a complete combustion of unit mass of a substance, considering the heat required for vaporization of water is the lower heating value (LHV). For example, LHV of natural gas is typically 10 percent lower than the HHV. While Eq. (2–66) can be used to estimate the energy content, experimental data on chemical energy in wastewater samples are collected using a bomb calorimeter.

For simple molecules, chemical energy can be calculated based on the enthalpy of reaction. The enthalpy of reaction is defined by Hess' Law as the difference between the sum of enthalpy of formation of reactants and the sum of enthalpy of formation of all products:

$$\text{H}_{\text{reaction}} = \sum \text{H}^{o}_{f\,\text{products}} - \sum \text{H}^{o}_{f\,\text{reactants}} \tag{17–1}$$

where $\text{H}_{\text{reaction}}$ = enthalpy of reaction
H^{o}_{f} = enthalpy of formation

The reaction is an exothermic reaction when the enthalpy of reaction is negative. Enthalpy of formation of chemical compounds found commonly in wastewater is shown in Table 17–1, and a more complete list can be found in references in chemical engineering. Calculation of the heat of reaction is illustrated in Example 17–1.

EXAMPLE 17–1 **Calculation of Enthalpy of Reaction** Calculate the enthalpy of reaction for the oxidation of methane.

The enthalpy of formation for each reactant and product at 25ºC is

$CH_{4(g)}$	−74.6 kJ/mole
$O_{2(g)}$	0 kJ/mole
$CO_{2(g)}$	−393.5 kJ/mole
$H_2O_{(l)}$	−285.8 kJ/mole

Solution

1. The oxidation of methane can be expressed as follows.

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$$

2. Determine the enthalpy for the oxidation of methane using Eq. (17–1).

$$H_{\text{reaction}} = \sum H^o_{f\,\text{products}} - \sum H^o_{f\,\text{reactants}}$$

$$H_{\text{reaction}} = [(H^o_{fCO_2}) + 2(H^o_{fH_2O})] - [(H^o_{fCH_4}) + 2(H^o_{fO_2})]$$

$$= [(-393.5) + 2(-285.8)] - [(-74.6) + 2(0)]$$

$$= -890.5 \text{ kJ/mole}$$

Comment Because the enthalpy of reaction was calculated for 25°C, water is in the liquid phase and the calculated value is the higher heating value at 25°C. The volume of one mole of methane at 25°C at atmospheric pressure is approximately 24L. Assuming 65 percent methane content by volume in digester gas, 1 m^3 of digester gas contains approximately 27 moles of methane. Thus, the HHV in digester gas can be estimated as 890 (kJ/mole) × 27 ($mole/m^3$) = 24,112 kJ/m^3 (~647 Btu/ft^3). Stationary combustion systems are operated at a much higher temperature and the latent heat of water vaporization must be accounted for by estimating the lower heating value.

Table 17–1

Enthalpy of formation for selected chemical compounds at 25°C[a]

Substance	State[b]	ΔH^0_f, kJ/mole	Substance	State[b]	ΔH^0_f, kJ/mole
Ca^{2+}	aq	−542.8	H_2O	g	−241.8
$CaCO_3$	s	−1206.87	HS	aq	−17.6
$Ca(OH)_2$	s	−986.6	H_2S	g	−20.6
$CaSO_4$	s	−1434.5	H_2S	aq	−39.3
CH_4	g	−74.6	H_2SO_4	l	−814
CH_3CH_3	g	−84.67	Mg^{2+}	aq	−466.9
CH_3COOH	aq	−488.4	$Mg(OH)_2$	s	−924.5
CH_3COO^-	aq	−486.0	Na^+	aq	−240.1
$C_6H_{12}O_6$	s	−1275	NH_3	g	−45.9
Cl_2	g	0	NH_3	aq	−80.83
Cl_2	aq	−23.4	NH_4^+	aq	−132.5
Cl^-	aq	−167.20	NO_2^-	aq	−104.6
CO_2	g	−393.51	NO_3^-	aq	−207.4
CO_2	aq	−412.92	O_2	g	0
CO_3^{2-}	aq	−677.10	O_2	aq	−11.71
HCO_3^-	aq	−692.0	OH^-	aq	−230.0
H_2CO_3	aq	−699.0	S^{2-}	aq	30.1
H_2O	l	−285.8	SO_4^{2-}	aq	−909.3

[a] From Sawyer et al. (2003).

[b] g = gas, aq = aqueous solution, l = liquid.

For larger and more complex molecules in wastewater, theoretical values cannot be calculated with Eq. (17–1) because the enthalpy of formation values for many of the reactants are not available. There have been attempts to find correlations between COD and chemical energy in wastewater, and the values ranging between 14.7 and 17.8 kJ/gCOD have been reported for untreated domestic wastewater (Shiraz and Bagley, 2004; Heidrich et al., 2011). However, as described by Heidrich et al. (2011), the amount of energy per gram COD can vary widely. Typical energy content in primary sludge has been reported to be between 23,000 and 29,000 kJ/kg dry solids (see Table 14–17 in Chap. 14). Determination of energy in primary sludge is illustrated in Example 17–2.

EXAMPLE 17–2 **Chemical Energy in Sludge Removed by Primary Clarification** The flowrate to a wastewater treatment plant is 1000 m^3/d. The average total suspended solids concentration in the wastewater is 720 g/m^3. Using the typical energy contents in primary sludge reported in Table 14–17, estimate the chemical energy removed by primary clarification assuming 50 percent solids removal.

Solution

1. Calculate TSS loading.

   $$\text{TSS loading} = 1000\ \text{m}^3/\text{d} \times 720\ \text{g/m}^3 = 720{,}000\ \text{g/d} = 720\ \text{kg/d}$$

2. Estimate the amount of chemical energy removed by primary clarification.

   $$\text{TSS removed} = (720\ \text{kg/d}) \times 0.5 = 360\ \text{kg/d}.$$

   Chemical energy in the primary sludge is 23,000 to 29,000 kJ/kg. Assuming 26,000 kJ/kg,

   $$\text{Chemical energy removed} = (360\ \text{kg/d}) \times (26{,}000\ \text{kJ/kg}) = 9{,}360{,}000\ \text{kJ/d}$$
   $$= 9.36\ \text{GJ/d}$$

Comment The amount of energy that can be recovered and utilized will depend on the solids processing, energy recovery and energy use efficiencies, as discussed later in this Chapter. It should be noted that the loss of dissolved and volatile organic compounds during sample preparation have been recognized and high variability in values between samples have been reported (Shiraz and Bagley, 2004; Heidrich et al., 2011).

Energy Content of Ammonia. As described in Sec. 15–5, thermal oxidation of ammonia is an exothermic reaction, and combustion of ammonia will release energy. The heat balance based on the heat of formation at 25°C at 1 atm is expressed as:

$$NH_3 + 0.75\ O_2 \rightarrow N_2 + 1.5\ H_2O \qquad \Delta H^\circ = -317\ \text{kJ/mole} \qquad (17\text{–}2)$$

$$NH_3 + O_2 \rightarrow 0.5\ N_2O + 1.5\ H_2O \qquad \Delta H^\circ = -276\ \text{kJ/mole} \qquad (17\text{–}3)$$

$$NH_3 + 1.25\ O_2 \rightarrow NO + 1.5\ H_2O \qquad \Delta H^\circ = -227\ \text{kJ/mole} \qquad (17\text{–}4)$$

Anhydrous ammonia has been used as a fuel in the past and is currently the subject of extensive research as a potential alternative fuel source. Even though the heat content is significantly lower than that of methane (802.6 kJ/mole or 50,163 kJ/kg), there is a potential to recover ammonia from nitrogen-rich waste streams and use the energy to supplement other fuel sources.

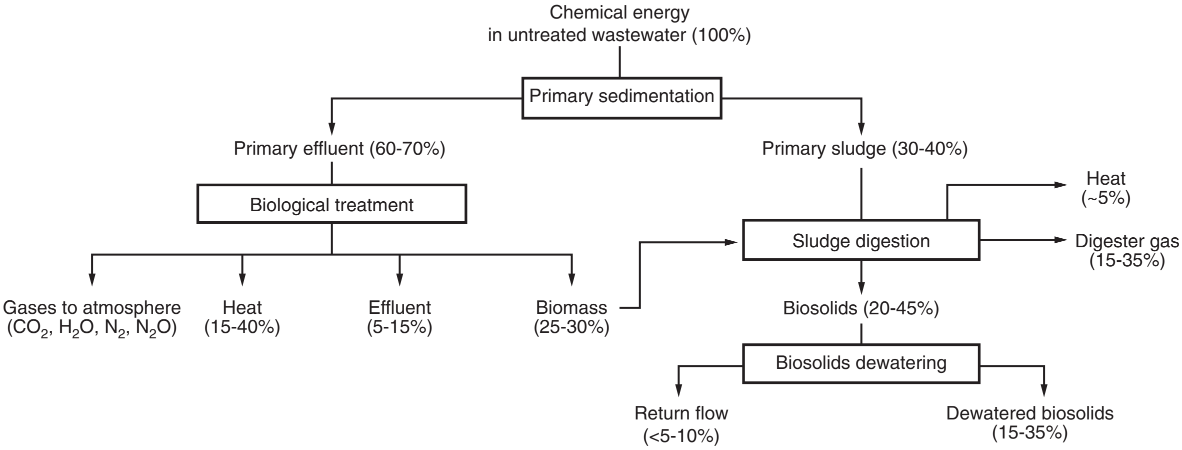

Figure 17–1

Fate of chemical energy in wastewater treatment with activated sludge and anaerobic sludge digestion. A range is shown for the percentages as they vary with the treatment technologies and wastewater characteristics.

Distribution of Chemical Energy during Wastewater Treatment. The distribution and fate of chemical energy in conventional wastewater treatment is illustrated conceptually on Fig. 17–1. Transformation of chemical energy occurs primarily during two major treatment processes: biological treatment of liquid stream, and treatment and processing of sludge. Even though each wastewater has different characteristics and distribution of energy varies with treatment processes, it is worth noting that a considerable amount of chemical energy is sent to the biological treatment process where additional energy is added to the process to convert chemical energy into CO_2, H_2O, N_2, N_2O, heat, and other byproducts that cannot be utilized as an energy source.

Heat generated from exothermic reactions can be significant in processes such as autothermal aerobic digestion (ATAD) and sidestream treatment involving oxidation and reduction of highly concentrated organic and nitrogenous compounds. In these processes, a heat balance must be prepared to determine if cooling of the treatment unit process or dilution of the treated stream is necessary (see Chap. 15) to maintain a desired range of operating temperature. However, in normal domestic wastewater, the heat generated from biochemical reactions is not significant enough to require heat balance evaluation.

Part of the chemical energy is retained in biomass, which can be transformed into an energy source such as biogas and syngas through sludge processing (see Chaps. 13 and 14). With a conventional treatment system, only a fraction of chemical energy that reaches solids processing can be recovered. Historically, wastewater treatment systems were not designed with the intent to maximize the flow of chemical energy to the processes capable of energy recovery.

Thermal Energy

The thermal energy in wastewater is in the form of temperature. When the temperature of a liquid or gas changes from T_1 to T_2, the change in thermal energy is expressed as:

$$Q = mc\Delta T \qquad (17–5)$$

where, Q = change in heat content in wastewater flowrate, kJ/h

m = mass flowrate of water, kg/h

c = specific heat of a substance, kJ/kg·°C

ΔT = temperature change, °C

Thermal energy can be recovered from water (e.g., wastewater effluent) or heated air, such as exhaust from unit processes involving combustion of fuel (e.g., engine generators, boilers, incinerators). It is common to utilize the excess heat in air and/or water for various uses within the treatment facility including digester heating, solids drying, hot water supply, and space heating. Excess heat can also be provided to users outside of the facility, if the amount of heat produced at the plant is large enough.

When the temperature of the wastewater is significantly different from the ambient temperature or the temperature of other streams at the treatment facility, there is a potential that heat can be transferred in a form that could be used for other purposes. Heat added to (or lost from) wastewater can be approximated by assuming that the specific heat of wastewater is equal to that of water at the given temperature (see Chap 2). The specific heat of water, c_w, is 4.1816 kJ/kg·°C at 20°C, and even though it varies with temperature the difference is within 1 percent over the range between 0 to 100°C. For example, if the temperature of wastewater is raised from 21 to 23°C and the flowrate is 160,000 L/h, the heat added to wastewater is

$$\begin{aligned} Q &= mc_w\Delta T \\ &= 160{,}000 \times 4.18 \times 2 \\ &= 1{,}337{,}600\,\text{kJ/h} \end{aligned}$$

Hydraulic Energy

Exclusive of chemical and heat energy, wastewater fluid can also contain energy in the form of elevation head, h_e, (the relative position of the influent to effluent free water surface), pressure head, h_p, (as in pressurized processes such as reverse osmosis) and, velocity head h_v, (associated with the kinetic energy of the moving fluid). These forms of energy are usually quantified in terms of the Bernoulli equation. It should be noted that each of the three terms represents a linear dimension. The energy involved, expressed in kJ or other appropriate units, is obtained by taking into account the corresponding mass of the fluid. The power, expressed in W, kJ/h, or other appropriate units, is the energy per unit time.

Elevation Head, h_e. Most conventional wastewater treatment plants are designed to allow wastewater to flow by gravity from the headworks to the receiving waters. To minimize the power requirements, the hydraulic profile is set to minimize the excess head at the end of the treatment process. Because the majority of wastewater treatment plants are located adjacent to the receiving water body, the plant is often designed to have minimal head at the discharge point.

Pressure Head, h_p. Some wastewater treatment processes such as reverse osmosis operate under pressurized conditions. The pressure head is expressed as p/γ, where γ is a specific weight of the fluid. The recovery of energy from reverse osmosis is considered in Sec. 11–7 in Chap. 11.

Velocity Head, h_v. Because the wastewater is moving through the plant, it also contains kinetic energy, expressed as $v^2/2g$. In general, the velocity head contribution to the total energy is relatively small.

Determination of Total Fluid Head. If H_t, represents the total head transferred to (+) or from (−) the fluid (e.g., in a pump, fan, or turbine) then application of the law of conservation of energy between any two points can be expressed as follows:

$$(h_e + h_p + h_v)_1 \pm H_t = (h_e + h_p + h_v)_2 + \text{losses} \tag{17–6}$$

The losses in Eq. (17–6) represent the head that has been transformed into nonrecoverable forms of energy (e.g., heat or noise). The general expression for an incompressible liquid may be rewritten as

$$\pm H_t = (p_2/\gamma - p_1/\gamma) + (v_2^2/2g - v_1^2/2g) + (z_2 - z_1) + h_L \tag{17–7}$$

where H_t = total head transferred to/received from fluid, m (ft)
p_1, p_2 = pressure, kN/m^2 (lb$_f$/in.^{2})
γ = specific weight of water, kN/m^3 (lb/ft^3)
v = velocity of water, m/s (ft/s)
g = acceleration due to gravity, 9.81 m/s^2 (32.2 ft/s^2)
z_1, z_2 = height above any assumed datum plane, m (ft)
h_L = headloss, m (ft)

Conversion of Fluid Potential Energy to Other Forms of Energy. The fluid energy as given by Eq. (17–7) can be converted to electrical power for a given flowrate using the following expression:

$$P_e = \rho Q g H_t \eta_t \eta_e \tag{17–8}$$

where, P_e = electrical power obtained, W
ρ = density of wastewater, kg/m^3
Q = flowrate, m^3/s
g = acceleration due to gravity, 9.81 m/s^2
η_t = efficiency of mechanical device (e.g., Pelton Wheel, reverse pump, pump, etc.) expressed as a fraction, dimensionless
η_e = efficiency of electrical conversion device expressed as a fraction, dimensionless

Efficiency factors for power generation systems are given in Sec. 17–7. The application of Eqs. (17–7) and (17–8) is demonstrated in Example 17–3.

EXAMPLE 17–3 **Determine Hydraulic Energy of Wastewater Discharge** Consider a wastewater treatment facility located near a coastline, with an effluent discharge point 3 m above mean sea level and an average effluent flowrate of 4 ML/d. Treated effluent flowing out of the chlorine contact tank has a velocity of 0.5 m/s. Calculate the potential energy contained in the effluent. Estimate the actual electrical energy output that can be obtained if a hydraulic turbine generator is located at sea level. Assume a turbine generator combination is to be used with an overall efficiency on 40 percent, The wastewater temperature is 20°C.

Solution

1. Determine the potential and velocity energy.
   a. The potential energy is equal to

$$(z_2 - z_1) = [0 - 3\text{ m})] = -3\text{ m}$$

   b. The velocity energy is equal to

$$(v_2^2/2g - v_1^2/2g) = 0 - (0.5\text{ m/s})^2/2g = -0.0127\text{ m}$$

2. Calculate the potential mechanical energy that can be transferred using Eq. (17–7) neglecting any losses.

$$H_t = (z_2 - z_1) + (v_2^2/2g - v_1^2/2g) = -3\text{ m} + (-0.0127)\text{ m} = -3.0127\text{ m}$$

Because the sign is negative, energy can be produced.

3. Calculate the electrical energy that can be produced with a turbine generator combination using Eq. (17–8) with a combined efficiency factor η and neglecting any other losses.

$$\begin{aligned} P_e &= \rho Q g H_t \eta \\ &= (1000\ \text{kg/m}^3)(4000\ \text{m}^3/\text{d})(9.81\ \text{m/s}^2)(3.0127\ \text{m})(0.40) \\ &= 47.3 \times 10^6\ \text{kg·m}^2/\text{s}^2\text{·d} \\ &= 47.3\ \text{MJ/d} \end{aligned}$$

Comment Depending on the receiving water, the hydraulic potential that could be made available for power generation may vary with tides, seasons or other factors altering the surface level. Recovery of hydraulic potential is further discussed in Sec. 17–7.

17–3 FUNDAMENTALS OF A HEAT BALANCE

In the following sections, the various forms of energy utilized in wastewater treatment and the management of that energy usage in wastewater treatment facilities are introduced and discussed. To understand the issues involved, it will be useful to review the basic concept involved in the preparation of heat balances.

Concept of a Heat Balance

The concept of heat balance is based on the first law of thermodynamics, i.e., enthalpy is conserved. The mathematical approach is similar to the mass balance calculation described in Chap. 1. For a given system boundary, the general heat balance analysis is given by:

1. General word statement:

$$\underset{(1)}{\begin{array}{c}\text{Rate of accumulation}\\ \text{of heat within the}\\ \text{system boundary}\end{array}} = \underset{(2)}{\begin{array}{c}\text{rate of flow of}\\ \text{heat into the}\\ \text{system boundary}\end{array}} - \underset{(3)}{\begin{array}{c}\text{rate of flow of}\\ \text{heat out of the}\\ \text{system boundary}\end{array}} + \underset{(4)}{\begin{array}{c}\text{rate of generation}\\ \text{of heat within the}\\ \text{system boundary}\end{array}} \tag{17–9}$$

2. The corresponding simplified word statement is

$$\text{Accumulation} = \text{inflow} - \text{outflow} + \text{generation} \tag{17–10}$$

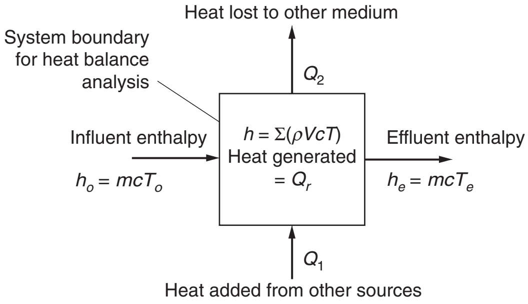
3. Assuming there is no change in mass flowrate and specific heat of the mass, symbolic representation of heat balance is (see Fig. 17–2):

$$\Delta H = mcT_o + Q_1 - mcT_e - Q_2 + Q_r \tag{17–11}$$

where ΔH = change of enthalpy within the system boundary
m = influent mass flowrate
c = specific heat of the mass
T = temperature
Q_1, Q_2 = heat added to or lost from the system boundary, such as added energy through mechanical mixing, or heat loss through the reactor wall
Q_r = heat generated/absorbed within the system boundary, such as heat generated /absorbed during due to chemical reaction and latent heat of vaporization

Figure 17–2

Conceptual diagram of heat balance.



Preparation of a Heat Balance

The preparation of a heat balance is similar to the preparation of a mass balance in that all sources of heat that enter, exit, or are released or taken up within the system boundary must be considered. In most cases, however, internal energy within chemical compounds is not considered except for the energy released into the system in the form of thermal energy. The steps given below should be followed in the preparation of heat balances, as the techniques involved are being mastered.

1. Prepare a simplified schematic or flow diagram of the system or process.
2. Draw a system boundary to define the limits over which the heat balance is to be applied. Proper selection of the system boundary is important because, in many situations, it may be possible to simplify the heat balance computations.
3. List all of the pertinent data and assumptions that will be used in the preparation of the heat balance on the schematic or flow diagram.
4. List all of the rate expressions for the biological or chemical reactions that occur in the process.
5. Select a convenient basis on which the numerical calculations will be based.
6. Solve the balance equations.

The application of the heat balance calculation is illustrated in Example 17–4.

EXAMPLE 17–4 **Heat Balance Calculation** Evaluate the heat balance for an anaerobic digester, using the following process information. How much additional heat will be required to maintain the digester temperature? Assume that the sludge in the reactor is well mixed and has a uniform temperature and specific heat. Ignore heat in the digester gas.

Process information	Unit	Value
Incoming sludge flowrate	m^3/d	100
Incoming sludge temperature	°C	10
Volume of sludge in the digester	m^3	2000
Liquid temperature in the digester	°C	32
Specific heat of sludge in the digester	kJ/kg·°C	4.2
Heat loss by conduction[a]	kJ/d	1.9×10^6
Heat added by sludge mixing	kJ/d	negligible

[a] Conduction losses occur through the digester walls above and below the ground level, the bottom, and the top, depending on the design of the digester.

Solution

1. Describe the heat balance.
   Accumulation/loss of heat = (heat in incoming sludge) + (heat added by sludge mixing) − (heat in effluent sludge) − (heat loss by conduction through the wall)
2. Develop a symbolic representation from Eq. (17–3).

$$\Delta H = mcT_o + Q_1 - mcT_e - Q_2 + Q_r$$

3. Using the given data and assuming specific gravity of water is 1.0, solve for ΔH.

$$\begin{aligned}\Delta H &= (100\,\text{m}^3/\text{d})(10^3\,\text{kg/m}^3)(4.2\,\text{kJ/kg})(10^\circ\text{C}) + 0 - (100\,\text{m}^3/\text{d})(10^3\,\text{kg/m}^3)\\ &\quad (4.2\,\text{kJ/kg})(32^\circ\text{C}) - (1.9 \times 10^6\,\text{kJ/d}) + 0\\ &= 4.2 \times 10^6 - 13.44 \times 10^6 - 1.9 \times 10^6\,\text{kJ/d}\\ &= -11.14 \times 10^6\,\text{kJ/d}\end{aligned}$$

To maintain the heat balance, an additional 11.14×10^6 kJ/d, or 11.14 GJ/d of heat must be added to the digester.

Comments For simplicity, heat in the digester gas was not included in the calculation. Even though a single number was assumed in this example to account for conduction losses, evaluation of the heat loss from the digester tank is a significant part of the heat balance calculation around the digester (see Chap. 13).

In normal municipal wastewater treatment, the heat balance around the liquid treatment train is important primarily to maintain temperature for biological treatment. However, it is sometimes observed that the temperature of mixed liquor is slightly higher than the incoming wastewater. The elevated temperature is generally attributed to biological oxidation of organics and nitrogen which is an exothermic reaction as discussed in Sec. 17–5 and Sec. 15–6 in Chap. 15. The aeration system will also contribute to the heat balance in bioreactors as compressed air, at an elevated temperature, is introduced into the bioreactor. Mixing in open activated sludge tanks can add heat (if done with the aeration system), but mixing also enhances the removal of heat liquid by evaporative cooling as moist air exits from the reactor. In sidestream treatment, heat generated from oxidation and reduction of nitrogen is significant and the heat balance must be evaluated to maintain the operating temperature with dilution water or a heat removal mechanism (see Sec. 15–11). Excess heat in the incoming wastewater and treated effluent can be recovered for beneficial purposes as discussed in Sec. 17–6.

17–4 ENERGY USAGE IN WASTEWATER TREATMENT PLANTS

The energy contained in wastewater and the fundamentals of the heat balance used to assess the potential for the recovery and utilization of energy were introduced in the previous sections. To achieve efficient use of energy and utilization of energy extracted from the treatment facility, it is useful to review the usage of energy in wastewater treatment plants. The review of energy usage in wastewater treatment plants is also important because the cost for energy ranges between 15 and 40 percent of the total operation and maintenance costs for wastewater treatment (WEF, 2009), the second highest after labor costs. The topics considered in this section include (1) types of energy sources, (2) energy use for wastewater treatment, (3) energy usage by various treatment processes, and (4) advanced and new wastewater treatment technologies.

Types of Energy Sources Used at Wastewater Treatment Facilities

The energy required to operate a wastewater treatment facilities is supplied by a number of different sources, but primarily by electricity. Electricity is used to operate motors for blowers, pumps and other facilities with moving parts. Electricity is also used for instrumentation and control equipment, lighting, and cooling and heating of buildings with air conditioning equipment. Fuel oils and natural gas are used primarily to operate boilers for heating, and to operate a stationary combustion system to produce electricity. Emergency generators are typically operated by fuel oils. The heat generated from the combustion system can also be utilized (combined heat and power, CHP). In some cases, reciprocating dual fuel engines are used to drive pumps or blowers. Digester gas is used commonly for both boilers and stationary combustion systems for electricity generation. Wind and solar electric power generation systems are used in some facilities, but typically for a minor power demand. The use of electricity from onsite power generation and the use of renewable energy such as solar, wind, tidal, and other energy has been considered and implemented in a number of wastewater treatment facilities (U.S. EPA, 2006a). However, the contribution of these energy sources to the total energy consumption has been minor due primarily to relatively low and stable cost of electricity.

Energy Use for Wastewater Treatment

At the present time, as discussed in Chap. 1, nearly all of the publicly owned wastewater treatment plants in the United States provide secondary or higher levels of treatment. Treatment plants with more stringent treatment limits generally require greater amounts of electric energy per volume of water treated. Plants that have biological treatment for nutrient removal and filtration use on the order of 30 to 50 percent more electricity for aeration, pumping, and solids processing than conventional activated sludge treatment (EPRI, 1994). Wastewater reclamation plants with advanced treatment processes described in Chap. 11 also require significantly more energy to operate.

Energy Use by Individual Treatment Processes

The energy requirements of wastewater treatment systems depend on the flowrate, the characteristics of the incoming raw wastewater, and the treatment process employed. Treatment processes and equipment requiring electric energy in a municipal wastewater treatment plant are presented in Table 17–2. Various types of electric motor-driven equipment are involved in these operations and processes including pumps, blowers, mixers, sludge collectors, and centrifuges. In conventional secondary treatment, most of the electricity is used for (1) biological treatment by either the activated sludge process that requires energy for aeration blowers or trickling filters that require energy for influent pumping and effluent recirculation; (2) pumping systems for the transfer of wastewater, liquid sludge, biosolids, and process water; and (3) equipment for the processing, dewatering, and drying of residuals and biosolids.

Typical energy requirements for individual treatment processes are reported in Table 17–3. The electrical energy required for wastewater treatment vary widely but typically between 950 MJ/10^3 m^3 and 2900 MJ/10^3 m^3 (between 1000 and 3000 kWh/Mgal) for most treatment facilities (AWWARF, 2007). The amount of electricity consumed varies with plant size, influent and effluent characteristics, pumping requirements for influent

Table 17–2

Commonly used electric motor driven equipment used in wastewater treatment

Process or operation	Commonly used electric motor driven equipment
Pumping and preliminary treatment	Chemical feeders for prechlorination, influent pumps, screens, screenings press, grinders and macerators, blowers for preaeration and aerated grit chambers, grit collectors, grit pumps, air lift pumps
Primary treatment	Flocculators, clarifier drives, sludge and scum pumps, blowers for channel aeration
Secondary (biological) treatment	Blowers for channel and activated sludge aeration, mechanical aerators, trickling filter pumps, trickling filter distributors, clarifier drives, return and waste activated sludge pumps
Disinfection	Chemical feeders, evaporators, exhaust fans, neutralization facilities, mixers, injector water pumps, UV lamps
Advanced wastewater treatment	Blowers for nitrification aeration, mechanical aerators, mixers, trickling filter pumps, pumps for depth filters, blowers for air backwash, pumps for membrane filtration
Solids processing	Pumps, grinders, thickener drives, chemical feeders, mixers for anaerobic digesters and blending tanks, aerators for aerobic digesters, centrifuges, belt presses, heat dryer drives, incinerator drives, conveyors
Ancillary systems	
Odor control	Odor control fans, chemical feeders
Process water	Pumps
Plant air	Compressors

and effluent, energy requirements for odor control, and type of treatment system employed. However, generally energy use per volume tends to be lower at larger treatment plants, and activated sludge processes tend to require more energy than trickling filters (see Fig. 17–3). A typical percentage distribution of energy use in a conventional activated sludge treatment plant is illustrated on Fig. 17–4.

The operational requirements for wastewater collection and treatment systems are correlated with the wastewater load (see Fig. 3–6 in Chap. 3). If a diurnal electricity demand curve were developed for the treatment facilities, it would be of a similar shape to the flowrate and loading curves shown on Fig. 3–6. Therefore the peak energy demand at a wastewater treatment facility would likely occur from midday to the early evening hours when peak electricity consumption occurs in the community.

Advanced and New Wastewater Treatment Technologies

With the introduction of new technologies for wastewater treatment, energy usage requirements will change, particularly where effluent from a conventional treatment process is treated further for reuse applications. As reported in Table 17–3, higher levels of treatment, or new technologies whose operation is based on electric energy, i.e., membrane treatment, UV disinfection, and advanced oxidation, tend to require more energy to operate.

Table 17–3

Typical energy consumption of various treatment processes on wastewater treatment[a]

Technology	Energy consumption[b]	
	$kWh/10^3$ gal	kWh/m^3
Conventional secondary treatment WWTP[c]	**0.38 to 0.67**	**0.10–0.18**
Wastewater influent pumping	0.12–0.17	0.032–0.045
Screens	0.001–0.002	0.0003–0.0005
Grit removal (aerated grit removal)	0.01–0.05	0.003–0.013
Trickling filters	0.23–0.35	0.061–0.093
Trickling filter-solids contact	0.35	0.093
Activated sludge for BOD removal	0.53–4.1	0.14
Activated sludge with nitrification/denitrification	0.87–0.88	0.23
Membrane bioreactor	1.9–3.8	0.5–1.0[d]
Return sludge pumping	0.03–0.05	0.008–0.013
Secondary settling	0.013–0.015	0.003–0.004
Dissolved air flotation	0.12–0.15	0.03–0.04
Tertiary filtration (depth filtration)	0.1–0.3	0.03–0.08
Tertiary filtration (surface filtration)		
Chlorination (sodium hypochlorite)	0.001–0.003	0.0003–0.0008
UV (ultraviolet) disinfection	0.05–0.2	0.01–0.05
Microfiltration/ultrafiltration	0.75–1.1	0.2–0.3
Reverse osmosis (without energy recovery)	1.9–2.5	0.5–0.65
Reverse osmosis (with energy recovery)	1.7–2.3	0.46–0.6
Electrodialysis (TDS range 800–1200 mg/L)	4.2–8.4	1.1–2.2
UV photolysis with O_3 or H_2O_2 (advanced oxidation)[e]	0.2–0.4	0.05–0.1
Sludge pumping	0.003	0.0008
Gravity thickening	0.001–0.006	0.0003–0.0016
Aerobic digestion	0.48–1.2	0.13–0.32
Mesophilic anaerobic digestion (primary plus waste activated sludge)[f]	0.35–0.6	0.093–0.16
Mesophilic anaerobic digestion with thermal hydrolysis pretreatment (primary plus waste activated sludge)[f]	0.58–0.6	0.015–0.02
Sludge dewatering (centrifuge)	0.02–0.05	0.005–0.013
Sludge dewatering (belt filter press)	0.002–0.005	0.0005–0.0013

17–5 ENERGY AUDITS AND BENCHMARKING

An energy audit is a procedure and methodology used to identify energy conservation opportunities. The performance of an energy audit is an important first step to identify inefficiencies with existing plant operation and opportunities to improve energy efficiency. Different levels of energy audits can be performed varying from a preliminary "walk-through" to obtain an overview of principal equipment to a detailed process audit in which the energy used by each unit processes is evaluated (EPRI, 1994). In general, one of the initial tasks in an energy audit is the evaluation of the unit processes known to consume a significant amount of energy, such as influent pumping, aeration for activated sludge plants, pumping systems at trickling filter plants, and sludge processing units. A typical procedure used to conduct an energy audit is presented in Table 17–4. Common energy audit recommendations are reported in Table 17–5.

Table 17–4

Typical procedure for energy audit

1. Establish energy and/or GHG reduction goals
2. Develop data collection questionnaire that includes
    - Energy demands
    - Process description
    - Operating parameters
    - Discharge goals
    - Equipment list with power rating, size, number in operation, etc.
    - Other important energy related information
3. Conduct an energy audit tour (visual inspection)
4. Evaluate energy consumption of:
    - Unit processes
    - Systems (i.e. secondary treatment, digestion, etc.)
    - Structures
5. Develop a matrix of energy conservation measures (ECMs)
    - Unit based
    - System/Process based
    - Structure based
    - Institutional (including changes in energy regulations including required design specification language)
6. Conduct economic analysis
    - Capital, operating expenditures (including labor)
    - Life cycle costs [(Capex + Opex)/useful life expectancy]
    - Simple payback (Capex/annual savings)
    - Compound payback (Capex + Opex)/annual energy savings
    - Net present value
    - Internal rate of return
    - Annual energy savings, [e.g., Capex/kWh, and Capex/MT CO_2(e) avoided]
    - Triple bottom line assessment
7. Produce report detailing the energy roadmap with relations to operational modifications, process modifications, and capital improvement plan modifications

Benchmarking Energy Usage

Benchmarking of energy use at a wastewater treatment plant is a fundamental and essential tool in assessing energy usage and conservation opportunities. Energy benchmarking is used to estimate the energy consumption reduction potential and to provide a basis for identifying increases or decreases in energy efficiencies as new processes, technologies, and energy conservation measures are employed. Benchmarking the energy usage of a wastewater treatment plant involves the comparison of energy consumption to a so called "standard" wastewater treatment plant. Because the design flowrates, influent loadings, process steps, operational modes, and treatment technologies can all impact energy consumption and vary significantly from plant to plant, the energy consumption must first be normalized to allow a comparison between treatment plants with different characteristics. For example, two physically identical plants with the same flowrate, but different BOD loadings will have different benchmark results when based on flow but should have more similar results when based on BOD loading.

Table 17–5

Summary of common audit recommendations for energy savings at several U.S. wastewater treatment plants[a]

1. Install adjustable speed drives on pumps and blowers for variable flowrate operations
2. Install DO monitoring and control in aeration tanks
3. Conduct periodic pumps tests and repair or replace inefficient pumps
4. Operate emergency generators to reduce peak hour power demand
5. Install CHP when replacing emergency generators
6. Install electric load monitoring devices
7. Install capacitors to improve power factor
8. Operate less reactors during prolonged under-loading conditions
9. Change or reduce pumping operations
10. Reduce odor control/ventilation areas where possible
11. Install motion sensors for lighting in areas not occupied frequently
12. Control heating and cooling in areas that are not occupied all day
13. Replace oversized motors
14. Change selected operations to off-peak periods

[a] Adapted in part from Burton (1996).

Benchmarking Protocol

In the protocol published by AWWARF (2007) the parameters that appear to have the greatest impact on energy consumption were identified based on the analysis of data collected from 266 wastewater treatment plants throughout the United States. Using multi-linear log-regression, an empirical model was developed for benchmarking energy in wastewater treatment plants. This method is based on the multi-parameter benchmark score method used by U.S. EPA Energy Star rating for buildings (U.S. EPA, 2007) with minor modifications.

In the AWWARF protocol, six parameters were identified as key variables affecting the energy use, including (1) daily average flowrate, (2) design flowrate, (3) influent and (4) effluent BOD concentrations, (5) fixed versus suspended media, and (6) conventional treatment versus biological nutrient removal. Using multi-parameter log-regression analysis, the following wastewater treatment plant energy use model was developed:

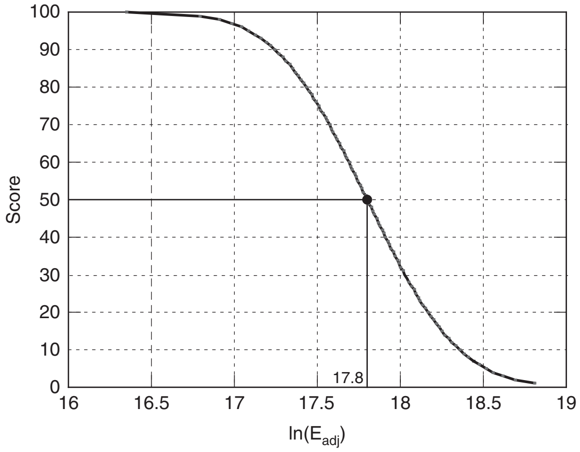
$$\begin{aligned}\ln(E_s) = {} & 15.8741 \\ & + 0.8944 \times \ln(\text{influent average Mgal/d}) \\ & + 0.4510 \times \ln(\text{influent BOD mg/L}) \\ & - 0.1943 \times \ln(\text{effluent BOD mg/L}) \\ & - 0.4280 \times \ln(\text{influent average flowrate / influent design flowrate} \times 100) \\ & - 0.3256 \times (\text{trickling filter? Yes-1, No-0}) \\ & + 0.1774 \times (\text{nutrient removal? Yes-1, No-0})\end{aligned} \tag{17–12}$$

where E_s = source energy use estimated from the model, kBtu/y (defined below)

Because the model was developed for treatment plants in the United States, the units used for the development of the model are U.S. customary units. An SI version is not available at the present time.

Figure 17–5

Benchmarking score plot for wastewater treatment plant energy use. (Adapted from AWWARF, 2007.)



Performance Rating. The value obtained from Eq. (17–12) is an estimate of the energy usage at a specific facility. To compare the estimated performance of the specific facility to other facilities, the ratio of the predicted performance to the average performance derived from the complete data set is used. The range of $\ln(E_s)$ values in the complete data set used to derive Eq. (17–12) ranges from approximately 16 to 19.6 with a mean value (50th percentile) of 17.8 (see Fig. 17–5). Thus the adjustment factor, F_{adj}, used to normalize the individual energy use factors is given as the following expression.

$$F_{adj} = \ln(E_s) / 17.8 \tag{17–13}$$

In effect the adjustment factor allows a utility to assess its benchmark score by its location on the distribution curve.

Conversion of Energy Usage Data to Source Energy Use. The source energy use is defined as the amount of raw fuel energy that is required to operate the facility (U.S. EPA, 2011). Whereas the energy usage data obtained at the wastewater treatment facility is the amount of energy measured at the point of use. The difference between the two values is due to the energy losses during production, transmission, and delivery. To allow for a consistent comparison, conversion factors (source energy factor, F_s) between the actual energy use and the source energy use were developed based at a national average, as presented in Table 17–6. It should be noted that the energy generated onsite from renewable energy sources such as the use of digester gas or solar power is not included in the source energy use calculation. The value

Table 17–6

Source energy factor used for the benchmarking of wastewater treatment plant energy usage[a]

	US customary units		SI units	
Energy Source	**Unit**	**Value**	**Unit**	**Value**
Electricity	kBtu/kWh	11.1	kBtu/kWh	11.1
Natural Gas	kBtu/therm	102.5	kBtu/MJ	0.97
Fuel Oil	kBtu/gal	141	kBtu/L	37.25
Propane	kBtu/gal	91	kBtu/L	24.04
Digester Gas	kBtu/ft^3	0.6	kBtu/m^3	21.2

[a] Adapted from AWWARF (2007).

for digester gas is included in Table 17–6 as a reference, and the use of the value is discussed in Example 17–5. Actual source energy use, E_{as}, is calculated as

$$E_{as} = \sum E_u \cdot F_s \tag{17–14}$$

where, E_{as} = Actual source energy use

E_u = Energy use measured at the point of use (= data from the treatment plant)

F_s = Source energy factor

The source energy factor will convert all energy use into the source energy use, and also convert the unit into kBtu/y, by which energy usage from various energy sources could be added to determine the total source energy use.

Calculation of Adjusted Energy Use. The adjustment factor is used to calculate the adjusted energy use factor, a normalized log-value of the energy use:

$$\ln(E_{adj}) = \ln(E_{as}) / F_{adj} \tag{17–15}$$

The adjusted energy use factors allow comparison between treatment facilities with different treatment levels and wastewater characteristics. The benchmark score can be obtained from Fig. 17–5, or the value for each score can be looked up from the AWWARF report (AWWARF, 2007). The score corresponds to the percentile in terms of normalized energy as compared to other studied plants. Benchmarking is illustrated in Example 17–5.

EXAMPLE 17–5 **Benchmarking of Energy Use at a Wastewater Treatment Plant** A BNR activated sludge process is used to treat the wastewater from a community. Based on the plant data given below, calculate the source energy usage and compare with the actual energy use to determine the benchmark score. How does the score changes if the use of energy generated onsite from digester gas was counted in the source energy use?

Item	Unit	Value
Energy use		
Electricity	kWh/y	14,100,000
Natural gas	m^3/y	17,300
Fuel oil #2	m^3/y	390
Digester gas production	m^3/y	1,047,900
Digester gas used	m^3/y	755,000
Digester gas flared	m^3/y	290,500
Digester gas vented	m^3/y	2400
Plant performance		
Annual average flowrate	m^3/d	100,000
Average influent BOD concentration	mg/L	180

(*continued*)

(*Continued*)

Item	Unit	Value
Average influent ammonium concentration	mg/L	18
Average influent total nitrogen concentration	mg/L	32
Average effluent BOD concentration	mg/L	4
Average effluent ammonium concentration	mg/L	1.5
Average effluent total nitrogen concentration	mg/L	8.3
Other required information		
Design flowrate	m^3/d	180,000
Population served	persons	430,000

Solution

1. Calculate the natural log of the source energy use value using Eq. (17–12) and the given data:

$$\begin{aligned}\ln(E_s\ \text{kBtu/y}) = {} & 15.8741 \\ & + 0.8944 \times \ln\{[100{,}000\ (\text{m}^3/\text{d})]/[3785\ (\text{m}^3/\text{Mgal})]\} \\ & + 0.4510 \times \ln(180) \\ & - 0.1943 \times \ln(4) \\ & - 0.4280 \times \ln(100{,}000/180{,}000 \times 100) \\ & - 0.3256 \times (0) \\ & + 0.1774 \times (1) \\ = {} & 15.8741 + 2.9284 + 2.3420 - 0.2694 - 1.7194 - 0 + 0.1774 \\ = {} & 19.33\end{aligned}$$

2. Calculate the adjustment factor from the value obtained in Step 1 using Eq. (17–13):

$$\text{Adjustment factor} = 19.33 / 17.8 = 1.086$$

3. Calculate the natural log of the source energy use value using the energy usage data from the wastewater treatment plant and source energy factor in Table 17–6.
   a. Calculate actual source energy use for the energy from outside sources (not including energy generated from digester gas) using Eq. (17–14).

$$\begin{aligned}E_{as}\ (\text{no digester gas}) = {} & (14{,}100{,}000\ \text{kWH/y})(11.1\ \text{kBtu/kWH}) \\ & + (17{,}300\ \text{m}^3/\text{y})(35.31\ \text{ft}^3/1\ \text{m}^3)(1.025\ \text{kBtu/ft}^3) \\ & + (390\ \text{m}^3/\text{y})(264.2\ \text{gal}/1\ \text{m}^3)(141\ \text{kBtu/gal}) \\ = {} & 156{,}510{,}000 + 626{,}135 + 14{,}528{,}358 \\ = {} & 171{,}664{,}493\ \text{kBtu/y}\end{aligned}$$

   b. Calculate source energy use for the energy including the energy generated onsite from digester gas.

$$\begin{aligned}\text{Digester gas energy} &= (755{,}000\ \text{m}^3/\text{y})(35.31\ \text{ft}^3/1\ \text{m}^3)(0.6\ \text{kBtu/ft}^3) \\ &= 15{,}995{,}430\ \text{kBtu/y}\end{aligned}$$

$$\begin{aligned}E_{as}\ (\text{with energy from digester gas}) &= 171{,}664{,}493\ \text{kBtu/y} + 15{,}995{,}430\ \text{kBtu/y} \\ &= 187{,}659{,}923\ \text{kBtu/y}\end{aligned}$$

4. Convert the source energy usage calculated in Step 3 to the natural log of the adjusted energy use using the adjustment factor from Step 2 and Eq. (17–15).
    a. Calculate $\ln(E_{adj})$ not including energy generated from digester gas.

$$\ln(E_{adj}) = \ln(171{,}664{,}493 \text{ kBtu/y}) / 1.086 = 18.96 / 1.086$$
$$= 17.46$$

    b. Calculate $\ln(E_{adj})$ including energy generated from digester gas.

$$\ln(E_{adj}) = \ln(187{,}659{,}923 \text{ kBtu/y}) / 1.086 = 19.05 / 1.086$$
$$= 17.54$$

5. Using Fig. 17–5, find the benchmark score with and without digester gas usage.

Score without counting the use of energy generated from digester gas = 78

Score counting the use of energy generated from digester gas = 72

Comment In this example, the treatment plant's normalized percentile score for energy usage, without including the use of energy generated from digester gas as specified in the protocol, is 78, or slightly better than the average of the treatment facilities used for the development of the model. Including the use of energy generated onsite from digester gas will lower the benchmark score to 72. In other words, if this treatment plant was generating digester gas but not utilizing it (i.e., flaring it) and depending solely on energy from outside sources, this plant would have scored 72 on benchmarking. Therefore the use of energy generated onsite from digester gas will significantly improve the benchmark score.

17–6 RECOVERY AND UTILIZATION OF CHEMICAL ENERGY

Recovery and utilization of chemical energy involves transformation of wastewater constituents containing chemical energy into fuel, and the use of the fuel for beneficial purposes. In some cases, pretreatment of the fuel is necessary before it is used. Recovery of chemical energy has been practiced at wastewater treatment facilities primarily by producing digester gas (biogas) from sludges with anaerobic sludge digestion, and digester gas has been used widely for boilers and other combustion systems to supplement other energy sources. Dried biosolids have also been used as an energy source where sludge incineration is practiced.

Fuels Derived from Wastewater

The types of fuels derived from wastewater constituents can be categorized as (1) gaseous fuels, (2) solids, and (3) liquids/oils. The gaseous fuels include biogas from anaerobic digestion and syngas from gasification. The solids include primary sludge, waste secondary sludge, and stabilized biosolids. Liquid fuels and oils could be produced from the solid contents of wastewater, but the generation and utilization of liquid fuels and oils derived from wastewater constituents is not common.

Generally, chemical energy in wastewater is extracted from the solid contents, and by means of a physical/chemical process or a biological treatment process. In anaerobic treatment processes (see Chap. 10), some dissolved organics are converted biologically to methane, but the use of anaerobic treatment processes for liquid treatment in municipal wastewater has been uncommon. In conventional municipal wastewater treatment facilities with aerobic biological treatment, only a fraction of the dissolved chemical energy is assimilated into biomass which is subsequently collected for the solids processing and converted into biogas through anaerobic digestion.

Biogas. The method used most commonly to recover energy from the solid contents of wastewater is to produce methane through anaerobic digestion (see Chap. 13). Typical production of digester gas through an anaerobic biological process varies between 0.75 and 1.12 m^3/kg volatile solids destroyed (12 to 18 ft^3/lb VSS). Typically, digester gas contains 55 to 70 percent methane, 30 to 40 percent CO_2, and small amounts of N_2, H_2, H_2S, water vapor, and other gases. The energy content of digester gas is typically in the range of 22 to 24 MJ/m^3 (600 to 650 Btu/ft^3) in HHV. The methane gas content depends primarily on the pH of the digester as it affects the amount of CO_2 that is released to the gas phase. The theoretical biogas production reaction, as described in Chap. 10, is

$$\begin{aligned} &C_vH_wO_xN_yS_z + \left(v - \frac{w}{4} - \frac{x}{2} + \frac{3y}{4} + \frac{z}{2}\right)H_2O \rightarrow \\ &\quad \left(\frac{v}{2} + \frac{w}{8} - \frac{x}{4} - \frac{3y}{8} - \frac{z}{4}\right)CH_4 + \left(\frac{v}{2} - \frac{w}{8} + \frac{x}{4} + \frac{3y}{8} + \frac{z}{4}\right)CO_2 + yNH_3 + zH_2S \end{aligned} \tag{10–4}$$

As shown in Eq. (10–4), ammonia and hydrogen sulfide are produced, and other volatile compounds are also produced during anaerobic digestion. Because some of the compounds could be detrimental to the combustion system, gas cleaning may be required before collected biogas is used for the combustion system. The cleaned biogas can also be used to generate electricity using a reciprocating engine, gas turbine, microturbine, or fuel cell. The use of biogas for boilers typically does not require gas cleaning. The biogas conveyance and storage system must be kept in a positive pressure to prevent accidental mixing of biogas with air, which could result in explosion.

Syngas. Syngas is a mixture of gases comprised mainly of CO, H_2, CO_2, and CH_4 generated through a gasification process (see Chap. 14) and has a lower heating value (LHV) ranging between 4 and 15 MJ/m^3 with a typical range in the wastewater application between 4.5 and 5.5 MJ/m^3 (120–150 BTU/ft^3). Energy content of syngas varies widely and depends on the gasification process technology and its operating conditions such as amount of air and moisture injected to the gasification process. The unit processes to produce syngas are described in Sec. 14–9 in Chap. 14.

Syngas can be oxidized immediately, or cleaned and used for internal combustion systems in a two stage system. Cleaned syngas could be processed further using a catalytic Fisher-Tropsch (FT) process to a liquid fuel, which can be used in an internal combustion engine-generator, boiler, or fuel cell. Liquid fuel can also be used for the production of various chemicals (Valkenburg et al., 2008). Limited information is available regarding the production rate of syngas, as it varies widely with the gasification process, characteristics of the feed solids, and the operating conditions used. In a full-scale installation of fluidized bed gasification process in Balingen, Germany, 1000 kg of dewatered sludge with 32 percent dry solid content was dried to produce 400 kg of dried sludge with 80 percent solids content, which generated to 510 m^3 of syngas and 160 kg of mineral granule (WERF, 2008).

Solid Fuels. Solid contents in wastewater are largely organic compounds. Depending on the water content of the sludges or biosolids separated from wastewater they can be incinerated without additional fuels. Typical heating values of sludges and biosolids are reported in Table 14–17 in Chap. 14, and theoretical values could be derived from Eq. (2–66) if the chemical composition is known (see Sec. 17–2).

Liquid Fuel and Oils. Technologies are available to produce liquid fuel and oils from the solid constituents present in wastewater. For example, syngas could be converted into a liquid fuel through the Fisher-Tropsch (FT) process, and char and oil are generated from pyrolysis of solid contents. However the production of oil and liquid fuel from wastewater solid contents has not been implemented in full-scale.

Energy Recovery from Gaseous Fuels with Engines and Turbines

Reciprocating engines, gas turbines, and microturbines are the principal technologies used to generate electricity from the combustion of gaseous fuels derived from wastewater. Even though it is practiced less commonly, pumps and blowers can be operated with a direct drive from the engines fueled by gaseous fuels. Typical energy recovery systems with engines and turbines include, as illustrated on Fig. 17–6, a gas generation process, gas holding vessel, compressors, gas cleaning, an engine/turbine, emission control (see Chap. 16), and a waste heat recovery system. Fuel cells are also used to generate electricity from biogas but by a different mechanism. Thus fuel cells are considered separately in this section.

Exhaust heat from these combustion processes can be used to heat water for building heating, heat anaerobic digesters, or to provide hot water supply, as discussed further in Sec. 17–6. It should be noted that the use of biogas in boilers and engines will result in the emission of flue gas, which may be subject to strict regulations to minimize air pollution. Emissions from boilers and engines are considered in Sec. 16–5 in Chap. 16.

Figure 17–6

(a)

(b) (c) (d)

Gas Pretreatment Requirements. Constituents in biogas and syngas that affect the operation of equipment to generate power and heat include hydrogen sulfide (H_2S), siloxanes, carbon dioxide (CO_2), and moisture (H_2O). Syngas also contains particulate matters that may need to be removed. Hydrogen sulfide (H_2S) is an odorous gas and highly corrosive. At relatively low concentrations H_2S is hazardous to human health. The immediately dangerous to life or health (IDLH) value used by the National Institute for Occupational Safety and Health (NIOSH) for H_2S is 100 ppm (CDC, 1994). An H_2S value of 100 ppm is often exceeded in biogas generated from anaerobic digestion. Siloxanes are known to cause detrimental impacts to the combustion systems. Water condensation occurs in the biogas transfer pipelines and a compressor, and enhances corrosion by hydrogen sulfide. To minimize these adverse impacts, digester gas is often cleaned before combustion. Carbon dioxide may be removed only when biogas is to be sold as natural gas (sometimes referred to as bio-methane), thus CO_2 removal is rarely practiced at a wastewater treatment facility unless there is an incentive to sell bio-methane instead of using the biogas within the facility. When biogas is mixed with natural gas at a treatment facility, it is common to mix natural gas with air to reduce the heat content to the level of biogas, instead of removing CO_2 from the biogas to raise the biogas heat content to that of natural gas. Because the air added to the natural gas is not sufficient to cause explosion, the removal of oxygen is not required for the natural gas/air mixing process.

Typical treatment systems for biogas and syngas are shown on Fig. 17–7. The types of gas cleaning technologies used for digester gas and syngas are reported in Table 17–7. Description of each gaseous compound and its treatment is described in detail in Sec. 13–9 in Chap. 13. In many cases, not all of these gas cleaning processes are necessary, and the cleaning requirements are determined according to the gas quality requirements for the end use.

Total System Efficiency. The total system efficiency, also known as thermal efficiency, is defined as the ratio of the total energy output, either work, heat, or electricity, to the total energy input. For an engine generator without heat recovery, total system efficiency is the electrical power output per fuel energy input. In a CHP system, the total system efficiency is a sum of the power output and useful net thermal output per total fuel input through a downstream heat recovery process per energy input by a fuel. Typical thermal efficiencies of internal combustion engines and fuel cell are presented in Table 17–8. As reported in Table 17–8, the overall thermal efficiency is improved significantly by employing CHP. Recovery of waste heat is further discussed in Sec. 17–6. Equipment suppliers should be consulted to obtain expected thermal efficiency for specific equipment, but thermal efficiency data in Table 17–8 may be useful for making preliminary estimates on the energy output based on the fuel consumption when accurate data on energy output

Figure 17–7

Typical gas cleaning process flow diagrams: (a) for biogas from anaerobic digestion and (b) syngas from gasification.

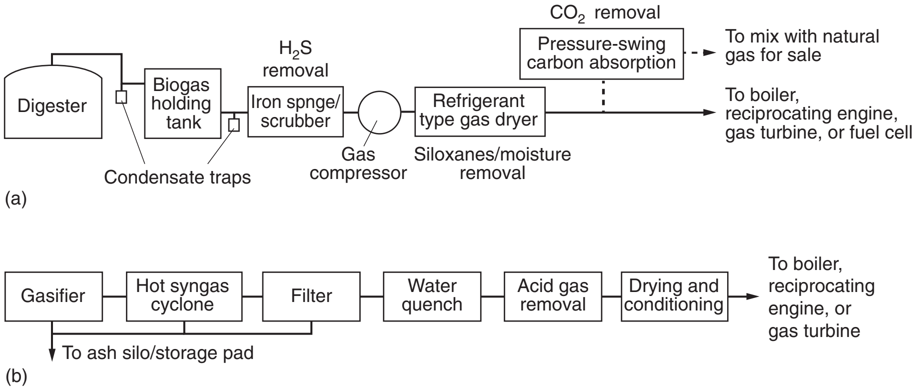

Table 17–7

Major contaminants in digester gas, and treatment method for their removal[a]

Gaseous compound	Typical concentration in digester gas, mg/L[b]	Treatment methods
Hydrogen sulfide (H_2S)	1000–2000	Adsorption Scrubber Chemical addition to digester
Siloxanes (in silica)	0.3–11	Refrigeration/drying Scrubber Adsorption (activated carbon, proprietary media)
Water vapor (H_2O)	Saturation	Solid desicants Liquid absorption Refrigeration/drying
Carbon dioxide (CO_2)	30 to 35%	Scrubber. CO_2 is removed only for the application to produce natural gas quality gaseous fuel and the application has been limited

[a] Compiled from various sources.

[b] Unless otherwise noted.

are not available. When digester gas is used for engines and boilers, the actual heat content of digester gas should be measured to accurately project the expected energy output.

Reciprocating Engine Generators. Reciprocating engines and gas turbines are used widely to produce electricity on site at wastewater treatment facilities using recovered chemical energy in the form of digester gas [see Figs. 17–8(a) and (c)]. Both spark ignition engines (Otto-cycle engines) and compression ignition engines (diesel-cycle engines) have been used with biogas. When compression ignition engines are used, a supplemental fuel oil will be added to induce the ignition. The typical size of the reciprocating engines ranges between 20 kW and 6 MW (see Table 17–8).

Gas Turbines. Gas turbines used at wastewater treatment facilities have a wind range of capacity [see Fig. 17–8(d)], in the range of 1 to 250 MW. Their electrical efficiency is slightly lower than reciprocating engines, varying from 30 and 40 percent. As shown in Table 17–8, overall thermal efficiency can be in the same range with reciprocating engines when it is used for CHP because exhaust gas from gas turbines has a higher temperature and can be used for boilers and a wide range of heat recovery processes. However, reciprocating engines have been used more commonly at wastewater treatment facilities because the reciprocating engines generally have a wider operational range than the gas turbines and the energy output could be adjusted more easily in response to the diurnal energy demand variations.

Microturbines. A microturbine is a smaller gas turbine, often packaged by the burbine suppliers. The typical size of microturbines used at wastewater treatment facilities range from 30 to 250 kW. In the typical microturbines, a recuperation cycle is used to utilize the heat in the exhaust gas to preheat the combustion gas. Remaining heat is recovered to produce hot water or connected to other thermal energy recovery devices. Microturbines are suited for distributed generation applications to supplement a specific electrical load, or to be used in parallel to serve large loads.

Table 17–8

Devices used to recover energy from digester gas and syngas

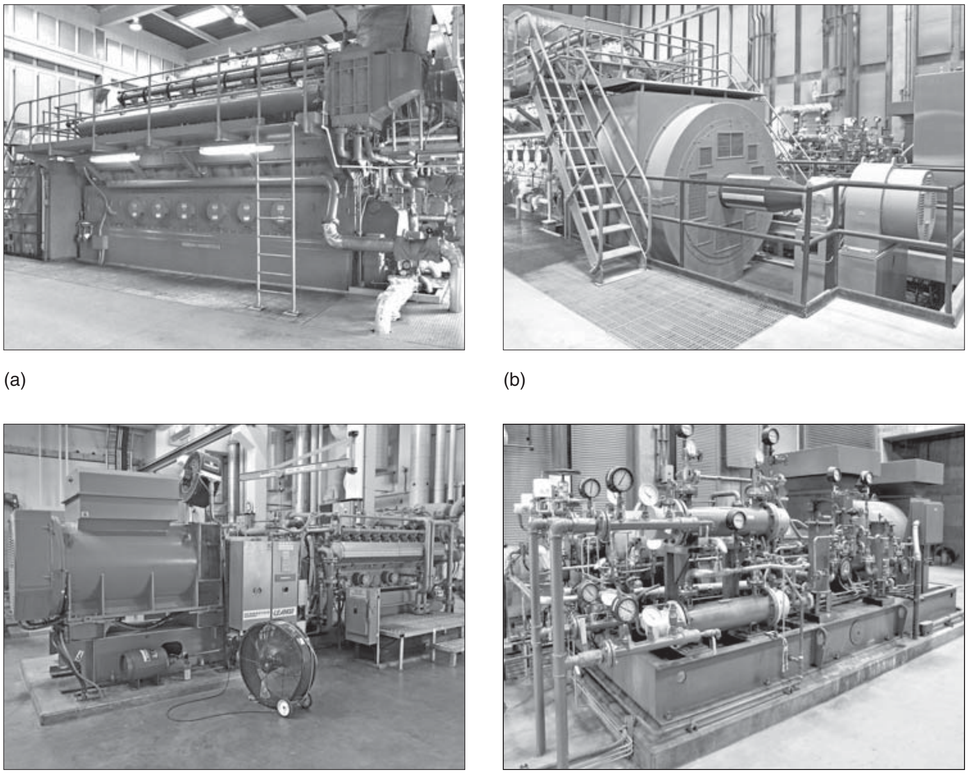
Device	Typical efficiency[a], %	Typical efficiency with CHP, %	Gas cleaning requirements	Typical size, kW	Conversion of energy
Reciprocating engine	25–50	70–80	siloxiane	20–6000	electricity, mechanical power, waste heat
Gas turbine (simple cycle)	25–40	70–80	siloxiane, H_2S	1000–250,000	electricity, mechanical power, waste heat
Gas turbine (combined cycle)	40–60	70–80	siloxiane, H_2S	1000–250,000	electricity, mechanical power, residual heat to produce steam for more electricity generation
Micro-turbine	25–35	70–85	siloxiane, H_2S	30–250	electricity, mechanical power, waste heat
Sterling engine	~30	~80	no cleaning required		electricity, mechanical power, waste heat
Fuel cell	40–60	70–85	siloxiane, H_2S, H_2O	200–3000	electricity, waste heat
Boiler	80–90+	-	typically no cleaning required		steam, hot water

[a] Efficiencies based on the manufacturers' rating for a new system, not including heat recovery.

Sterling Engine. Sterling engine is an external combustion engine and a wide variety of fuels can be used without the level of gas cleaning required for internal combustion engines. Electrical efficiency is approximately 30 percent, and a total system efficiency can be up to 80 percent when heat recovery is included.

Energy Recovery from Gaseous Fuels with Boilers

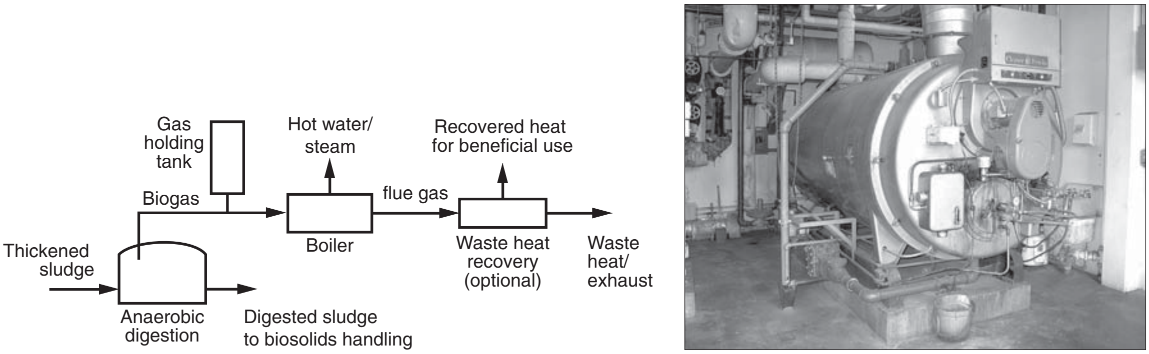
Boilers are used at wastewater treatment facilities to generate hot water or steam for steam turbines, space heating, and hot water supply. Heating requirements for wastewater treatment processes include heating of anaerobic digester and building heating and various solids handling processes such as sludge pretreatment and sludge drying (see Chaps. 13 and 14). Boilers are used also for heating of administration and control building, as well as hot water supply. Typically gas pretreatment is not included when biogas or syngas is used only for the boilers, and it is designed to maximize the thermal efficiency of the boiler, even though further recovery of heat from the waste heat is possible (see Fig. 17–9).



(a) (b) (c) (d)

Figure 17–8

Typical devices utilizing biogas generated at wastewater treatment facilities: (a) view of large reciprocating dual fuel engine, (b) generator connected to engine shown on (a), (c) view of alternative dual fuel engine, and (d) view of gas turbine generator.



(a) (b)

Figure 17–9

Energy recovery system utilizing biogas in a dual-fuel boiler: (a) process flow diagram and (b) view of boiler.

Types of Boilers. The typical boilers used commonly at wastewater treatment facilities are hot water boilers to provide building heating, heating for treatment processes, and hot water supply. The boilers producing steam are also used especially when a high temperature heat source is necessary for sludges and biosolids processing, such as thermal hydrolysis. Boilers can generally be categorized as fire tube type and water tube type. In fire tube boilers, hot gases flow through the tubes to heat water that surrounds the tubes to generate hot water and steam. Fire tube boilers are suited for smaller, low pressure (less than 17 bar or 250 $lb_f/in.^2$) steam generation. In water tube boilers, water runs through the tubes which are placed in a combustion chamber, filled with hot combustion gases. Water in the tube is heated and produces steam in the steam drum. Water tube boilers are suited for producing higher (higher than 17 bar or 250 $lb_f/in.^2$) pressure steam.

Thermal Efficiency of Boilers. Selection of the type and size of boilers depends on the amount and quality of heat to be delivered and the types of fuel to be used. Either dual-fuel or gas boilers could be used with biogas. It should be noted that sometimes the term "thermal efficiency" is used specifically for the efficiency of the heat exchanger but does not count radiation and convection losses. The term "boiler efficiency" may be used instead for the thermal efficiency to account for the radiation and convection losses. Typically, the thermal efficiency of boilers is higher than 80 percent based on the manufacturers' specifications, and it is affected by the flue gas temperature, fuel type, amount of excess air, ambient temperature, and heat losses. Condensing boilers are the type of boilers equipped with preheating of the cold feed water. By preheating the feed water, overall efficiency can be improved to greater than 90 percent (see Table 17–8). Build up of soot or scaling in boilers will result in reduced thermal efficiency. Periodic cleaning and maintenance are necessary to maintain the thermal efficiency of boilers.

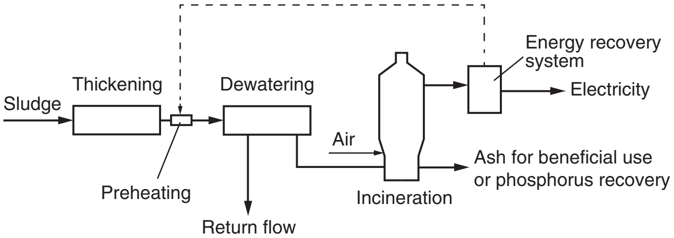
Energy Recovery from Solid Fuels

Thermal oxidation (i.e., incineration) of solid contents is a process typically used by medium- to large-size plants with limited disposal or reuse options (Chap. 14). To maximize the energy recovery from thermal oxidation, the solid contents are used directly without a solid stabilization process even though incineration of stabilized biosolids is also practiced. The energy recovery system from solid fuels typically includes sludge/biosolids thickening, dewatering, drying, thermal oxidation, and energy recovery system. Part of the heat from the incineration is used to preheat the incoming sludge and air (see Fig. 17–10). The flue gas contains particulate matters and other pollutants, and appropriate emission control must be placed to meet the air emission requirements.

The two most important parameters to determine energy balance are dewatered cake solids content and volatile solid content. Typically the dewatered solids content must be greater than 22–28 percent solids to balance energy release and evaporative cooling. Solids content is also an important operating parameter as it controls the combustion temperature. Higher temperature will result in the emission of nitrogen oxides and formation of amalgam from the ash, whereas lower temperature will result in an incomplete combustion and increased emission of particulate matters (see Sec. 16–5 in Chap. 16). The overall heat balance can vary based on the solids calorific value and overall efficiencies of the drying, gasification, and energy recovery systems. Undigested sludges typically have a higher volatile content so supplemental fuel use can be eliminated at a lower solids content. Anaerobically digested biosolids contain lower calorific values per unit dry material as some of the volatile material is consumed and converted to biogas. Digested sludge with chemical addition within the treatment system generally contains lower calorific value

Figure 17–10

Typical process flow diagram for the recovery of chemical energy by combustion of sludges and biosolids.



than digested sludge without chemical precipitation (Barber, 2007). Because the calorific value of digested biosolids is lower, a higher dewatered solid content is required to achieve an energy neutral drying and gasification process.

Combustion of Sludge and Biosolids. Combustion of solid and semi-solid sludge and biosolids has been implemented in some parts of world where land application and/or landfill disposal is not economical. The main types of combustors used for biosolids combustion include multiple hearth, fluidized bed, and electric infrared. Devices used to recover energy from wastewater solids are summarized in Table 17–9.

Combustion Stoichiometry. The stoichiometric expression for the complete combustion of sludges and biosolids, discussed in Sec. 14–4 in Chap. 14 and repeated here for convenience, is:

$$C_aO_bH_cN_d + (a + 0.25c - 0.5b)O_2 \rightarrow aCO_2 + 0.5cH_2O + 0.5dN_2 \tag{14–3}$$

If it is assumed that dry air contains 23.15 percent of oxygen by weight, the amount of air required for complete oxidation is approximately 4.3 times the calculated amount of required oxygen. In addition, excess air is required to induce near sufficient turbulence and mixing in the combustion chamber. For the incineration of dried sludges and biosolids, typically about 50 percent of excess air is required. Excess air will also affect the combustion temperature, and the air to fuel ratio must be controlled to maximize the efficiency of combustion and minimize the emission of pollutants such as nitrogen oxides, carbon monoxide, volatile organic compounds and other potentially hazardous compounds (see Chaps. 14 and 16).

Table 17–9

Devices used to recover energy from wastewater solid contents[a]

Device	Output[a]	Remarks
Fluidized bed incinerator	Waste heat	• Used widely for dewatered sludge incineration • Typical feed solids content 20 to 35 percent
Multiple heath incinerator	Waste heat	• Used widely for dewatered sludge incineration • Typical feed solids content 20 to 35 percent
Fluidized bed gasifier	Syngas, waste heat	• Uniform product • Require high solids content (>85 percent) • Operating temperature 700 to 900°C
Fixed bed updraft gasifier	Syngas, waste heat	• Relatively low solids content is acceptable (70 to 80 percent) • Relatively high tar content in syngas • Operating temperature ~1000°C
Fixed bed downdraft gasifier	Syngas, waste heat	• Require high solids content (>80 percent) • Relatively low tar content in syngas • Operating temperature 900 to 1000°C • Unconverted carbon 4 to 7 percent
Entrained flow gasifier	Syngas, waste heat	• Relatively low solids content is acceptable • Low tar and CO_2 • Low CH_4

[a] Adapted in part from DOE (2002) and McKendry (2002).

[b] Depending on the heat balance, waste heat could be used to operate turbine to generate electricity and steam or hot water.

Heat Released from Combustion. Part of the heat released from the combustion of solid materials is stored in the combustion product to raise the temperature of the material, and partly transferred by convection, conduction, and radiation to the wall of the combustion system. Depending on the dewatering and drying process, sludges and biosolids may contain a significant amount of water which will be vaporized in the combustion chamber, taking up latent heat of evaporation. As discussed in Chap. 14, the heat required to maintain the combustion system at the final temperature is expressed as:

$$Q = \sum(Q_S) + Q_e + Q_L = \sum C_P W_S(T_2 - T_1) + W_W\lambda + Q_L \qquad (14\text{–}4)$$

where Q = total heat, kJ (Btu)
Q_s = sensible heat in the ash, kJ (Btu)
Q_e = latent heat, kJ (Btu)
Q_L = heat loss
C_p = specific heat for each category of substance in ash and flue gases, kJ/kg·°C (Btu/lb·°F)
W_s = mass of each substance, kg (lb)
T_1, T_2 = initial and final temperatures
W_w = mass of water, kg (lb)
λ = latent heat of evaporation, kJ/kg (Btu/lb)

By comparing the required heat and heat content in the combusted material as calculated by Eq. (2–66), additional energy requirement, or the excess heat that could be recovered and utilized, can be calculated. In Example 17–6, a heat balance for combustion of biosolids is presented.

EXAMPLE 17–6 **Computation of Heat Balance for Combustion of Biosolids** Dewatered biosolids with the following characteristics is to be combusted in an incinerator. Using the information, given below, on the operating conditions for the incinerator and related process data, determine the air requirement and develop a heat balance. Determine heat content of the flue gas after it was used to preheat the inlet air. For simplicity, assume all combustible materials listed below are oxidized to CO_2, H_2O, N_2 and SO_2, and ignore SO_2 in heat balance calculations.

Biosolids composition and elemental analysis

Element	Percent of total weight
Combustible	
Carbon	14.2
Hydrogen	1.0
Oxygen	5.2
Nitrogen	0.3
Sulfur	0.4
Inerts	8.9
Water	70
Total	100

Operating conditions

Item	Unit	Value
Ambient air temperature	°C	20
Relative humidity at 20°C	%	50
Target combustion temperature	°C	850
Heat loss	% of gross heat input	0.5

Thermodynamic properties

Component	Unit	Value
Specific heat of water	kJ/kg·°C	4.19
Specific heat of biosolids	kJ/kg·°C	1.26
Specific heat of dry air	kJ/kg·°C	1.01
Specific heat of water vapor	kJ/kg·°C	1.88
Specific heat of the ash	kJ/kg·°C	1.05
Latent heat of water evaporation	kJ/kg	2257

Air composition at 20°C and 50 percent humidity

Gas	Percent
N_2	77.1
O_2	20.7
CO_2	0.04
H_2O	1.17
Other gas (ignore in calculations)	1.00

Enthalpy of ideal gas, kJ/mole

	20°C	850°C
N_2	8.53	34.2
O_2	8.54	35.7
CO_2	9.18	49.6
H_2O	9.74	41.1

Solution

1. Estimate the air requirement.
   a. Estimate the stoichiometric requirement to completely oxidize the sludge, assuming CO_2, H_2O, N_2, and SO_2 are the only combustion products. Set up a computation table to determine the moles of oxygen and kg of air required per kg of biosolids.

Component	Weight fraction	Atomic weight, kg/mole	Atomic weight units[a], mole/kg	O_2 required[b], mole	Combustion reaction and products	Product gas formed, mole/kg
Carbon	0.142	0.012	11.83	11.83	$C + O_2 \rightarrow CO_2$	11.83
Hydrogen	0.010	0.001	10.00	2.50	$4H + O_2 \rightarrow 2H_2O$	5.0
Oxygen	0.052	0.016	3.25	−1.63	$2O \rightarrow O_2$	0
Nitrogen	0.003	0.014	0.214	–	$2N \rightarrow N_2$	0.11
Sulfur	0.004	0.0321	0.125	0.062	$S + O_2 \rightarrow SO_2$	0.12
Water	0.70	0.018			H_2O (vapor)	38.9
Inerts	0.086					
Total	1.00			12.83		56.0

[a] Atomic weight unit = weight fraction/atomic weight.

[b] Moles required = atomic weight unit × mole of O_2 required per atom being oxidized based on the combustion reaction. For oxygen, O_2 saved due to oxygen in the biosolids is recorded, indicated with a negative sign.

From the calculations above, 1 kg of biosolids will require 12.8 moles of O_2. Oxygen content in the air = 20.7 percent by volume at 20ºC and 50 percent humidity, and assuming mole fraction = volume fraction, moles of air required is:

Air required = 12.8/0.207 = 62.0 mole air/kg biosolids

b. Determine the amount of gas generated from combustion of 1 kg biosolids.
For CO_2, 1 mole C is converted to 1 mole CO_2. From the summary above, CO_2 formed is 11.8 mole/kg biosolids (assuming complete combustion). Similarly, H_2O from hydrogen, N_2 from nitrogen, and SO_2 from sulfur are calculated and summarized in the table. Note that the water content in biosolids (70 percent) also becomes water vapor.

2. Develop a heat balance for various quantities of excess air for a unit mass of biosolids. Consider 0, 50, and 100 percent excess air and prepare a computation table to summarize the results. Ignore SO_2 for the rest of the calculations.

a. Determine air flows.
From Step 1, stoichiometric air requirement is 62.0 mole/kg biosolids
For 50 percent excess air: 62.0 × 1.5 = 93.0 mole/kg biosolids

b. Determine heat content of added air.
From air composition and enthalpy data given in the problem statement, heat content of added air at 20ºC without excess air is

$$H = [(8.53 \times 0.771 + 8.54 \times 0.207 + 9.18 \times 0.0004 + 9.74 \times 0.0117 \text{ (kJ/mole)}] \times 62.0$$
$$\text{mole air/kg biosolids} = 524 \text{ kJ/kg biosolids} = 0.524 \text{ MJ/kg biosolids}$$

Heat content with 50 and 100 percent excess air is calculated as summarized in the computation table.

c. Determine the heat content in biosolids at 20ºC.
Solid content of biosolids is 30 percent and specific heat of dry biosolids is given in the problem statement. Thus heat content is 0.30 × 1.26 × 20 = 7.56 kJ/kg biosolids. Water content of biosolids is 70 percent. Thus, the heat content is 0.70 × 4.19 × 20 = 58.7 kJ/kg biosolids. Total heat content is 7.6 + 58.7 = 66.3 kJ/kg biosolids = 0.066 MJ/kg biosolids.

d. Determine the flue gas composition for 0, 50, and 100 percent excess air flows and calculate heat content at 850ºC. Calculations for 0 percent excess air flow is shown as an example.

   i. Determine gas composition.

      N_2: (N_2 from N in biosolids) + (N_2 in the air) = 0.11 (mole/kg biosolids) + 62.0 (mole air/kg biosolids) × 0.771 = 47.9 mole/kg biosolids

      O_2: With no excess air, all oxygen in the air is used. For 1 kg of biosolids, 12.8 moles of oxygen is used

      CO_2: 11.8 (mole/kg biosolids) + 62.0 (mole air/kg biosolids) × 0.0004 = 11.9 mole/kg-biosolids

      H_2O: [5.00 + 38.9 (mole/kg biosolids)] + 62.0 (mole air/kg biosolids) × 0.011 = 44.6 (mole/kg biosolids)

      Similarly, the flue gas composition with excess air is calculated and the results are summarized in the table.

   ii. Calculate the heat content using the data given in the problem statement.

      N_2: 47.9 × 34.2 = 1638 kJ/kg biosolids

      O_2: 0 × 35.7 = 0 kJ/kg biosolids

      CO_2: 11.9 × 49.6 = 587 kJ/kg biosolids

      H_2O: 44.6 × 41.1 = 1832 kJ/kg biosolids

      Total = 1638 + 0 + 587 + 1832 = 4057 kJ/kg biosolids = 4.057 MJ/kg biosolids

e. Calculate the heat content remaining in the ash.

   Assuming complete combustion, ash = inert. Heat content is
   0.089 × 1.05 × 850 = 79.4 kJ/kg biosolids = 0.079 MJ/kg biosolids

f. Estimate the heat released from combustion of biosolids, assuming complete combustion.

   Using Eq. (2–66) and elemental analysis data given in the problem statement, estimate the heat contents of the solids:

   $$\text{HHV (MJ/kg)} = 34.91\text{ C} + 117.83\text{ H} - 10.34\text{ O} - 1.51\text{ N} + 10.05\text{ S} - 2.11\text{A}$$

   $$\begin{aligned}\text{HHV (MJ/kg)} &= 34.91 \times 0.142 + 117.83 \times 0.010 - 10.34 \times 0.052\\ &\quad -1.51 \times 0.003 + 10.05 \times 0.004 - 2.11 \times 0.089\\ &= 5.446\text{ MJ/kg-biosolids)}\end{aligned}$$

g. Estimate evaporative cooling from the vaporization of water in biosolids and water formed by combustion of biosolids.

   From 1 kg of biosolids, 43.9 moles of water are formed. Latent heat of vaporization is 2257 kJ/kg. Therefore, latent heat of vaporization associated with every kg of biosolids is

   $$[(43.9 \times 18)/1000] \times 2257 = 1783\text{ kJ/kg-biosolids} = 1.783\text{ MJ/kg-biosolids.}$$

h. Estimate the heat loss. Assume 0.5 percent of gross heat input.

   Gross heat input = (heat of biosolids) + (heat of inlet air) + (heat of combustion) − (heat loss from evaporation). Note that latent heat of vaporization should be subtracted from the gross heat input as the heat of combustion calculated in Step f above is HHV.

   Gross heat loss = (0.524 + 0.066 + 5.446 − 1.783) × 0.005 = 0.021 MJ/kg-biosolids

3. Evaluate the heat balance to determine the air flow to maintain the operating temperature at 850ºC.

From the summary table below, energy balance is barely positive with stoichiometric air flow, and the balance is negative with excess air flow. If the heat balance is linear to the air flow, heat balance is exactly zero at 4.3 percent excess air.

	Unit[a]	Stoichiometric air flow	With 50% excess air	With 100% excess air
Air added	mole/kg biosolids	60.3	90.4	120.5
Flue gas composition				
N_2	mole/kg biosolids	46.6	69.8	93.0
O_2	mole/kg biosolids	0	6.2	12.5
CO_2	mole/kg biosolids	11.4	11.5	11.5
H_2O	mole/kg biosolids	45.1	45.5	45.9
Heat content of added air at 20°C	MJ/kg biosolids	0.524	0.786	1.05
Heat content of biosolids at 20°C	MJ/kg biosolids	0.066	0.066	0.066
Flue gas heat content at 850°C	MJ/kg biosolids	4.057	5.119	6.180
Ash heat content at 850°C	MJ/kg biosolids	0.079	0.079	0.079
Energy released from combustion	MJ/kg biosolids	5.446	5.446	5.446
Heat loss by evaporation of water	MJ/kg biosolids	1.783	1.783	1.783
System heat loss	MJ/kg biosolids	0.021	0.023	0.024
Net energy balance		0.095	−0.7	−1.5

[a] Units are per kg biosolids on a wet basis.

Note: Because values were calculated on a spreadsheet and rounded, some values may not match exactly with manual calculations.

4. Determine the water content that will allow self-sustained combustion. From Step 3, the heat generated by combustion of chemical contents in the biosolids is barely sufficient to maintain the heat balance. Therefore in this example, 30 percent solids, 70 percent water content was the limit to sustain combustion. At water content of 71 percent, the heat balance is −0.12 MJ/kg biosolids. It is important to note that at stoichiometric air flow, the heat content in the flue gas is approximately 4.1 MJ/kg biosolids. The heat in the flue gas could be used to preheat biosolids and inlet air or to generate electricity and/or hot water.

Comment The dewatered sludge solid content assumed in this example is on the higher end of the typical water content with conventional centrifuge. Even though the calculations used in this example may not be completely representative of the actual combustion system as ideal conditions were assumed, they are helpful in illustrating how to conduct a preliminary assessment of the dewatering/drying requirements and operational conditions such as excess air requirement and operating temperature. In biosolids incineration facilities, inlet air is often preheated with flue gas to save the use of supplemental fuel. In a typical incineration facility, a solid content of 26 to 28 percent is considered the threshold needed to sustain combustion without supplemental fuel, but no significant excess energy will be available for other purposes. During the plant start up, supplemental fuel must be used to raise the temperature of the reactor.

Energy Recovery from Syngas

There are two approaches to utilize energy from syngas. One is to clean the syngas and use it for conventional boilers and engine generators, often referred to as two-stage gasification. The other approach is to use the syngas directly in the thermal oxidation chamber, referred to as close-coupled gasification.

Two Stage Gasification. In two stage gasification systems, as depicted on Fig. 17–11(a), the syngas produced from gasifying the dried biosolids is cleaned and the cleaned syngas can be used as a fuel source for an internal combustion engine. Cleaning the syngas is required to remove sulfur, siloxanes, and other contaminants such as tar that could damage the engine. The syngas cleaning process is not fully developed for the application of biosolids and currently considered in the innovative phase. Syngas cleaning, however, is commercially practiced in the coal industry, but on a much larger scale.

Close-Coupled Gasification. Close-coupled gasification, illustrated on Fig. 17–11(b) does not require syngas cleaning and instead the syngas is thermally oxidized. Syngas oxidation generates high temperature, approximately 980°C (1800°F), flue gas which can be used for thermal heat recovery. The energy recovered from the flue gas can be used as the energy source to dry to the biosolids to the desired dryness and thus minimize or eliminate the need for fossil fuels (e.g., natural gas or fuel oil). The hot flue gas can also be used as an energy source for generating electricity through the use of boiler and steam turbine or an organic Rankine cycle (ORC) engine. Electricity generation with close-coupled gasification is practiced commonly on other types of biomass, however, this system is not common for biosolids because it is generally more economical to use the energy to offset the drying energy requirement.

Energy Recovery with Fuel Cell

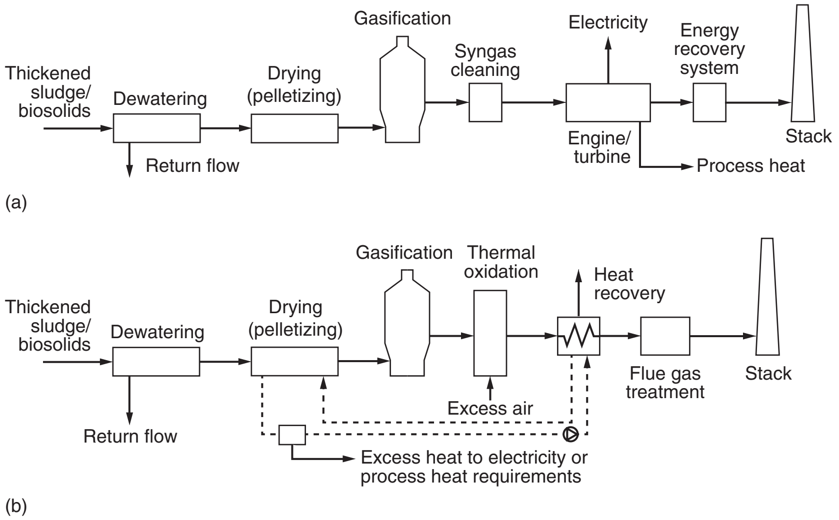
Fuel cell systems used at wastewater treatment facilities utilize methane gas generated from anaerobic digestion. In the fuel cell system, methane gas is used to generate hydrogen as expressed by Eqs. (17–16) and (17–17):

$$CH_4 + 2H_2O \rightarrow CO + 3H_2 \tag{17–16}$$

$$2H_2O + CO \rightarrow H_2 + CO_2 \tag{17–17}$$

Figure 17–11

Recovery and utilization of chemical energy by gasification: (a) two-stage gasification and (b) closed-couple gasification.



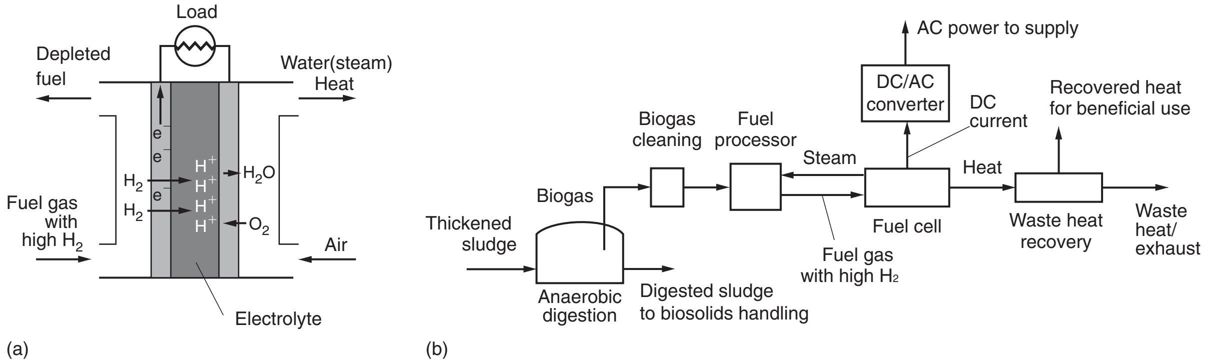


Figure 17–12

Fuel cell energy recovery system: (a) schematic illustration of fuel cell (adapted from U.S. EPA, 2006b) and (b) typical process flow diagram of a fuel cell system used at a wastewater treatment facility.

Hydrogen gas is then introduced to the anode side of the fuel cell system, where electrons are released and protons move within the fuel cell to the cathode. On the cathode side of the fuel cell, protons react with oxygen to produce water [see Fig. 17–12(a)].

Fuel cells are in general sensitive to impurity in the source fuel, and pretreatment is necessary to remove at least hydrogen sulfide (H_2S) and halides before digester gas can be sent to fuel cells. Fuel-cell systems also require essentially non-detect for siloxanes. Cleaned gas is mixed with steam to induce the reactions shown in Eqs. (17–16) and (17–17), and introduced into the fuel cell stack. Steam is recycled from the fuel cell where protons (H^+) and oxygen react on the cathode side of the fuel cell to produce heat and water. Electricity generated from a fuel cell is in direct current (DC), and is converted to alternating current (AC) for use in AC circuits. A typical process flow diagram is shown on Fig. 17–12(b).

Among a number of fuel cell types being used or studied, three fuel cell types: phosphoric acid fuel cells (PAFC), molten carbonate fuel cells (MCFC), and solid-oxide fuel cells (SOFC) are considered promising for the application at wastewater treatment facilities (U.S. EPA, 2006b). Of the three, PAFC has an advantage that the system is relatively tolerant to impurities in the source fuel. For example, phosphoric acid fuel cells have been installed at four wastewater treatment facilities operated by the New York City Department of Environmental Protection (Carrio, 2011). Waste heat produced from the fuel cell system can be recovered for other purposes (cogeneration). A comparison of the three fuel cell types is reported in Table 17–10. The total system efficiency of a fuel cell system is typically 40 to 60 percent without additional heat recovery. With heat recovery, total system efficiency can vary 70 to 85 percent.

17–7 RECOVERY AND UTILIZATION OF THERMAL ENERGY

Recovery and utilization of thermal energy involves transferring heat energy from a heat source to a heat demand. In heat recovery systems, thermal energy is exchanged from one medium to the other, sometimes with additional energy input, and conveyed to the point of use where the recovered energy is used for an intended purpose, such as space heating, heating of an anaerobic digester, or electrical power generation.

Table 17–10

Fuel cell systems used at wastewater treatment facilities[a]

System	Typical power output, kW	Efficiency, %	Advantage	Disadvantage
Alkaline (AFC)	10–100	60	• High performance due to fast cathode reaction in alkaline electrolyte • Low cost components	• Sensitive to CO_2 in fuel and air • High electrolyte management needs
Phosphoric acid (PAFC)	100–400	40	• Suitable for combined heat and power due to high operating temperature • Tolerant to fuel impurities	• Expensive catalyst (Pt) • Long start-up time • Low current and power
Molten carbonate (MCFC)	300–3000	45–50	• High efficiency compared to PAFC • Fuel flexibility • A variety of catalysts could be used • Suitable for combined heat and power due to high operating temperature	• Susceptible to high temperature corrosion and breakdown of cell components • Long start-up time • Low power density

[a] Adapted from DOE (2011).

Sources of Heat

Major sources of thermal energy in wastewater treatment facilities include heat from the combustion processes, as discussed in Sec. 17–5, and sensible heat in wastewater. Excess heat from engine generators and boilers has been used widely to heat water for building heating, anaerobic digesters, or hot water supply. In some wastewater treatment plants, lower quality heat such as the residual heat from the exhaust air stream in heat recovery ventilation systems and the heat in treated wastewater effluent has been recovered and used for various purposes.

Combined Heat and Power (CHP) System. In a CHP system, or cogeneration system, both electricity and usable heat are generated. Typically thermal energy is transformed into hot water or steam and used for space heating, digester heating, drying, and other purposes. The typical range of total system efficiency from internal combustion engines without CHP is between 25 and 50 percent, as reported in Table 17–8, depending on the type of engine and operational conditions, whereas the total system efficiency with CHP can be in the range of 70 to 85 percent.

Low Grade Waste Heat. Low grade waste heat is the heat either coming directly out of combustion processes or after the heat has been recovered from the heat source by other heat recovery systems, and considered not sufficient to generate steam or high temperature hot water (80 to 90°C) directly. The low grade waste heat may have the temperature from 30°C or lower (e.g., wastewater effluent) to as high as 230°C (e.g., exhaust air from existing heat recovery devices), depending on the heat recovery system considered

(DOE, 2008). Devices such as heat pumps and organic Rankine cycle engines have been used to recover energy from low grade waste heat.

Other Sources of Heat. Digested sludge, process air exiting bioreactors, and air in the building exhaust also contain heat that can be used for preheating incoming sludge or process air. Sidestream treatment processes can be a potential source of excess heat as temperature of sidestream tends to be higher than normal wastewater and due to high concentrations of nitrogen, the heat generated from oxidation and reduction of nitrogen is typically significant enough to require dilution of the sidestream or heat removal through a heat exchanger (see Chap. 15). However, the feasibility of heat recovery and its use at a specific treatment facility has to be evaluated as the cost savings from the use of recovered heat may not be justifiable based on the installed cost of the heat recovery equipment and conveyance of recovered heat to the point of heat demand or use.

Demands for Heat

Heating requirements in wastewater treatment facilities are primarily for sludge and biosolids processing, building heating, and generation of hot water for various uses. Heating requirements in solids processing include anaerobic digester heating to maintain the operating temperature and for drying sludges and biosolids. Effluent disinfection by pasteurization, a relatively new development for wastewater applications, also requires significant amount of heat (see Sec. 12–10 in Chap. 12).

Heating and Cooling of Buildings. Typically, heating, ventilation, and air conditioning (HVAC) requirements are assessed during the design of building structures and a dedicated HVAC system is installed to maintain the climatic condition in the buildings. For high level assessment, the estimates on heating demand may be developed from published energy data. More detailed heating demand estimates are typically developed using microclimate-specific energy models. Major heating requirements must be identified and heat recovery considered during the design phase when heat supply for major facilities is considered. Smaller heat recovery systems may be considered separately for specific heating needs and available heat. In rare cases, excess heat at a wastewater treatment plant may be exported to outside of the facility, either to a specific building or to be integrated with a district heat system. Typically, however, the amount and quality of heat is not significant enough for energy input to district heating systems and the use is limited to within the treatment facility as the piping distances are much shorter.

Digester Heating. In conventional mesophilic anaerobic digestion, the heating of the digester is the most significant heating demand. The heating demand in sludge processing will increase significantly with thermophilic anaerobic digestion and also when thermal hydrolysis is applied for the pretreatment of the sludge. Heating of the feed sludge up to the operating temperature is the largest heating demand, and additional energy may be required to maintain the digester temperature, depending on the heat loss from the digester walls, floor, and the roof (see Example 13–7 in Chap. 13).

Drying. Sludge and biosolids drying is an energy intensive operation, and it can raise the treatment facility's energy demand significantly. Heating demand is determined based on the temperature of incoming sludges/biosolids and initial and final water contents. The heat transfer rate is estimated from the heat-transfer coefficient, contact area of heat source, and the temperature difference between the sludge and heating medium as expressed in Eqs. (14–6) and (14–7) (See Sec. 14–3 in Chap. 14). Depending on the heat recovery system employed, the heat required for drying can be supplied by combusting the dried sludge. In Example 17–6, the heat balance for a sludge drying process is presented.

EXAMPLE 17–7 **Computation of Heat Balance for Sludge Drying Process** Two different sludges and anaerobically digested biosolids are to be dried and subsequently combusted to generate heat for a sludge drying process. Heat content of the sludges and biosolids are presented below. Assume the sludge drying process requires 3.5 MJ to remove 1 kg of water from sludge, and dried cake has 90 percent solids content. Determine the initial water content above which heat content of the solids is sufficient for the drying process. Assume the heat loss through the transfer of heat from the combustion process to sludge drying process is inclusive of the heating requirement (3.5 MJ/kg).
Latent heat of water vaporization is 2.257 MJ/kg.

Type of feed	Heat content, MJ/kg
Primary sludge	11.6
Waste activated sludge	14.0
Anaerobically digested biosolids	16.3

Solution

1. Calculate the mass of wet cake for 1000 kg dry solids and solids contents between 15 and 35 percent.
   For 15 percent solids content, the mass of wet cake is

   Wet cake = (1000 kg)/0.15 = 6666.7 kg

   Set up a spreadsheet to calculate the mass of wet cake between 15 and 35 percent solids content.
2. Calculate the amount of water to be evaporated and the heat required to dry wet cake from the initial solids content to 90 percent.

   Mass of 90 percent solids content cake = (1000 kg)/0.90 = 1111.1 kg

   The amount of water to be evaporated for 15 percent cake is

   Water to be evaporated = 6666.7 − 1111.1 = 5555.6 kg

   Heat required to evaporate = 5555.6 × 3.5 = 19,444 MJ

   Similarly, calculate the amount of water to evaporate for the range of solids content and compute the heat required to evaporate water.
3. Calculate heat generated from combustion of the 90 percent solids.
   For primary sludge, 1000 kg of dry solids will generate 1000 × 11.6 = 11,600 MJ
   The remaining water (10 percent, or 111.1 kg) will be evaporated.

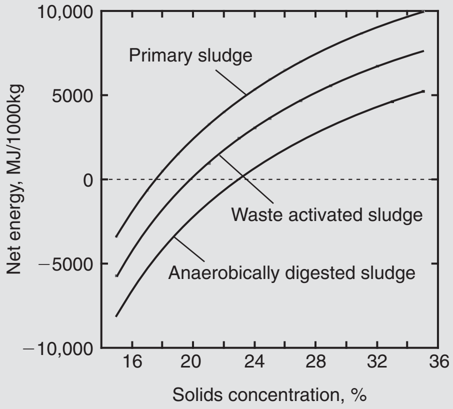
   The latent heat of vaporization is 111.1 × 2.257 = 250.8 MJ

   Heat generated from the combustion of 90 percent solids cake = 11,600 − 250.8 = 11,349 MJ.

4. Calculate the net heat balance and plot the results for the three types of sludge for the range of solids content.
   For primary sludge with 15 percent solids content, the heat balance is

   Net heat generated = 11,349 MJ − 19,444 MJ = −8905 MJ.

   Similarly, calculate the heat balance and plot the results for primary sludge, waste activated sludge, and digested sludge. The result is shown on the following plot.



Using the solver function on the spreadsheet program, the solids contents to achieve zero net energy are 20.0, 19.8, and 17.6 percent for primary sludge, waste activated sludge, and digested sludge, respectively.

Comment Depending on the initial solids concentration and efficiency of the solids combustion and drying process, heat generated from combustion may be sufficient to operate the drying process without supplemental fuel. Detailed evaluation of the thermal efficiency was not included in this example, but a simplified evaluation is often used for a preliminary assessment.

Devices for Waste Heat Recovery and Utilization

Suitable heat recovery applications are determined based on the thermal energy contents and the type of output (e.g., electricity, hot water, hot air, cold water, cold air). Examples of devices used at wastewater treatment facilities to recover and utilize heat include heat exchangers, heat pumps, and heat absorption chillers. Organic Rankine cycle engines have also been used to recover energy from waste heat to produce electricity.

Heat Exchanger. A heat exchanger is a device that transfers heat from one source (hotter fluid) to another (colder fluid) through a conductive material that separates fluids with different temperatures. Heat exchangers are used widely at wastewater treatment plants, especially where anaerobic digesters are used to stabilize sludges and produce digester gas. Exhaust heat from the water jacket of engine generators is often used for digester heating and heating of buildings. Various types of heat exchangers have been installed at wastewater treatment plants. Common heat exchanger types are (1) coil heat exchangers, (2) plate heat exchangers, (3) shell-and-tube heat exchangers [see Fig. 17–13(a)], and (4) spiral heat exchangers [see Fig. 17–13(b)].

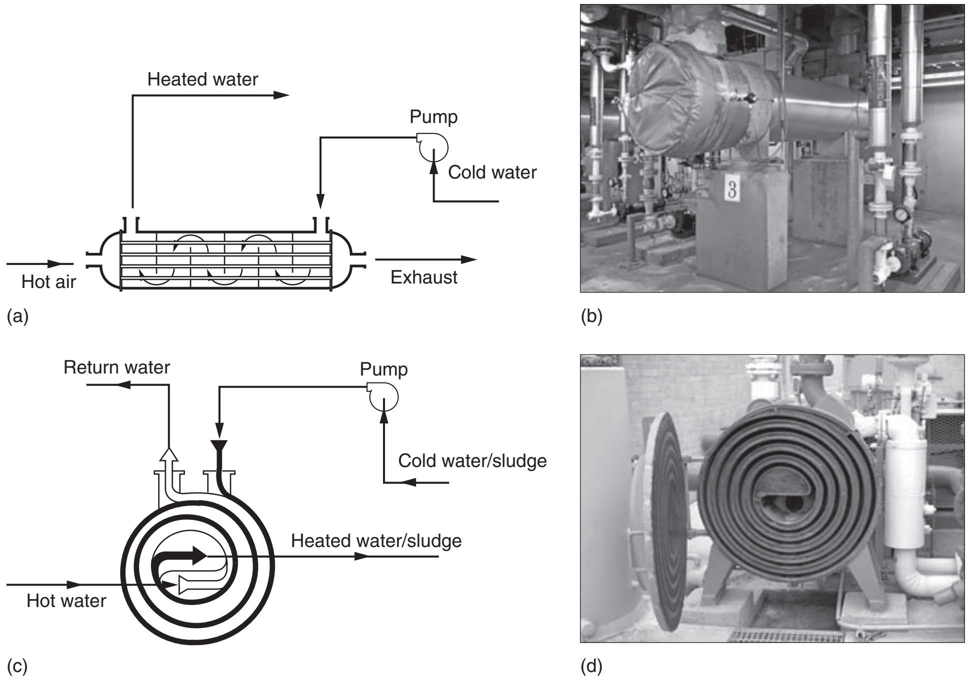
A simplified schematic of a shell-and-tube heat exchanger is shown on Fig. 17–14. In simpler forms, heat exchanger configurations can be categorized as cocurrent [see Fig. 17–14(a)] and countercurrent [see Fig. 17–14(b)]. Overall heat transfer with a shell-and-tube heat exchanger is expressed as

$$Q = UAF\Delta T \tag{17–18}$$

where Q = total heat load transferred, MJ/h (Btu/h)
U = heat transfer coefficient, MJ/m^2·h·°C (Btu/ft·h·°F)
A = surface area, m^2 (ft^2)

Figure 17–13

Typical heat exchangers used at wastewater treatment facilities: (a) schematic of shell-and-tube heat exchanger for the recovery of heat from engine exhaust, (b) view of a shell-and-tube heat exchanger, (c) schematic of spiral heat exchanger for sludge heating, and (d) view of inside of a spiral heat exchanger.



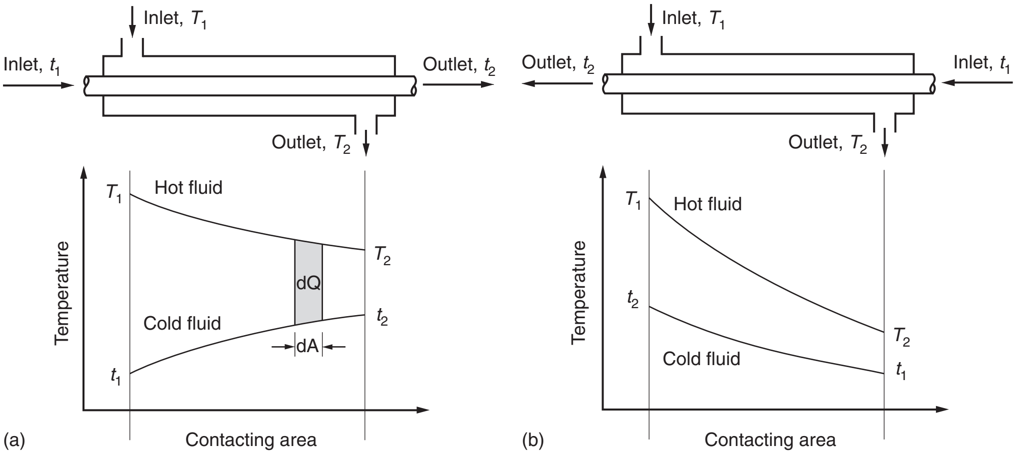


Figure 17–14

Simplified diagram of heat exchangers and corresponding temperature gradients: (a) cocurrent type and (b) counter current type.

F = correction factor for specific flow arrangements within the heat exchanger, unitless
ΔT = mean temperature difference, °C (°F)

Heat Transfer Coefficient. The heat transfer coefficient depends on the conduction heat transfer coefficients for the materials used, and to a lesser degree the heat convection resistance (Holman, 2009). A detailed analysis of heat exchangers can be found in references on chemical engineering (for example, Green and Perry, 2007). The typical range of heat transfer coefficients for various materials are reported in Table 17–11. The correction factor, F, for various heat exchanger configurations could be found in references on heat exchangers, such as Holman (2009), Kuppan (2000), and others.

Table 17–11

Typical heat transfer coefficients for various materials[a]

Heat exchanger type and media	Heat transfer coefficient, U W/m²·K
Steam condenser	1100–5600
Feed water heater	1100–8500
Water to water heat exchanger	850–1700
Finned-tube heat exchanger, water in tubes, air across tubes	25–55
Water-to-oil heat exchanger	110–350
Finned-tube heat exchanger, steam in tubes, air over tubes	28–280
Ammonia condenser, water in tubes	850–1400
Alcohol condenser, water in tubes	255–680
Gas-to-gas heat exchanger	10–40

Adapted from Hewitt (1992).

Temperature Difference. The temperature difference between hot fluid and cold fluid changes along the heat exchanger. Temperature profiles of two fluids in a cocurrent flow double-pipe heat exchanger are illustrated on Fig. 17–14(a). Through an incremental area, dA, heat dQ is transferred, and the total heat transferred across the heat exchanger is an integral of the incremental heat transfer. Solving for the total energy transfer, the mean temperature difference, ΔT_{LM}, in Eq. (17–18) for a double-pipe heat exchanger can be written as

$$\Delta T_{LM} = \frac{(T_2 - t_2) - (T_1 - t_1)}{\ln[(T_2 - t_2)/(T_1 - t_1)]} \tag{17–19}$$

where T_1, T_2 = temperature of hot fluid, °C
t_1, t_2 = temperature of cold fluid, °C

The temperature difference expressed by Eq. (17–19) is termed *log mean temperature difference* (LMTD). The equation is also valid for counter current flow [see Fig. 17–14(b)]. When the LMTD is used to calculate the heat transfer for other configurations a correction factor, F, is used to estimate the mean temperature difference. Thus, the overall heat transfer equation is described as shown previously in Eq. (17–18).

Fouling Considerations. When selecting heat exchangers, the designer must take into account the fouling factors which will impede the heat transfer. Consideration of the fouling factor, is a critical design factor, especially when the fluid is not within a closed loop and is not a clean fluid. Generally, selection of a heat exchanger would be determined by the cost and specifications by manufacturers providing packaged heat exchangers. The characteristics of the fluid from which heat is recovered, including the type of fluid, temperature, any constituents in the fluid, and desired heat recovery are put together and manufacturers are consulted. Critical information that would determine the feasibility of heat recovery and the type of heat exchanger includes the heat transfer requirements, capital cost, physical size, pressure drop across the heat exchanger, and ease of cleaning. Design of a heat exchanger that meets the heat transfer requirements will depend on the relative weights of cost versus pressure drop and physical size limitations (Holman, 2009). The use of Eq. (17–18) and Table 17–11 would be useful in conducting a preliminary assessment before detailed information is collected for design.

Heat Pump. The heat pump is a device that uses a refrigerant to take heat from one source typically at a lower temperature and transfer it to another medium which usually has a higher temperature (DOE, 2003). A simplified schematic is shown on Fig. 17–15. Briefly, the low temperature-low pressure refrigerant is vaporized using a heat source. The vaporized refrigerant is compressed to a high pressure-high temperature vapor by a compressor which requires energy (electricity). It then goes through another heat exchanger to transfer the latent heat of vaporization to a heating medium as the refrigerant is condensed to liquid. The refrigerant that is condensed to liquid still retains relatively high temperature. In the expansion valve, the temperature and pressure of the refrigerant is lowered. The low pressure, low temperature refrigerant goes back to the first step to be vaporized by taking up heat from wastewater effluent. The heat transferred to a medium could be used for heating of buildings, water, digesters, and other purposes.

When wastewater is used as a heat source, usually an intermediate medium such as propylene glycol is used to take heat from wastewater by a heat exchanger suitable for wastewater, and glycol is used to operate the heat pump. The intermediate step is recommended to avoid fouling of the heat exchanger within the heat pump. The use of a heat pump for heating can also provide a side benefit by lowering the temperature of the effluent to be discharged to receiving water that is sensitive to temperature difference. The most common use of heat pump at wastewater treatment facilities is for space-heating and ventilation preheating.

The same principle for a heat pump could also be used on an opposite direction to cool a medium. A refrigerator is an example of a cooling cycle heat pump. In a warm climatic condition, wastewater can be used as a heat sink (i.e., heat taken out for cooling is disposed) in a heat pump operation to provide space cooling. In a large scale system, both heating and cooling cycles could be used so that the heat pump system could be utilized throughout a year. A district energy system installed in Tokyo is such an example (Funamizu et al., 2001). It is a key design consideration to determine if the heat pump system would be used only for heating, or used for both heating and cooling.

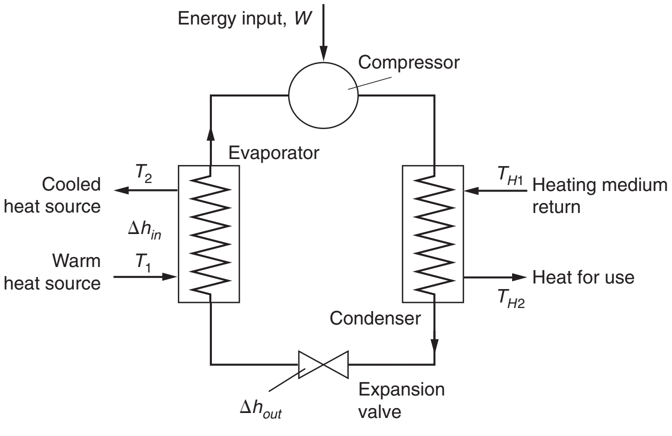
Heat Balance. Referring to Fig. 17–15, the heat transferred from the effluent, Δh_{in}, J/s, is

$$\Delta h_{in} = m_o C_o (T_1 - T_2) \tag{17–20}$$

where m_o = mass flowrate of effluent, kg/s
C_o = specific heat of heat source, J/kg·°C
T_1 = heat source temperature entering the heat pump, °C
T_2 = heat source temperature exiting the heat pump, °C

Figure 17–15

Schematic illustration of a heat pump system.



The heat transferred from the heat pump to the heating water, Δh_{out}, is

$$\Delta h_{out} = m_{\mathrm{H}} C_{\mathrm{H}} (T_{\mathrm{H2}} - T_{\mathrm{H1}}) \tag{17–21}$$

where m_{H} = mass flowrate of heating medium, kg/s
T_{H1} = heating medium temperature entering the heat pump, °C
C_{H} = specific heat of heating medium, J/kg·°C
T_{H2} = heating medium temperature exiting the heat pump, °C

Energy loss through the piping, h_c, is

$$h_c = h_f + h_a = g m_e H(2cL) + UA\Delta T \tag{17–22}$$

where, h_f = energy loss due to friction headloss, J/s
h_a = heat loss through the pipe, J/s
g = acceleration of gravity, m/s^2
H = headloss per unit pipe length, m/m
c = friction loss per unit pipe length, m/m
L = distance between heat pump and heat delivery point, m
Other terms were defined previously [see Eq. (17–18)].

If the electricity used to compress the refrigerant is W_1 (J/s) and the compressor efficiency is E_c, the energy balance is as follows:

$$m_o C_o (T_1 - T_2) + E_c W = m_{\mathrm{H}} C_{\mathrm{H}} (T_{\mathrm{H2}} - T_{\mathrm{H1}}) + h_c \tag{17–23}$$

where E_c = compressor efficiency, unitless
W = energy input, J/s

Coefficient of Performance. Coefficient of performance (COP) is an expression used to quantify heat pump performance in terms of the heat delivered from a unit of energy input.

$$\mathrm{COP} = h_h/h_w \tag{17–24}$$

where, COP = coefficient of performance, unitless
h_h = heat output from the heat pump, Joule (or J/s)
h_w = energy input to the heat pump, Joule (or J/s)

Using the terms shown previously, COP can also be written as

$$\mathrm{COP} = \frac{m_{\mathrm{H}} C_{\mathrm{H}} (T_{\mathrm{H2}} - T_{\mathrm{H1}})}{W} = E_c W + C_o(T_2 - T_1) - h_c/W \text{ (use the same format as the term before)} \tag{17–25}$$

The level of COP achievable for the specific application will depend on the climatic condition and the type of application. Therefore a direct comparison of COP values between different applications does not provide meaningful information, but the estimate of COP for alternatives may be useful for a decision making process. In relatively cold climate, such as central Canada, heat recovery from wastewater effluent could provide sufficient energy to heat a small building within a wastewater treatment facility, and typical COP would be in the range of 3 to 4, depending on the pumping power and fluid temperatures. In more temperate regions, the use of heat pump for both heating and cooling can provide a significant contribution to energy savings. In some cases, higher COP values are achievable with cooling (i.e., use wastewater effluent as a heat sink).

Waste Heat Utilization for Cooling and Refrigeration. Low grade waste heat, such as exhaust heat of engine generators that has gone through a series of heat exchangers, could be utilized to operate heat absorption chillers or other technologies to provide cooling and refrigeration (see Fig. 17–16). In absorption chillers, lithium bromide is used

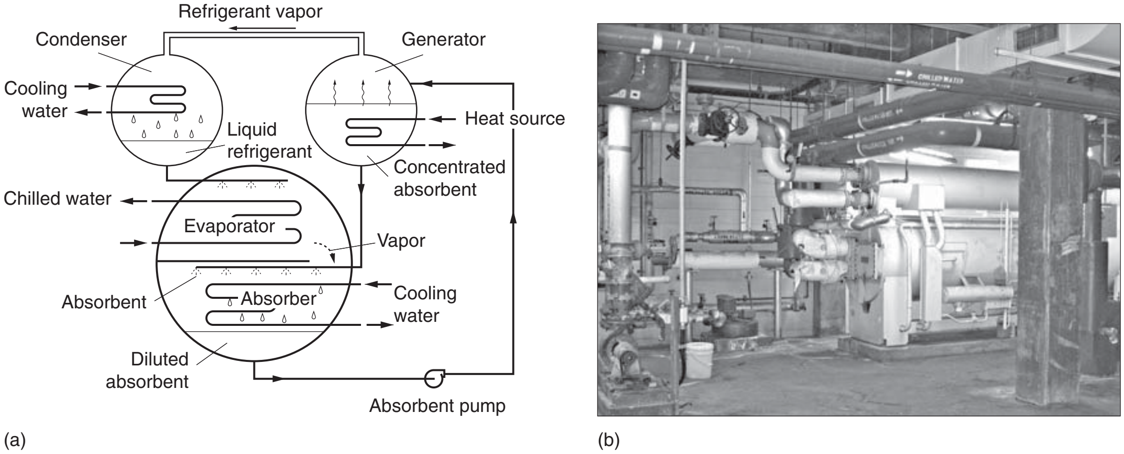


Figure 17–16

Chiller using low grade heat: (a) schematic of chiller composed of generator, condenser evaporator and absorber and (b) view of typical chiller (courtesy of Philadelphia Water Department).

typically to absorb the vaporized water (refrigerant) to create a vacuum environment. Water absorbed in the lithium bromide solution is vaporized with the low grade heat, and concentrated lithium bromide solution is recirculated. Water vapor is sent to a condenser, and sent back to the vacuum environment, where it boils at a low temperature and evaporative cooling is used to produce chilled water. The quality of energy source suitable for the absorption chillers varies with the chiller types, but suitable heat source is typically between 70 and 130°C.

The performance of absorption chiller or other cooling and refrigerating systems can be quantified in a similar manner as the heat pump, in terms of COP. The range of COP depends on the energy source and the cooling requirement. When hot water is used as a heat source, the COP value can be 4.0 or higher. Because the design of chillers will involve evaluation of the heat source, chilled water temperature, cooling water temperature and other site specific conditions, manufacturers of chillers should be consulted and a computer modeling is used to determine the sizing and operating conditions.

Organic Rankine Cycle Engine. The organic Rankine cycle (ORC) engine is an electrical power generator utilizing an organic refrigerant. The mechanism of ORC engines is similar to that of the heat pump, and a generator is used in place of the expansion valve. The ORC is capable of generating electricity from waste heat as low as 67°C (150°F), and the efficiency is generally 10 to 20 percent (DOE, 2008).

Design Considerations for Thermal Energy Recovery Systems

Evaluation of the characterization of waste heat is an important step to determine the feasibility of thermal energy recovery and the selection of the recovery systems. Important parameters that must be determined include (DOE, 2008):

1. Heat quantity
2. Heat temperature/quality
3. Composition
4. Minimum allowed temperature
5. Operating schedules, availability, and other logistics
6. Diurnal and seasonal variations in the parameters identified above

Heat Recovery from Combustion Systems. Waste heat from combustion systems such as exhaust heat from engine generators has sufficiently high temperature to generate hot water or steam. At treatment facilities utilizing digester gas for power generation, it is common to design the system to utilize waste heat for other purposes through a CHP system (see Chap. 13).

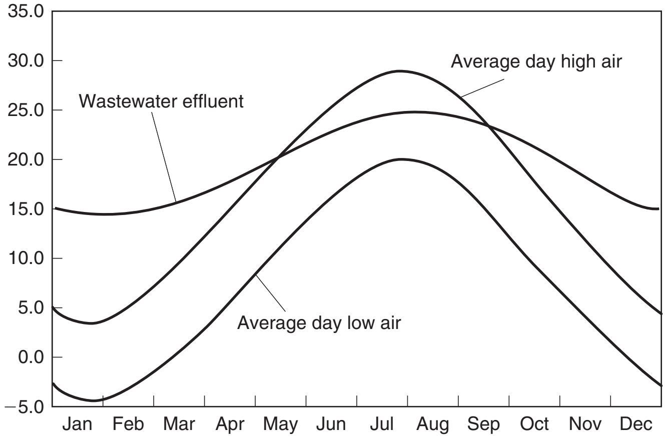
For a biosolids incineration system, the applicability and selection of a CHP technology is based on the amount of biosolids to be processed and the amount of excess energy in the hot flue gas generated. Another factor which can affect the selection of an appropriate type of CHP is the size of the facility and the goals for energy recovery. Small to medium size facilities, with a goal of producing electricity may use a technology such as the ORC with ~10–20 percent electrical efficiency to recover energy from excess flue gas generated. Larger facilities with similar goals may select high pressure steam turbines with approximately 15–38 percent electrical efficiency. Economic and operational issues must be evaluated to determine if an add-on CHP system is practical and what the appropriate size and type of system should be.

Heat Recovery from Wastewater. The temperature of wastewater is typically higher than that of potable water, and the variation in wastewater temperature is smaller than that of ambient temperature (see Fig. 17–17) throughout a year. The heat from wastewater is a reliable source of thermal energy for beneficial uses during the colder season, and it can be used as a heat sink during the warmer season. Depending on the size of the treatment facility, thermal energy can be used to supplement heating requirements within the wastewater treatment facility, or integrated into a district heating/cooling system. Because the available heat in wastewater is low, a heat pump is used to extract heat from wastewater (Pallio, 1977). Depending on the availability of heat, heating of a specific building within a wastewater treatment facility may be considered, or it may be integrated into the centralized heating system for the entire treatment plant. The estimation of heat to be recovered from wastewater is illustrated in Example 17–7. Heat recovery from raw wastewater in the collection system or at the beginning of the treatment facility can also be considered. When heat is recovered from raw wastewater, the impact of lowered wastewater temperature on the treatment performance must be evaluated (Wanner et al., 2005).

In North America, heating or cooling capacity of air conditioning equipment is often measured in terms of the tons of refrigeration. One ton of refrigeration is approximately 12,000 Btu/h or 3.517 kW. Similarly, the power requirement for the heat extraction is often expressed in brake horse power (bhp) per ton of refrigeration. One horse power (hp) is approximately 0.745 kW. Thus, if a power requirement for a heat pump is rated as 1.0 bhp/ton, then 0.745 kW is required to provide 3.517 kW of heat extraction.

Figure 17–17

Seasonal variation of ambient temperature and wastewater temperature in north eastern United States.



EXAMPLE 17–8 **Heat Pump for Effluent Heat Recovery** A water to water heat pump is to be used to provide heating in a building at a wastewater treatment plant. The heat source is treated effluent. The lowest effluent temperature is 12°C, and temperature drop of the effluent in the shell and tube heat exchanger is assumed to be 4°C. A 40 percent propylene glycol mixture is used as an intermediate heat transfer medium to extract heat from the effluent, and the heat pump will have an 8°C entering temperature and a 5°C leaving fluid temperature. The peak heating requirement for the building was estimated to be 360 kW.

A heat pump supplier was contacted and a heat pump was selected requiring 0.222 kW electrical input per kW heat output to extract 300 kW from the effluent.

1. Calculate the COP for the heat pump, and the heat output and the electrical power input in kW of the heat pump. For simplicity, assume compressor efficiency = 1
2. Three circulation pumps, 14, 11, and 15kW, are used to transfer effluent to the heat exchanger and to pump the glycol on each side of the heat pump system. Calculate the overall system COP including pumping power.
3. Given the energy to be extracted from wastewater and assumed temperature drop, determine the wastewater flowrate that needs to be transferred to the heat pump system.

Solution

1. Calculate the COP for the heat pump using Eq. (17–24).

   Power input = 0.222 kW per 1 kW of output

   $$\text{COP} = \frac{1.0}{0.222} = 4.5$$

   Using Eq. (7–25) and ignoring the heat loss from the transfer of the heating medium,

   $$4.5 = \frac{W + m_o C_o (T_1 - T_2)}{W} = \frac{W + 300}{W}$$

   Power input = W = 86 kW

   Using Eq. (17–23),

   Total power output = 300 kW + 86 kW = 386 kW

2. Calculate the COP for the entire system.

   $$\text{COP} = \frac{386\,\text{kW}}{(86\,\text{kW} + 14\,\text{kW} + 11\,\text{kW} + 15\,\text{kW})}$$
   $$= 3.06$$

3. Calculate the wastewater flowrate to be transferred to the heat pump system.

   300 kW = 300 kJ/s

   Specific heat of water = 4.2 kJ/kg·°C

   Assume density of water = 1.0

   $$\text{Wastewater flowrate required, m}^3\text{/s} = \frac{(300\,\text{kJ/s})}{(4.2\,\text{kJ/kg·°C})(1000\,\text{kg/m}^3)(4°\text{C})}$$
   $$= \frac{300}{4.2 \cdot 1000 \cdot 4} = 0.0179\ \text{m}^3\text{/s} = 1.07\ \text{m}^3\text{/min}$$

Comment Additional energy required to convey (i.e., pump) wastewater and heated water or glycol can be significant if the heat extracted by a heat pump is used for a large area or outside of the wastewater treatment facility (e.g., for district heating system).

17–8 RECOVERY AND UTILIZATION OF HYDRAULIC POTENTIAL ENERGY

Utilization of hydraulic potential energy involves conversion of hydraulic potential energy into electricity, and transferring of hydraulic pressure in a stream to different parts of the treatment process. The purpose of this section is to introduce (1) the type of devices used to recover energy from hydraulic potential, (2) the hydraulic energy recovery applications adopted by wastewater treatment facilities, and (3) considerations for the selection and design of hydraulic energy recovery systems.

Type of Hydraulic Potential Energy Recovery Devices

Hydraulic turbines for electrical power generation are the primary machines used for the recovery of hydraulic potential energy from the main liquid process flow. Devices to utilize the pressure head or kinetic energy of the stream are usually integrated into a specific energy-intensive unit process to reduce the energy requirement of the process. Electrical power generated from hydraulic potential energy can be sent to the electrical distribution system within the treatment facility to supplement the electricity drawn from the electrical grid or directly connected to the grid and sold to the electric utility.

Hydraulic Turbines. Turbines are turned by water flow, and the movement of the turbine is directed to the attached generator to produce electricity. Hydraulic turbines to generate electricity are essentially pumps in reverse. An electrical generator connected to the turbine produces electricity rather than an electric motor which consumes electricity to move water. The type of turbine follows the flow and head characteristics of the related pumps. The head and flow ranges for most wastewater treatment facilities would place the hydroturbines generators in the small ($<$ 5 MW) or micro ($<$ 250kW) range.

The two types of hydraulic turbines are: (1) reaction turbines, and (2) impulse turbines. In the reaction turbines, water pressure is applied to the face of the runner blades to turn the turbine. Radial (Francis) turbines, and axial type (Kaplan and propeller) turbines are the common reaction turbines. In the impulse turbines, water entering the turbine has sufficient velocity (i.e., kinetic energy), and turn the turbine as a high velocity water hits the buckets on the periphery of the runner. Common impulse turbines include Pelton turbines [see Figs. 17–18(a) and (b)], Turgo turbine, and cross-flow turbines (ESHA, 2004). Impulse turbines exhaust to atmosphere and are not suitable for energy recovery from force mains or where the continuity of the water column must be maintained through the turbine to capture the available head. The application ranges for various types of hydraulic turbines are graphically presented on Fig. 17–19. The Pelton and Turgo are the best fit for low flow and high head conditions. The axial flow Kaplan-type turbines are suitable for low head, high flow conditions that would be typical of wastewater treatment plant effluent streams. Crossflow turbines are used most commonly for small scale applications, and suitable for low head applications.

Devices for the Transferring of Pressure Head. Hydraulic turbochargers and pressure exchangers used for the nanofiltration and reverse osmosis systems are the examples of devices used to reduce energy requirements by transferring hydraulic potential energy from a stream to the other part of the process. Hydraulic turbochargers utilize the hydraulic head in the membrane reject stream to boost the inlet pressure for the membrane modules. The use of energy recovery devices in membrane treatment systems are discussed in detail in Sec. 11–6 in Chap. 11.

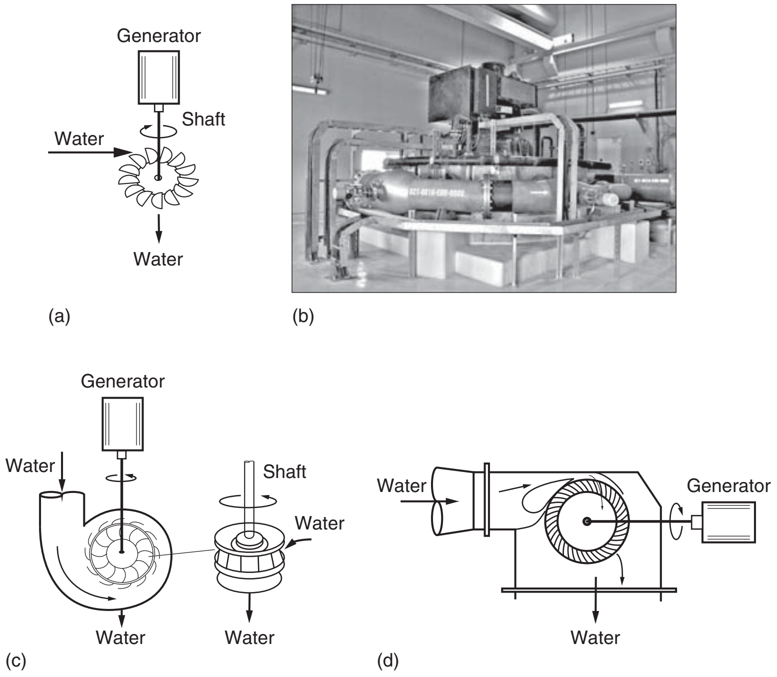


Figure 17–18

Examples of hydraulic turbines: (a) schematic of a pelton wheel turbine, (b) view of pelton turbine used with raw wastewater for power generation in Jordan, (c) schematic of Francis turbine, and (d) schematic of crossflow turbine. (Adapted from BHA, 2005.)

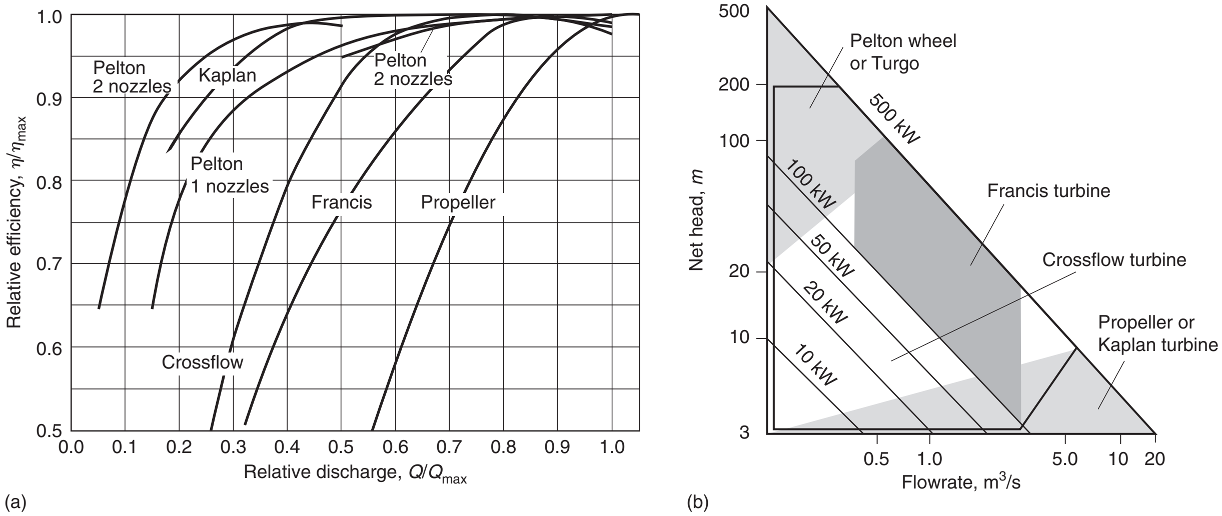

Figure 17–19

Guidelines for the selection of hydraulic turbine: (a) typical turbine efficiency for various turbine types, and (b) range of operation for hydraulic turbine based on the net head and flowrate (adapted from the BHA, 2005, and ESHA, 2009).

Application of Hydraulic Energy Recovery Devices

The two most common applications to recover hydraulic potential energy from wastewater treatment facilities are (1) recovery of hydraulic potential at the influent or effluent of the wastewater treatment plant and (2) recovery of residual head from high-pressure membrane treatment processes.

Recovery of Hydraulic Potential and Net Head. The hydraulic energy that can be converted to electrical energy from a turbine-generator system is defined previously as.

$$P_e = \rho Q g \Delta H \eta_t \eta_e \qquad (17\text{–}8)$$

Typical turbine efficiency is reported on Fig. 17–19(a). Typically, generator efficiency for new generators is between 90 and 95 percent. In practical applications, additional efficiency factors may need to be considered. For example, where power is to be generated using a turbine and generator combination, other factors such as penstock efficiency and transformer efficiency must be considered to account for the efficiency for the entire electrical power generation system.

Selection of Hydraulic Turbines. The key criteria in selecting the type, geometry, and dimensions of the turbine include the following (ESHA, 2004):

1. Available head
2. Flowrate range
3. Variation in tailwater elevation
4. Cost
5. Available space and access

Generally, impulse turbines are suitable for high head, low flowrate streams, and reaction turbines are suitable for low head, high flowrate streams.

Design Considerations for Hydraulic Turbines for Wastewater. When a hydraulic turbine is used with raw wastewater, the turbine is located downstream of preliminary treatment to remove large debris, and wastewater flows through a penstock to the turbine, just before the main treatment facility. Pelton turbines may have an advantage for raw wastewater as they are less prone to the damage by small debris. However, Pelton turbines require significant head, in form of kinetic head, and are not suitable for typical wastewater treatment plants.

For the recovery of hydraulic energy from the treated effluent before discharge to the receiving water, the use of low head reaction type turbines such as Francis and Kaplan turbines, or crossflow turbines for small scale applications, are more applicable than the impulse turbines. Because wastewater effluent at the end of the treatment processes will have minimal kinetic energy, the turbine may have to be located close to the discharge point to maximize the head. General guidance for the selection of turbine types is provided on Fig. 17–19. It is important to understand the range of flowrate and the available head in determining the appropriate turbine. The ranges of net head, H_n, for major types of hydraulic turbines are presented in Table 17–12.

Table 17–12

Typical range of net head for major hydraulic turbine types[a]

Turbine type	Range of net head, H_n, m
Kaplan and propeller	2–40
Francis	25–350
Pelton	50–1300
Crossflow	2–250

[a] Adapted from ESHA (2004).

Recovery of hydraulic head from wastewater plant effluent flow will not fit the typical range of turbines used for hydroelectric generating facilities. The recovery of energy from a large WWTP (432 ML/d) with 7 meters of available head is illustrated in Example 17–9.

EXAMPLE 17–9 **Power Generation from Wastewater Discharge Location** Estimate the power that can be generated by a hydro-power generation unit located at the effluent discharge for the following conditions. Also, select the type of turbine that would be most suitable the given conditions.

Parameter	Unit	Value
Available head	m	7
Flowrate	m^3/s	5
Penstock efficiency	%	0.92
Turbine efficiency	%	0.8
Generator efficiency	%	0.92
Transformer efficiency	%	0.95

Solution

1. Estimate the the power that can be generated using Eq. (17–8).

   $$P_e = (1000)(5)(9.81)(7)(0.8)(0.92) = 2.53 \times 10^5 \text{ W} = 253 \text{ kW}$$

2. Selection of turbine type.
   From Fig. 17–19(b), for the flow and available head, a Kaplan or propeller turbine could be used.

Comment Consideration should be given to looking at the hydroturbine as a pump in reverse and coupling the appropriate pump to a generator. The reverse pump may not be as efficient as a turbine designed specifically for hydropower, but it may be difficult to find a hydroturbine in the flow and head ranges seen at wastewater treatment facilities. Note that flywheels are often used to prevent freewheeling of the turbine if the connection to the electrical system is interrupted.

Use of Residual Pressure Head in Treatment Processes

For industrial and indirect/direct potable reuse applications, reverse osmosis has become a common treatment unit process used to remove dissolved constituents that are otherwise difficult to remove. In water reuse applications, typical feed water pressure for the RO unit is in the range of 12 to 18 bar, and the concentrate (brine) will retain the pressure ranging 10 to 16 bar. Because transfer of the brine usually does not require as much head to the discharge point or to the brine storage, the residual pressure is often used to recover energy. Devices used for the recovery of energy from the residual pressure sources were discussed previously in Sec. 11–6. Typically, the energy recovery from RO units are considered economically viable for larger treatment plants as the energy savings is close to proportional to the flowrate whereas the additional costs for the energy recovery devices are not proportional to the size of the units.

17–9 ENERGY MANAGEMENT

Important energy management considerations include maximizing the use of available energy as discussed in previous sections, reducing the use of energy at wastewater treatment facilities, increasing the energy production onsite by utilizing waste from other sources, and utilizing renewable energy such as solar or wind power. In addition, a wide range of management goals must be evaluated, including (NYSERDA, 2010)

1. Improving energy efficiency and managing total energy consumption
2. Controlling peak demand for energy
3. Managing energy cost volatility
4. Improving energy reliability

In addition to these management goals, greenhouse gas reduction has become a management goal for wastewater treatment facilities. Assessment of greenhouse gas emissions is described in Sec. 16–6 in Chap. 16. Topics considered in this section include (1) process optimization and modification for energy saving, (2) process modification for increased energy production, (3) peak flowrate management, and (4) selection of energy sources. It should be noted that the topics covered in this section are illustrative of what can be done to improve energy management, and are not meant to be inclusive of all energy management opportunities. Additional information on energy management can be found in a number of publications including WEF (2009), and U.S. EPA (2008, 2010, 2012).

Process Optimization and Modification for Energy Saving

Opportunities to improve energy efficiency in existing wastewater treatment facilities are identified through the energy audit described in Sec. 17–4. Typically, the evaluation following the energy audit involves process optimization and modification. Examples of process optimization and modifications for energy saving are summarized in Table 17–13. Energy saving may be achieved through operational changes to existing processes or a modification to processes and equipment. Even though the opportunities for energy saving from operational changes are limited, they can be made with little or no capital cost. Process modifications and the use of energy efficient equipment could make improvements in energy management, but may require significant capital expenditures. A life cycle cost analysis should be conducted for the shortlisted options to determine if the energy savings generated by making the change justify the capital cost of the change. To illustrate the energy reduction through process modifications, energy saving opportunities with large pumps and activated sludge aeration systems are considered below.

Major Pumps at Wastewater Treatment Facilities. Many wastewater treatment facilities require raw wastewater be pumped at the headworks to provide sufficient hydraulic head for wastewater to flow through the rest of the liquid treatment processes by gravity. These pumps, often identified as *main sewage pumps (MSPs)*, are typically the largest pumps at a wastewater treatment plant. The MSPs are required to handle a wide range of flowrates through diurnal variations of the flowrate as well as the wet weather flows. Treatment facilities designed for nutrient removal typically have significant mixed liquor or return activated sludge (WAS) flows. In MBR systems, the recycle flow is often 6 times the influent wastewater flowrate to maintain high MLSS concentrations (see Chap. 8). Energy efficiency in these major pumps can affect the overall energy efficiency of the treatment facility significantly.

Table 17–13

Example of process optimization and modifications to manage energy consumption

Operational modification	Expected outcome	Potential issues
Main sewer pump control	Reduced energy requirement	Modification to the pumps may be necessary
Wastewater loading distribution by flow equalization	Reduced peak-hour energy use	
DO control in activated sludge	Reduced power consumption Increased process performance reliability	Usually require online monitoring of DO and other parameters Increased monitoring requirements Potential process upset if online analyzers are not working properly
Conversion of nitrification to nitritation or simultaneous nitrification/denitrification	Reduced oxygen requirement	precise process control is required for nitritation
Use of energy efficient diffusers	Reduced air flow requirement	Air flow distribution should be checked
Use of energy efficient blowers	Reduced energy requirement	Some energy efficient blowers may not be suitable for deep reactors due to pressure head limitations
Use of energy efficient UV lamps	Reduced energy requirement	
Energy recovery system for RO	Reduced energy requirement	
Use of off-peak hours for biosolids dewatering	Reduced peak-hour energy use	

The overall efficiency of a pumping system is defined as

$$E = E_p \times E_m \times E_c \tag{17–26}$$

where E = overall efficiency
E_p = pump efficiency
E_m = motor efficiency
E_c = control efficiency

The relative efficiency of each of the three elements identified in Eq. (17–26) is reported in Table 17–14. Pump and motor efficiencies depend on the selection of specific models, whereas the control efficiency can vary depending on the type of the control device used. The same principle applies to the control of blowers as described in the following discussion.

Variable Frequency Drive. The flow control efficiency depends on the type of control used, and the use of variable frequency drives (VFDs) is the most energy efficient, corresponding to the higher end of the range of control efficiency reported in Table 17–14. Operationally, VFDs manipulate the frequency of the alternating current to vary the speed

Table 17–14

Pump systems used for wastewater treatment and typical efficiency[a]

Pump system component	Range, %	Typical value, %
Pump	30–75	60
Flowrate control	20–98	60
Motor	85–95	90
Overall efficiency	5–80	

[a] Adapted from U.S. EPA (2010).

of a motor. With a VFD, the pump can continue to operate along the same pump system curve while shifting the performance curve [see Fig. 17–20(a)]. Throttling and bypass controls artificially shift the system curve while maintaining the power input, thereby reducing the actual flow delivered from the pump [see Fig. 17–20(b-d)]. Stop/start control does not use part of the output that is available (U.S. EPA, 2010).

Aeration Control for the Activated Sludge Process. Energy demand associated with aeration of the activated sludge process could be managed by (1) controlling the aeration rate to match actual oxygen requirements, (2) using energy efficient and appropriately sized blowers, (3) using diffusers with higher oxygen transfer efficiencies for

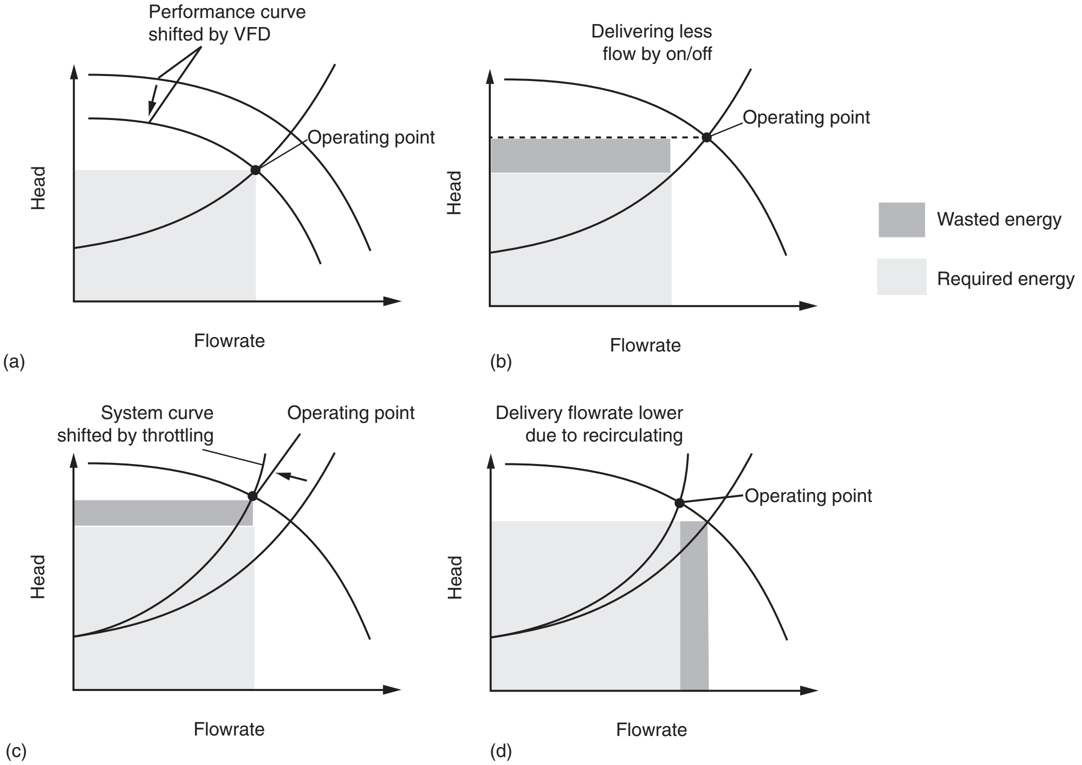

Figure 17–20

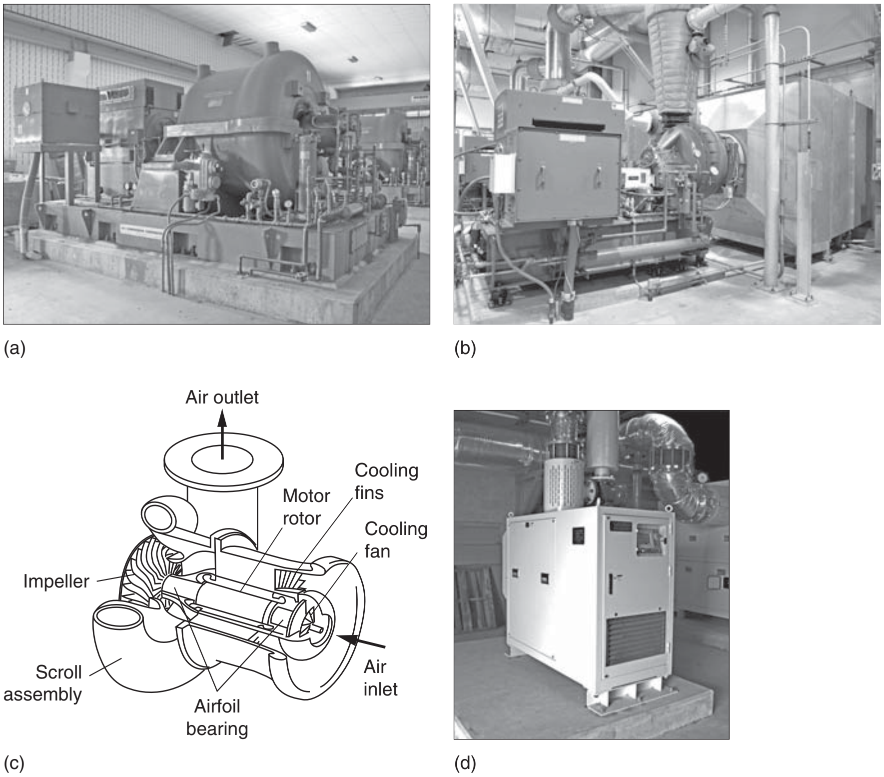
Pump efficiency with various control methods: (a) with VFD control, (b) energy loss due to intermittent pumping, (c) energy loss due to throttling, and (d) energy loss due to recirculation. (Adapted from U.S. DOE, 2006.)

Figure 17–21

Examples of aeration blowers for activated sludge process: (a) view of large centrifugal blower driven by 1120 kW (1500 hp) electric motor, and (b) view of single stage centrifugal blower with adjustable inlet guide vanes, (c) schematic of high speed turbo blower (adapted from APG Neuros), and (d) view of high speed turbo blower installation in self contained sound-dampening enclosure.



the given locations and other conditions, and (4) controlling organic loading entering the activated sludge process. Minimizing energy loss from inefficient piping of air supply system can also contribute to the overall energy demand, but the contribution is generally minor compared to other factors (WEF/ASCE 2010).

Excessive DO concentration in the aerobic zone of BNR processes is not only wasteful of energy but can result in the carryover of DO into anoxic or anaerobic zones. Excessive DO can also result in biological oxidation of organic carbon meant for denitrification. A deoxigenation zone is often allocated to avoid the DO intrusion into anoxic and anaerobic zones.

Blowers. The types of blowers used commonly in North America include single stage centrifugal, multi stage centrifugal, rotary lobe positive displacement, and high speed single stage turbo blowers (see Fig. 17–21 and Fig. 5–72 in Sec. 5–11 in Chap. 5). High speed turbo blowers are relatively new technology that utilizes air bearings or magnetic bearings to achieve high speed. Comparison of the blower types and blower efficiencies are summarized in Table 17–15. It should be noted the technologies for blowers are advancing quickly and most recent information should be consulted to determine the applicability of the turbo blowers. Airflow control devices include inlet dampers, inlet guide vanes at the inlet to the blower, and outlet dampers. Inlet guide vanes are used most commonly with centrifugal blowers and are more energy efficient than dampers or throttling. Inlet guide vanes create swirls to the airstream entering the blower, lowering the load on the blower, and are an effective airflow control between 80 and 100 percent of full flow. Another method of airflow control is fan speed adjustment, typically by VFD (DOE, 1989). Similar to the pumps, the use of VFD is an energy-efficient control of the air flowrate. The turn-down ratio, the ratio between the lowest operable flowrate to the maximum flowrate, for the specific blower must be evaluated so that the air flowrate for both

Table 17–15

Types of blowers and typical blower efficiency[a]

Blower type	Range of discharge pressure Bar	Nominal blower efficiency %	Nominal turndown % of rated flow[b]
Positive displacement, VFD	0.55–1.03	45–65	50
Positive displacement hybrid, VFD	0.20–1.5	70–80	25
Centrifugal, multi-stage, throttled	0.55	60–70	60
Centrifugal, multi-stage, inlet guide vanes	0.55	60–70	60
Centrifugal, multi-stage, VFD	0.55	60–70	50
Centrifugal, single stage, internally geared[c]	0.83	75–80	45
Centrifugal, single stage, gearless (high-speed turbo)	1.03	75–80	45–50

[a] Adapted, in part, from U.S. EPA (2010).

[b] The value depends on the blower pressure.

[c] Constant Speed with dual vane system, Outlet diffuser vanes and inlet guide vanes.

low loading and high loading conditions can be provided by the selected blower and the VFD (U.S. EPA, 2010). For example, a high efficiency constant speed blower may be used to cover the base flow without a VFD, and additional blowers, either the same size or a smaller size, could be equipped with a VFD to provide the required range of air flow.

Aeration Diffusers. Oxygen transfer efficiencies of various diffuser types were discussed in Sec. 5–11 in Chap. 5. Most activated sludge facilities designed and constructed in the 1970s and 1980s and earlier employed coarse bubble diffusers or surface aerators. As these facilities approach their design life and design capacity, their replacement with higher

EXAMPLE 7–10 **Energy Saving by DO Control** Using the complete-mix activated sludge process to treat 22,700 m^3/d of primary effluent for COD removal without nitrification as shown in Example 8–3 in Chap. 8, estimate the reduction in power demand by changing the DO setpoint from 3.5 mg/L to 2.0 mg/L.

Use the following design information extracted from Example 8–3 and supplemental information necessary to determine the energy demand.

Parameter	Unit	Value
Required oxygen transfer rate, OTR_f	kg/h	111.3
Alpha factor, α	–	0.50
Fouling factor, F	–	0.90
Beta factor, β	–	0.95
Dissolved oxygen surface saturation concentration at 12°C, C_{st}	mg/L	10.78
Dissolved oxygen surface saturation concentration at standard temperature (20°C), C^*_{s20}	mg/L	9.09

(*continued*)

(*Continued*)

Parameter	Unit	Value
Pressure correction factor, P_b/P_s		0.94
Steady-state DO saturation concentration, $C^*_{\infty 20}$		10.64
Empirical temperature correction factor, θ		1.024
Temperature of mixed liquor	°C	12
Ambient temperature	°C	15
Oxygen in the air	kg/kg air	0.232
Oxygen transfer efficiency, OTE	%	25
Universal gas constant	kJ/kmole	8.314
Blower inlet absolute pressure	kPa	101.3
Blower discharge absolute pressure	kPa	121.5

For simplicity, assume the same oxygen transfer efficiency of 25 percent for both DO concentrations.

Solution

1. Determine the SOTR for DO in aeration basin = 3.5 mg/L using Eq. (5–70).

$$\text{SOTR} = \left[\frac{\text{OTR}_f}{(\alpha)(F)}\right]\left[\frac{\text{C}^*_{\infty 20}}{(\beta)(\text{C}_{\text{st}}/\text{C}^*_{\text{s}20})(\text{P}_\text{b}/\text{P}_\text{s})(\text{C}^*_{\infty 20}) - \text{C}}\right][(1.024)^{20-t}]$$

Using the data given above, SOTR is calculated as

$$\text{SOTR} = \left[\frac{(111.3 \text{ kg/h})}{(0.50)(0.90)}\right]\left\{\frac{10.64}{\left[0.95\left(\frac{10.78}{9.09}\right)(0.94)(10.64) - 3.5\right]}\right\}(1.024^{20-12}) = 409.6 \text{ kg/h}$$

2. Determine air flowrate in terms of kg/min.

$$\text{Air flowrate, kg/min} = \frac{(\text{SOTR kg/h})}{[(E)(60 \text{ min/h})(0.232 \text{ kg O}_2\text{/kg air})]}$$

$$= \frac{409.6}{(0.25)(60)(0.232)} = 117.7 \text{ kg/min}$$

3. Calculate an estimated power requirement using Eq. (5–77a) in Chap. 5.

$$P_w = \frac{wRT_1}{28.97\, n\, e}\left[\left(\frac{p_2}{p_1}\right)^n - 1\right]$$

Using the data give above, P_w is calculated as

$$P_w, \text{kW} = \frac{(117.7/60)(8.314)(273.15 + 15)}{28.97(0.283)(0.85)}\left[\left(\frac{121.5}{101.3}\right)^{0.283} - 1\right]$$

$$= 35.6 \text{ kW}$$

4. Repeat Steps 1 through 3 for DO = 2.0mg/L.

$$\text{SOTR} = \left[\frac{(111.3\ \text{kg/h})}{(0.50)(0.90)}\right]\left\{\frac{10.64}{\left[0.95\left(\dfrac{10.78}{9.09}\right)(0.94)(10.64) - 2.0\right]}\right\}(1.024^{20-12}) = 343.3\ \text{kg/h}$$

$$\text{Air flowrate, kg/min} = \frac{(\text{SOTR kg/h})}{[(\text{OTE})(60\ \text{min/h})(0.232\ \text{kg O}_2/\text{kg air})]}$$

$$= \frac{343.3}{(0.25)(60)(0.232)} = 98.6\ \text{kg/min}$$

$$P_w, \text{kW} = \frac{(98.6/60)8.314\cdot(273.15 + 15)}{28.97\cdot 0.283\cdot 0.85}\left[\left(\frac{121.5}{101.3}\right)^{0.283} - 1\right]$$

$$= 29.8\ \text{kW}$$

5. Compare the energy demand at DO setpoint at 3.5 and 2.0 mg/L.
From Step 3 and Step 4, the energy requirement for aeration is reduced from 35.6 to 29.8 kW by reducing the DO setpoint from 3.5 to 2.0 mg/L. The reduction in energy requirement is 16.2 percent.

Comment The energy demand estimate with Eq. (5–77) is for a single-stage centrifugal blower and assuming the air flowrate is controlled by VFD. The estimated energy saving cannot be recognized if the air flow is controlled with throttling and other methods which do not reduce energy consumption with reduced air flowrates.

oxygen transfer efficiency aerators will, in most cases, save energy. When such a retrofit/upgrade is considered, it is also important to review and make necessary improvements in the air piping, air flow meters, and the DO monitoring and control system.

Process Modification for Increased Energy Production

Increased energy production can be achieved by improving the removal of organic material from wastewater prior to biological secondary treatment for anaerobic digestion, and by improving the volatile solids destruction in the anaerobic digesters. In recent years, the use of waste products from other sources has been studied for the enhanced energy production at wastewater treatment facilities. Enhanced energy production with waste products from other sources such as food waste, fats, oil and grease, and waste from industrialized livestock operations can be implemented at a wastewater treatment facility. Depending on the scale of the energy production, it may be possible to produce more energy than the treatment facility consumes (net energy positive). The use of renewable energy generated onsite, such as solar and wind power, has been implemented on a smaller scale, however, the contribution of these energy sources is relatively minor in comparison to the total energy demand at a wastewater treatment facility.

Additional Removal of Organic Matter from Wastewater. One effective way to remove additional organic matter from wastewater is through primary effluent filtration. In recent studies, it has been possible to remove up to 70 percent of the TSS remaining in primary effluent. Primary effluent filtration is considered in Sec. 5–9 in Chap. 5. Another technology that has been tested and found to remove a significant fraction of COD and TSS from raw wastewater is charged bubble flotation, also considered in Sec. 5–9 in Chap. 5, in which air bubbles are coated with a polymer. In the coming years it is anticipated that a variety of new technologies will be developed to capture the organic matter in wastewater before aerobic oxidation. Removal of organic matter at the primary treatment can also be improved by chemically enhanced primary treatment (CEPT) but care must be taken in evaluating the effectiveness of CEPT for the enhanced energy recovery because the increase in inorganic precipitates in the sludge could potentially lower the efficiency of biogas production with anaerobic digestion. Other design considerations with enhanced removal of organic matter include the impacts of iron on UV disinfection (when iron salts are used for precipitation), and carbon requirements for denitrification in BNR processes.

Process Modifications to Enhance Digester Gas Production. It is often recognized that older anaerobic digesters are not operated and maintained to maximize the production of biogas. Two common issues are insufficient digester heating and insufficient digester mixing. Another common loss of energy is due to leakage in biogas piping and storage facilities. Improvements in the operating conditions of the existing anaerobic digesters and biogas capturing could improve the amount of energy available for beneficial use. In addition to these operational and maintenance issues, methods to enhance solids loading and digester performance are discussed in detail in Sec. 13–9 in Chap. 13.

Use of Waste Products from Other Sources. Anaerobic digesters are often designed with multiple tanks but not all tanks are built in the beginning, and additional space is allocated for the later stage of the design horizon. Even with the phasing of the digester expansion, anaerobic digesters often operate at below the design capacity. The excess capacity available in most anaerobic digesters can be utilized to increase the digester gas production. The use of food waste, fat, and grease for enhanced production of biogas has been studied extensively in recent years, based on the fact that enhanced biogas production could be implemented with minimal modifications to the existing anaerobic digestion processes. The use of food waste, fat, and grease for the enhanced production of biogas is considered in Chaps. 10 and 13.

Use of Renewable Energy Sources. Considerations for the use of renewable energy sources such as wind and solar energy have become a common practice in many buildings but implementation at wastewater treatment facilities has been relatively minor, typically due to space limitations. It is considered more commonly when a building or the facility is pursuing a sustainability certificate, such as a LEED (leaders in energy and environmental design) program, but often these energy sources could fill only a small fraction of the total energy demand at a treatment plant. Common usage of renewable energy at a wastewater treatment facility includes the use of solar panels for lighting, and the use of solar energy for the production of hot water.

Peak Flowrate Management (Peak Energy Usage)

The pricing structure for the electricity for large power users such as wastewater treatment facilities typically includes a demand charge based on the peak equipment power demand, and energy charge based on the amount of energy consumed. The pricing for the energy, in most cases, is different during peak demand hours. In some regions, a spot market is adopted for the electricity pricing. When considering energy management in terms of energy cost savings, one of the effective measures is to shift the use of electricity during the hours with lower energy charge. The shift could be made, for example, by operating sludge dewatering only during off-peak hours.

Flow equalization can be an effective measure to divert part of the wastewater entering the facility during the peak power demand (highest power cost) hours and treat it during off-peak hours. Peak flowrate management not only reduces the use of power during peak demand hours, but also allows for more uniform flow and loading to the treatment processes which will also increase the energy efficiency for most electrically driven equipment. Flow equalization of return flows for treatment in off hours will also reduce peak demand. Flow equalization of return flows is considered in Chap. 15.

Opportunities exist for managing energy use in wastewater treatment by employing the concept of demand-side management. The electric power industry has long recognized the importance of integrating traditional supply-side planning with demand-side management to reduce peak demand. The goal of demand-side management is to change the electrical load characteristics (the amount of energy used at different times of the day) by improving energy efficiency and managing equipment operation. In demand-side management, it is also recognized that continued load growth will occur as the systems expand to meet new domestic and industrial wastewater collection and treatment requirements.

Selection of Energy Sources

Wastewater treatment agencies typically sign contracts with an electrical power supplier and suppliers of fuels (e.g., natural gas, fuel oils and other fuels) to set the pricing. The pricing for electrical power can be a based on a fixed plus usage fee, which can be a fixed rate or dynamic rate. When the electrical power charge is based on the dynamic pricing, a significant cost saving can be expected by implementing peak flowrate management with flow equalization, by which aeration power demand could be shifted to off-peak hours, or during the time electrical power cost is lower.

The mechanism of fuel cost contracts may affect the selection and design of mechanical equipment as different types of contracts become available for the wastewater treatment facilities. For example, a 20-y contract for natural gas at a fixed price can lead to the selection of direct drive motors fueled by natural gas over electrical motors. The fixed price contract can be compared to the purchase of electrical power which can be unpredictable.

17–10 FUTURE OPPORTUNITIES FOR ALTERNATIVE WASTEWATER TREATMENT PROCESSES

The principal sources of energy in wastewater have been identified and discussed previously in Sec. 17–2. The means used currently to recover and utilize energy from the available sources has been discussed in Secs. 17–5 through 17–7. The purpose of this section is to highlight briefly some innovations that are being developed that will make it possible to (1) recover additional energy from the various sources, (2) reduce energy usage through the implementation of different biological treatment technologies, and (3) reduce energy usage though the implementation of alternative treatment process options. Energy reduction through the use of improved process equipment is discussed in the previous section dealing with energy management.

Enhanced Energy Recovery of Particulate Organic Matter

Currently, conventional primary clarification achieves about 50 percent removal of the applied TSS and 30 to 40 percent of incoming COD. The TSS and COD not removed by sedimentation must be treated in the downstream biological treatment process. If all of the particulate COD could be removed before biological treatment, additional energy could be recovered from the material removed and the amount of energy need for carbonaceous oxidation could be reduced.

The TSS and associated COD can be removed by depth, surface, or membrane filtration. Primary effluent filtration (PEF) has been studied since the late 1970s (Matsumoto et al.,1980, 1982). Using PEF in combination with primary sedimentation, removal rates of TSS and COD around 90 and 60 percent, respectively, can be achieved. The PEF process was not adopted widely because the cost of energy at the time the process was first studied was less than $0.03/kWh and the recovery of energy was not an issue. With the current interest in the recovery of energy, the desire to reduce energy usage, and the development of a number of new filtration technologies, there is a resurgence of interest in PEF. A major advantage of PEF is that a separate waste stream is not created, because the solids removed by filtration, either continuously or intermittently, can be mixed with the primary sludge. Primary sludge from PEF or CEPT processes is converted readily to biogas using anaerobic digestion. Alternatively, the solids can be diverted to a fermenter for the production of volatile fatty acids for use in the enhanced removal of phosphorus (see Sec. 8–8 in Chap. 8).

Reduced Energy Usage in Biological Treatment

As discussed in Chap. 7 and more extensively in Chap. 15, new biological processes are being developed that offer potential savings in energy and chemical consumption, especially with respect to the removal of nitrogen. For example, the use of nitritation/denitritation and partial nitritation and deammonification processes can be used to reduce both oxygen and carbon demand. Nitrogen removal through nitritation/denitritation would require 25 percent less oxygen and 40 percent less external carbon source than conventional nitrification/denitrification processes. With partial nitritation and deammonification, the requirement for oxygen is 60 percent less and demand for an external carbon source is nearly 90 percent less than the conventional nitrification and denitrification (see Chap. 15).

When partial nitritation and deammonification is used for sidestream treatment and the main treatment process is also designed for nutrient removal, the use of external carbon in the sidestream treatment may be eliminated and the remaining nitrate treated in the main stream process, which will simplify the chemical dosing system for the sidestream treatment. While the application of this process is predominantly for the treatment of recycle flow with high ammonium concentration, studies are ongoing to apply the process for the treatment of main stream wastewater at ambient temperatures (Al-Omari et al., 2012).

Reduced Energy Usage through the Use of Alternative Treatment Processes

Future treatment process flow diagrams will incorporate alternative biological processes as well treatment without biological processes to achieve more effective reduction and utilization of the energy in wastewater. Examples of alternative approaches are illustrated on Fig. 17–22. With advances in treatment technologies, a number of alternative approaches are expected to emerge.

Anaerobic Treatment at Ambient Temperature. Anaerobic processes which were discussed in detail in Chap. 10 are in general less energy intensive than aerobic processes as they do not require aeration for the bulk removal of bCOD. Anaerobic processes also generate biogas containing methane which could be recovered and used for heat and power generation. In the future, it is anticipated that treatment process flow diagrams will be developed for the anaerobic treatment of wastewater at ambient temperature (McCarty, 2011).

Use of Trickling Filters for Treatment of Filtered Wastewater. Another example of an alternative treatment process flow diagram involves the use of a cloth screen for primary treatment followed by a filtration step as discussed above. The filtered effluent could be applied directly to a tricking filter in a single stage, or two stage process where nutrient removal is an issue. A sedimentation tank would not be needed following the trickling filter as the small amount of residual solids could be removed, if needed, with a high-rate filtration process (Koltz, 1985).

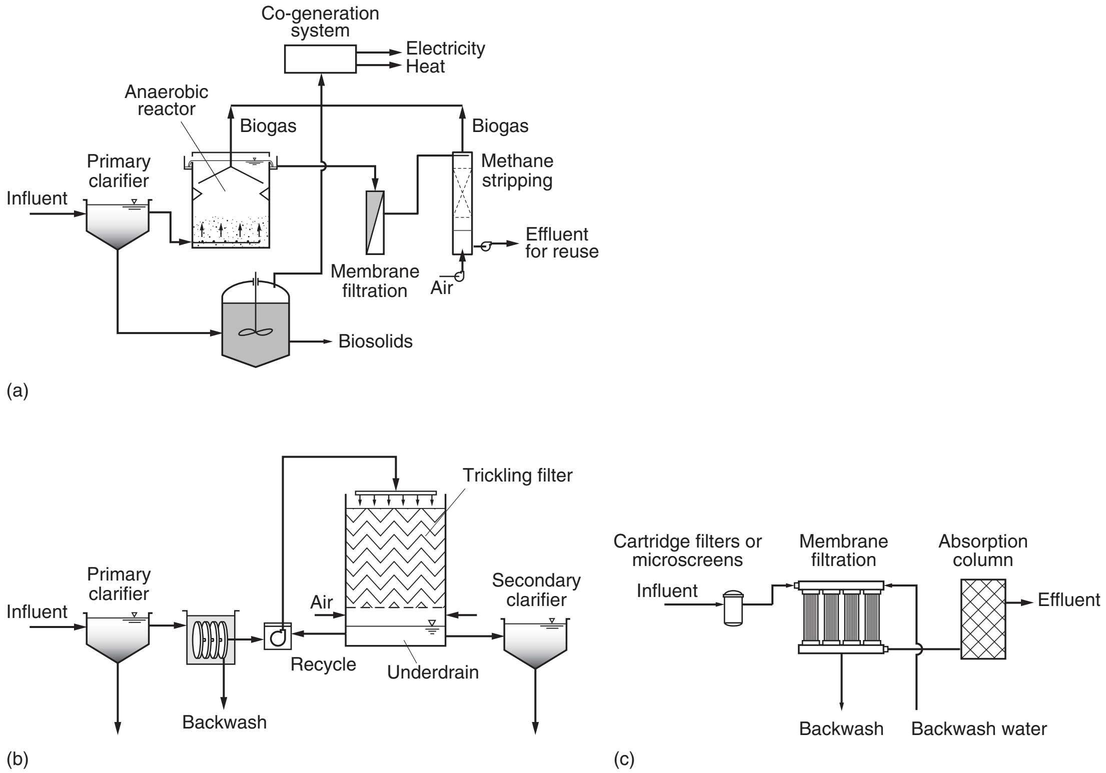


Figure 17–22

Process flow diagrams of alternative wastewater treatment processes: (a) anaerobic treatment at ambient temperature (adapted from McCarty, 2011), (b) trickling filter for treatment of filtered wastewater, and (c) membrane absorption process.

Membrane-Absorption Process. It is also anticipated that processes will be developed to treat wastewater that will not employ biological treatment. Filtered wastewater, as discussed above, could be processed further with a variety of different membranes. Any residual organic matter passing the membrane could be removed by adsorption. In turn, the adsorbed organic matter could be digested or processed thermally (Adams et al., 2011).

Prospects for the Future

The key to thinking about alternative treatment processes is that the technologies available currently, or under development, will make it possible to alter the characteristics of wastewater to optimize any given treatment process while maximizing the recovery and utilization the energy in wastewater.

PROBLEMS AND DISCUSSION TOPICS

17–1 Review three current (since 2005) peer-reviewed articles on co-digestion of wastewater sludge and food waste. Summarize the key findings with respect to increased gas production. Discuss the obstacles/challenges with implementation of co-digestion based on your review.

17–2 Given the following summary information for a wastewater treatment plant, determine the benchmark score for this treatment plant using the AWWARF methodology described in Sec. 17–4. Calculate the benchmark score for 30, 60, and 100 percent use (value to be selected by instructor) of biogas to offset natural gas use. Assume LHV of 35 MJ/m^3 for natural gas, 22 MJ/m^3 for digester gas.

Parameter	Unit	Value
Flowrate (annual average/design capacity)	10^3 m^3/d	24/30
Influent BOD	mg/L	120
Influent ammonium	mg N/L	24
Influent total nitrogen	mg N/L	36
Effluent BOD	mg/L	6.2
Effluent ammonium	mg N/L	2.1
Effluent total nitrogen	mg N/L	5.5
Energy use		
Electricity	kWh/y	3,600,000
Biogas production	m^3/y	605,000
Biogas used	m^3/y	0
Natural gas	m^3/y	372,700

17–3 Using the data presented in Example 17–5 for a wastewater treatment facility, calculate the benchmarking score when all biogas is utilized to generate electricity and heat is recovered to offset natural gas use. Assume typical energy efficiencies for CHP as reported in Table 17–8.

17–4 A wastewater treatment facility receives raw wastewater at an average flowrate of 7500 m^3/d, with a velocity of 1.5 m/s, and a pressure head of 2.5 bar. Identify the type of hydroturbine that could be used to generate electricity using the incoming raw wastewater, and estimate the potential power generation. Use Fig. 3–14 to estimate the peaking factor and Fig. 17–19 to estimate the average efficiency at the average flowrate when the turbine is sized for the peak flowrate. Discuss potential operational issues in using raw wastewater for hydraulic turbine.

17–5 Calculate the heat balance for sludge combustion assuming the following solids composition (to be selected by instructor). Use the procedure presented in Example 17–6.

	Sample constituent composition, % by wt		
Element	1	2	3
Combustible			
Carbon	13.3	18.9	15.0
Hydrogen	0.9	1.3	1.2
Oxygen	4.9	6.9	5.3
Nitrogen	0.3	0.4	0.3
Sulfur	0.4	0.5	0.4
Inerts	8.3	11.9	7.8
Water	72	60	70
Total	100	100	100

17–6 Determine the coefficient of performance for the heat pump as well as the entire system and the wastewater flowrate necessary to provide the heating requirement based on the information summarized in the table below (to be selected by instructor).

Parameter	Unit	Value
Heating requirement (value to be selected by instructor)	kW	(1) 200 (2) 240 (3) 280
Heat pump electrical input	kW per kW output	0.24
Wastewater temperature	°C	15
Temperature drop through heat exchanger	°C	5
Total power requirements for pumps (value to be selected by instructor)	kW	(1) 40 (2) 45 (3) 50

17–7 For Problem 17–6 above, discuss benefits and potential issues to extract heat from raw wastewater in the collection system, instead of the wastewater effluent, for district heat supply in a small commercial area.

17–8 For Example 17–10 and Example 8–3 in Chap. 8, the treatment process operated at the design capacity is upgraded with a primary effluent filtration device between primary clarifiers and activated sludge process, and BOD loading to the activated sludge process was reduced by 20, 30, or 40 percent (value to be selected by instructor). Calculate the air requirement and aeration power demand for the same COD removal without nitrification process. Assume the DO set point is 2.0 mg/L.

17–9 The wastewater treatment plant in Example 8–3, designed for BOD removal, is currently operating at 60 percent of its capacity. The municipality is experiencing lower population growth in the service area as compared to the projected growth when the treatment plant was designed and built. As part of an integrated resource recovery scheme being studied by the municipality, you are asked to determine if implementing the use of kitchen food waste grinders in residential homes will result in saving energy. It is projected that installation of food waste grinders will result in 600, 1000, or 1200 kg/d (value to be selected by instructor) increase in biodegradable COD loading, of which 75 percent will be captured as primary sludge, and 20 percent will be treated in the activated sludge process. Primary sludge is transferred to anaerobic digestion to produce biogas.

a. Determine the aeration power demand at 60 percent loading.

b. Estimate the increased aeration power demand if the use of food waste grinders was implemented.

c. Determine the increase in digester gas production if food waste grinders were implemented (assume anaerobic digester has sufficient capacity)

d. Assuming 45 percent engine efficiency and 93 percent generator efficiency, determine whether the implementation of food waste grinders will result in overall energy saving.

For simplicity, ignore the increased biomass and biogas production from WAS and the corresponding energy savings from heat recovery in the calculations.

17–10 A wastewater pump station is used to transfer 20,000 m^3/d screened raw wastewater from a wet well to an aerated grit chamber. The pump station contains three pumps. Two pumps are used continuously and one pump serves as a standby, with an on/off control. Discuss potential changes to the pump system that can be made for energy conservation and explain how the savings are achieved.

Wastewater Management: Future Challenges and Opportunities

WORKING TERMINOLOGY

Term	**Definition**
Climate change	Significant change in measures of climate such as temperature, precipitation or wind, lasting for an extended period of time (decades or longer).
Decentralized (satellite) treatment system	System used for the treatment of wastewater located close to the point of reuse. Satellite treatment plants generally do not have solids processing facilities; solids are returned to the collection system for processing in a central treatment plant located downstream. Three types of satellite systems are identified: (1) interception type, (2) extraction type, and (3) upstream type.
Direct potable reuse	The introduction of purified water either directly into the potable water supply distribution system downstream of a water treatment plant, or into the raw water supply immediately upstream of a water treatment plant.
Histogram	A graphical representation of the frequency with which an event occurs over a range of different conditions.
Indirect potable reuse	The planned incorporation of purified water into a raw water supply, such as in potable water storage reservoirs or a groundwater aquifer, resulting in mixing, dilution, and assimilation, thus providing an environmental buffer.
Linear correlation	The linear relationship between two variables.
Low impact design (LID)	A design approach that protects surface and ground water quality, maintains the integrity of aquatic living resources and ecosystems, and preserves the physical integrity of receiving streams with designs that are in harmony with nature.
Natural disasters	Extreme sudden natural events such as floods, tornadoes, hurricanes, heat waves, or droughts that injure people and damage property.
NPDES	The National Pollution Elimination Discharge System (NPDES) was established based on uniform technological minimums with which each point source discharger has to comply.
Pareto analysis	A statistical decision making technique to select a limited number of tasks or variables that will result in a significant overall impact.
Pilot plant studies	Studies conducted at test beds at a scale larger than bench-scale, to establish the suitability of a process in the treatment of a specific wastewater under specific environmental conditions and to obtain data that can be used for full-scale design and operation.
Population demographics	The study of populations based on statistics such as economics; migration patterns; and birth, deaths, and disease.
Potable reuse, direct	See Direct potable reuse.
Potable reuse, indirect	See Indirect potable reuse.
Privatization	Private sector ownership and operation of facilities and services used by government entities in performing their public function.
Satellite treatment system	See decentralized treatment.
Sustainability	The principle of optimizing the benefits of a present system without diminishing the capacity for similar benefits in the future.
Triple bottom line	Project analysis in which profit (economics), people (social) and planet (environment) are considered equally.
Uncontrollable events	Events in nature beyond the control of humans, such as tornadoes and hurricanes.
Unintended consequences	Consequences (outcomes) that are not anticipated or intended by a particular action.
Variability, inherent	Based on the laws of chance, all physical, chemical, and biological treatment processes exhibit some measure of variability with respect to the performance that can be achieved. Variability is inherent in biological treatment processes.
Wet-weather flow	The runoff that results when it rains or snows.

The concepts and elements involved in the general design of wastewater treatment plants have been presented and discussed in the previous chapters. The purpose of this chapter is to consider the various concepts and design elements in light of the challenges and opportunities for wastewater management in the future. The topics considered are (1) a general discussion of some important future challenges and sustainability issues, (2) the impact of global and uncontrollable events, (3) upgrading existing treatment plant performance through process optimization, (4) upgrading existing treatment plant performance through process modification, and (5) the management of wet-weather flows. Important future challenges and sustainability issues and the impact of global and uncontrolled events are discussed first because improvements to existing plants as well as the design of new plants must be undertaken in light of these challenges and issues. Wherever possible, reference will be made to the pertinent section and/or chapter where additional information can be found on the individual topics discussed in this chapter.

18–1 FUTURE CHALLENGES AND OPPORTUNITIES

In the twentieth century the primary focus of wastewater treatment was on the removal and treatment of settleable and floatable solids, organic matter expressed as biochemical oxygen demand (BOD), total suspended solids (TSS), and pathogenic microorganisms (see Chap. 1). Late in the twentieth century, nutrient removal and odors also became issues, and controlled, non-potable use of reclaimed water became a common practice in many parts of the world (Asano et al., 2007). In the twenty-first century, as a result of numerous environmental issues and events, a paradigm shift has occurred in how wastewater is viewed. In the twenty-first century, wastewater is no longer viewed as a waste requiring disposal, but as a "renewable recoverable source of energy, resources, and potable water" (Tchobanoglous, 2010; Tchobanoglous et al., 2011). In light of this view of wastewater, it is appropriate to consider briefly some challenges as well as the opportunities that will become increasingly important in the future, including: (1) asset management, (2) the need to design wastewater treatment plants (WWTPs) for the recovery of energy and resources, (3) the need to produce effluent suitable for the production of potable water, (4) the implementation of decentralized (satellite) treatment systems, (5) integrated wastewater management, (6) the use of low impact development, and (7) the use of the triple bottom line for project evaluation. It should be noted that the challenges discussed below are beyond the need to meet more stringent discharge standards for trace organics and residuals processing as discussed in Chap. 4. The impact of global and uncontrollable events on the future of wastewater management is considered in the following section.

Asset Management

With aging infrastructure and reduced funding for repair and replacement, wastewater agencies are exploring a number of different techniques that can be used to prioritize future capital expenditures that will yield the greatest value added for the consumer. Asset management, in its many forms, is one of the techniques now being investigated and applied. The U.S. EPA defines asset management (AM) as "Managing infrastructure assets to minimize the total cost of owning and operating them, while delivering the service levels customers desire" (U.S. EPA, 2012a). The U.S. EPA further reports (U.S. EPA, 2012b) the implementation of AM based decisions have the potential to save 20 to 30 percent of future lifecycle costs within U.S. wastewater utilities and defined strategies and procedures have reportedly shown operational cost savings and more efficient working practices.

Objectives of Asset Management. The principal objective of AM is to develop sufficient information in an organized fashion to support strategic decision making. All agencies conduct some form of AM, but since the late 1990's there has been an increased emphasis on the adoption of more focused approaches that encourage the understanding and reporting of all aspects of the lifecycle of an asset. From the initial conceptual need through to complete implementation, owners can draw from a wide range of proven techniques and available technologies to assist in the design, operation, and maintenance of new and replacement assets. The application of these techniques and technologies rely on the collection and analysis of data that enable the owner to analyze a range of performance metrics to support strategic decision making.

Practice of Asset Management. To date, the most widespread development and implementation of AM has been in Australia, New Zealand, and the UK where the performance of all aspects of the water and wastewater industries are more closely regulated. From the experience gained in these countries, it is clear that although it takes a number of years to see true financial returns, there are very real benefits by adopting more advanced AM techniques. While regulatory requirements in the United States do not require the implementation of AM, many agencies including WEF, AWWA, and the Association of Metropolitan Water Agencies (AMWA) have taken a lead role in promoting AM. The U.S. EPA continues to blend education of the principles and tools, with a formal need for implementation as a component of compliance regulations for individual agencies and owners.

Asset Management Methodologies. There are many AM techniques and technologies and it is beyond the scope of this text to discuss each of them adequately. Numerous publications are available to provide guidance but the fundamental core is in understanding the required performance from an asset and being able to operate and maintain the asset cost-effectively. In general, AM techniques include (1) developing an asset inventory, (2) assessment of the condition of asset, (3) determining the level of service to be provided, (4) identifying the critical asset to sustain the performance, (5) determining the cost for the entire life cycle of the asset, and (6) determining the best long-term strategy. Agencies that have a mature understanding of AM will likely have a better understanding of the condition and remaining life of their infrastructure and of the best maintenance methodologies. This level of knowledge can prove to be beneficial as agencies, with such an approach, are considered to be well managed businesses. Information on AM is also needed to justify funding either to customers, financial institutions, or within their own organization.

Ramifications of Asset Management. While much of the current focus of AM is related to existing infrastructure, it is clear that the lifecycle of every asset is significantly influenced by the decisions that are made at the concept and design stages. The designer has the opportunity to determine the optimum performance of the asset while considering criteria relevant to operations and maintenance. The correct combination of these interrelated factors will enable the end user to derive the most benefit with assets that provide the anticipated levels of service with reduced operations, maintenance, and energy costs.

While the principles of AM are considered by many to be the most effective way to manage infrastructure, there are many organizations in the United States that are still in the early stages of developing suitable approaches. Organizations that have adopted more advanced AM methodologies are however seeing benefits both in terms of performance levels and financial management. It is clear, therefore, that a more defined implementation of AM should be considered for all aspects of infrastructure management from the development and justification of need, to the ultimate disposal.

Design for Energy and Resource Recovery

The chemical and heat energy content of wastewater has been delineated and discussed previously in Chaps. 2, 14, and 17. As noted in the earlier discussions, wastewater treatment plants could potentially become net exporters of energy, and especially so if external sources of energy contained in food waste and fats, oils, and grease are included. The challenge in the future is how to extract the energy in wastewater most effectively. For example, food waste could be ground up in kitchen food waste grinders and transported to the wastewater treatment facilities in the collection system, or it could be intercepted at various upstream locations and extracted from the wastewater using a micro- or clothscreen such as described in Sec. 5–9 in Chap. 5. The solids removed from the wastewater could be placed directly in an anaerobic digester. Alternatively, conventional aerobic treatment processes could be replaced with ambient-temperature low hydraulic retention time anaerobic treatment processes (McCarty, 2011). Heat recovered from wastewater could be used for drying screenings as well as in other applications, especially in the processing of biosolids. The key concept here is to think about how the characteristics of wastewater could be altered to enhance the recovery of energy from wastewater.

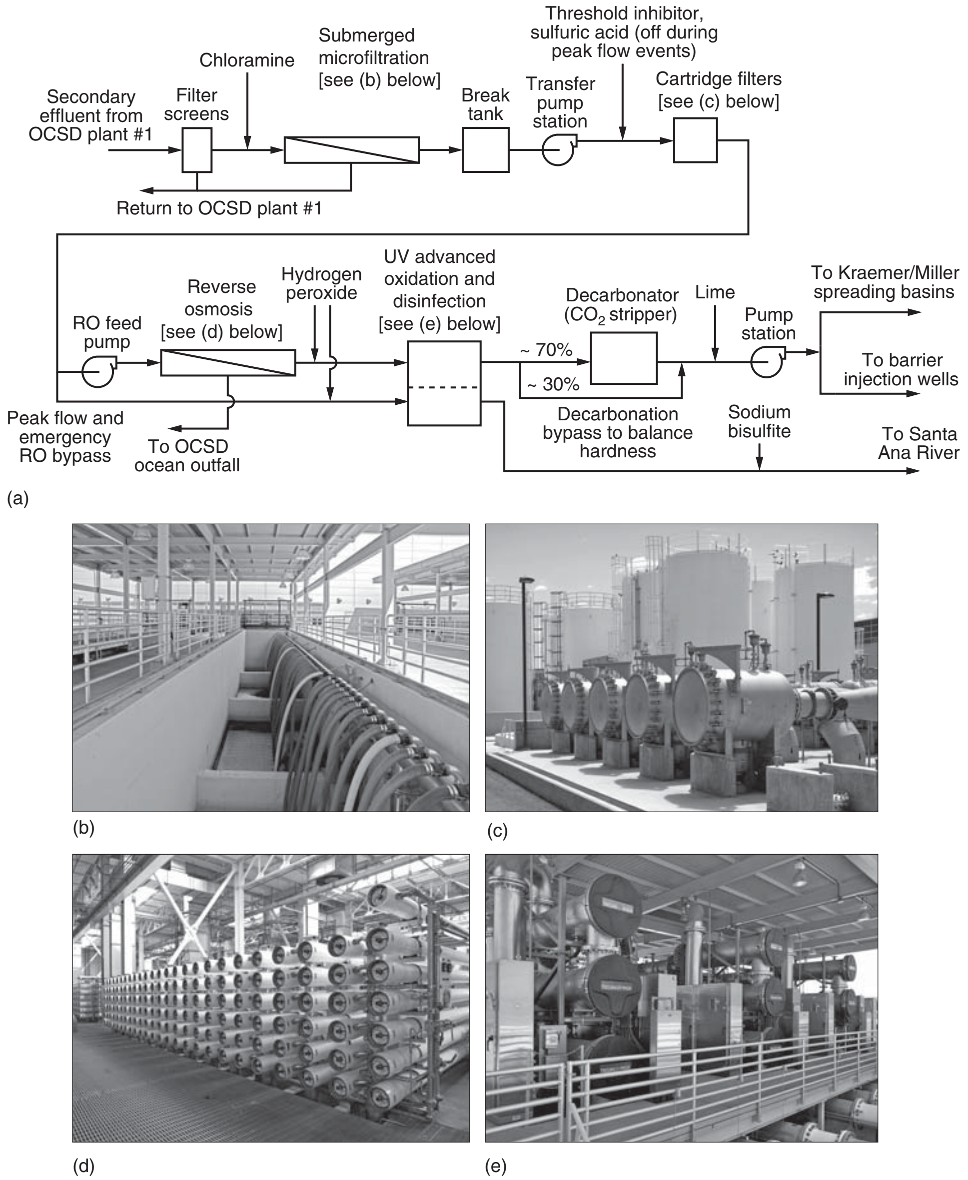
In the future, the recovery of resources from wastewater will occur simultaneously with the recovery of energy. To date, the removal of nitrogen and phosphorus has received the greatest attention as nitrogen and phosphorus discharge standards have become more stringent. The option of recovering, rather than simply removing, these constituents has became economically feasible, especially from return flows. Biological phosphorus removal was considered in Sec. 8–8 in Chap. 8. The recovery of nitrogen and phosphorus in the form of struvite is considered in Sec. 6–5 in Chap. 6 and Sec. 15–4 in Chap. 15. The recovery of nitrogen as ammonium sulfate is considered in Sec. 15–5 in Chap. 15. The recovery of resources from fly ash following combustion is considered in Sec. 14–4 in Chap. 14. The recovery of nutrients including nitrogen, phosphorus, and potassium from urine (see Table 3–15 in Chap. 3) is another resource recovery opportunity that has received considerable attention, especially in Europe and Australia. What role urine separation will play in the United States remains to be seen. Clearly, finding the optimum cost and energy-effective approach for the recovery of resources, coupled with the recovery of energy and potable water from wastewater will be a major challenge in the future.

Design of Wastewater Treatment Plants for Potable Reuse

As a result of population growth, urbanization, and climate change, public water supplies are becoming stressed, and the chances of tapping new water supplies for metropolitan areas are getting more difficult, if not impossible. As a consequence, existing and new water supplies must go further. One way to achieve this objective is by increased water reuse, particularly in supplementing municipal water supplies by means of indirect or direct potable reuse (IPR or DPR) (Leverenz et al., 2011; Tchobanoglous et al., 2011). As a result of the development and demonstration of full-scale advanced treatment processes (see Fig. 18–1), the use of purified water that has been recovered from municipal wastewater directly for potable purposes is now considered to be a viable alternative (NRC, 2012). It is also recognized that there is a continuum of possibilities. The challenge for the future is how to design or upgrade treatment plants so that the effluent produced will be

Figure 18–1

Advanced water treatment facility at the Orange County Water District, Fountain Valley, CA: (a) schematic flow diagram for 2.65×10^5 m^3/d (70 Mgal/d) advanced water treatment facility, (b) microfilters, (c) cartridge filters, (d) reverse osmosis module, and (e) advanced UV oxidation reactors.



suitable for the production of purified water. Technical issues involved in the implementation of potable reuse are identified in Table 18–1.

When considering wastewater treatment plants for potable reuse, a key question is, what should the treatment plant of the future look like? In examining existing treatment process flow diagrams for IPR and DPR, it can be concluded that the production of purified water for DPR was an afterthought. Basically, additional unit processes were tacked on to the end of the existing secondary treatment process flow diagrams to remove specific compounds. However, at some point in the future there will need to be a complete rethinking of urban infrastructure to obtain the highest levels of performance and reliability. For water and wastewater systems, the advanced infrastructure model will likely include decentralization (also known as distributed), remote management, resource recovery, source separated waste streams, and application of specific optimization of water quality.

Table 18–1

Technical issues in the implementation of potable reuse

Consideration	Comments / questions
Source control	• Identification of constituents that may be difficult to remove (depends on technologies used) • Development of baseline sources and concentrations of selected constituents • Define the improvements that need to be made to existing source control programs where DPR is to be implemented
Influent monitoring	• Development of influent monitoring systems, including constituents, parameters, and monitoring recommendations • Investigate potential benefits of various influent monitoring schemes that may be used for early detection of constituents • Consideration of how influent monitoring data could be used to adapt treatment operations depending on variable influent characteristics
Flow equalization	• Determination of the optimum location and type (inline or offline) in secondary treatment process with respect to enhanced reliability and removal of trace constituents • Determination of optimum size of flow equalization before advanced treatment • Quantify the benefits of flow equalization on the performance and reliability of biological and other pretreatment processes
Wastewater treatment	• Quantify benefits of optimizing conventional (primary, secondary, and tertiary) processes to improve overall reliability of entire system • Quantify the benefits of complete nitrification or nitrification and denitrification on the performance of membrane systems used for DPR applications
Performance monitoring	• Determine monitoring schemes to document reliability of treatment performance for each unit process and validate end-of-process water quality
Analytical/monitoring requirements	• Selection of constituents and parameters that will require monitoring, including analytical methods, detection limits, quality assurance/quality control methods, and frequency • Determination of how monitoring systems should be designed in relation to process design • Development of appropriate monitoring systems for use with alternative buffer designs
Advanced wastewater treatment (water purification)	• Develop baseline data for treatment processes employing reverse osmosis. OCWD can be used as a benchmark • Development of alternative treatment schemes with and without demineralization that can be used for water purification • Quantify benefit of second stage (redundant) reverse osmosis
Engineered storage buffer	• Development of sizing guidelines based principally on existing analytical, detection, and monitoring capabilities to assess technical and economic feasibility of utilizing engineered storage buffer • Characterize the impact of existing monitoring response times on the safety and economic feasibility of implementing an engineered storage buffer
Balancing mineral content	• Development of recommendations for balancing water supply mineral content in consideration of site-specific factors, such as magnesium and calcium • Determination of potential impacts of various water chemistries on infrastructure and public acceptance • Development of specifications for chemicals used for balancing water quality

(*continued*)

Table 18–1 (*Continued*)

Consideration	Comments / questions
Blending	• Development of guidance on what level of blending, if any, is required based on the quality of the purified water and alternative water sources • Investigation of the significance of and rationale for blend ratios in terms of engineered buffer, protection of public health, public acceptance, and regulatory acceptance • Investigation of potential impacts of purified water on drinking water distribution system, e.g., corrosion issues, water quality impacts, etc.
Emergency facilities	• Stand-by power systems in the event of power loss or other emergency • Availability of all replacement parts and components that would be required in the event of a process breakdown • Process redundancy so that treatment trains can be taken offline for maintenance • Facilities for the by-pass or discharge of off-spec water in the event that the water does not meet the established quality requirements
Pilot testing	• Utilization of a review panel for advice and recommendations on the design, operation, monitoring plan for a project's pilot system to ensure that it will be representative of the proposed full-scale system • Development of monitoring protocol for collection of baseline data for "raw" water input to AWT pilot plant; how much testing and for what duration (e.g., 6 mo to 1 y). • Development of pilot study design so that results can be used to assess reliability with proposed source water

From Tchobanoglous et al., (2011).

What is needed is the development of integrated water management systems in which new wastewater treatment plants are planned and designed from the ground up to optimize treatment performance with respect to the production of purified water, along with the recovery of energy and resources.

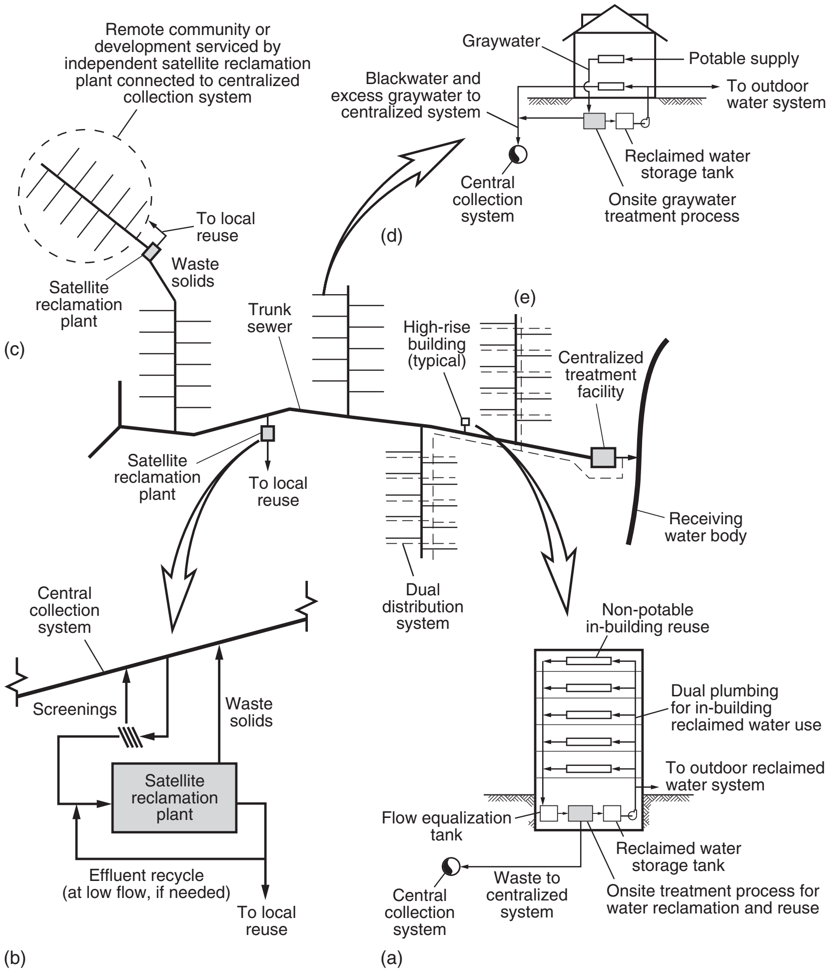
Decentralized (Satellite) Wastewater Treatment

In most collection and treatment systems, wastewater is transported through the collection system to a centralized treatment plant located at the downstream end of the collection system near the point of dispersal (disposal) to the environment. Because centralized wastewater collection systems are generally arranged to route wastewater to these remote locations for treatment, water reuse in urban areas is often inhibited by the lack of a dual distribution system (i.e., purple pipe). The infrastructure costs for storing and transporting reclaimed water to the points of use are often prohibitive, thus making reuse uneconomic. An alternative to the conventional approach of transporting reclaimed water from a central treatment plant is the concept of decentralized (satellite) treatment at upstream locations with localized reuse and/or the recovery of wastewater solids.

Decentralized wastewater systems are used to treat wastewater at or near the point of waste generation and reuse (see Fig. 18–2). Decentralized treatment plants generally do not have solids processing facilities; solids are returned to the collection system for processing in a central treatment plant located downstream. Individual decentralized systems can be used for water reclamation and reuse for applications such as landscape irrigation, toilet flushing, cooling applications, and water features. Use of decentralized systems is predicated on the assumption that the existing collection system can be utilized for the

Figure 18–2

Schematic illustration of four types of satellite water reclamation systems: (a) interception type where wastewater to be reclaimed and recycled is intercepted before discharge to a centralized collection system, (b) extraction type (i.e., sewer mining) in which wastewater is extracted (i.e., pumped) from a centralized collection system for local reuse, (c) upstream type for treatment and reuse for a remote community or development with solids discharged to a centralized collection system, and (d) satellite system for individual home.



transport of solids and reduced flow. Onsite reclamation systems may obviate the need for large-scale dual piping systems, which are generally prohibitively expensive in urbanized areas and reduce the need to expand existing treatment plants to meet future growth projections. Two notable examples of the use of decentralized wastewater treatment systems are in the Los Angeles, CA area as illustrated on Fig. 18–3. Both the City of Los Angeles and the County Sanitation District's of Los Angeles County upstream treatment plants discharge screenings and biological solids to the large treatment plants located near the ocean where the treated effluent is discharged. The implementation of decentralized wastewater treatment will require a new approach to the management and reuse of wastewater (Tchobanoglous and Leverenz, 2013).

Low Impact Development

Low impact development (LID)(also known as low impact design) is a concept that has been applied to the management of wet-weather flow. With respect to the management of wet-weather flows, the goal of LID is to control both rainfall and stormwater runoff, at or near the source. Both engineered and vegetated natural systems are utilized to filter the rainfall runoff and replenish groundwater locally through infiltration (see Fig. 18–4).

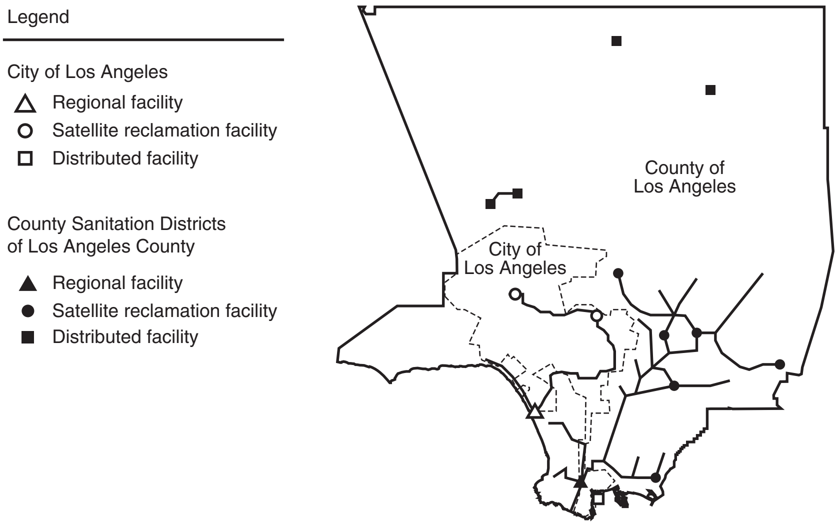


Figure 18–3

Diagram of satellite and centralized treatment systems in the City of Los Angeles and the County Sanitation Districts of Los Angeles County. Waste solids from the upstream plants are processed at the main downstream plants.

It should be noted that interventions such as the use of rain barrels, cisterns, vegetated roof covers, rain gardens, porous pavements, and grassed swales are all part of the LID strategy. By retaining and infiltrating a portion of the runoff, the quantity of flow discharged to stormwater or combined wastewater collection systems can potentially be reduced substantially.

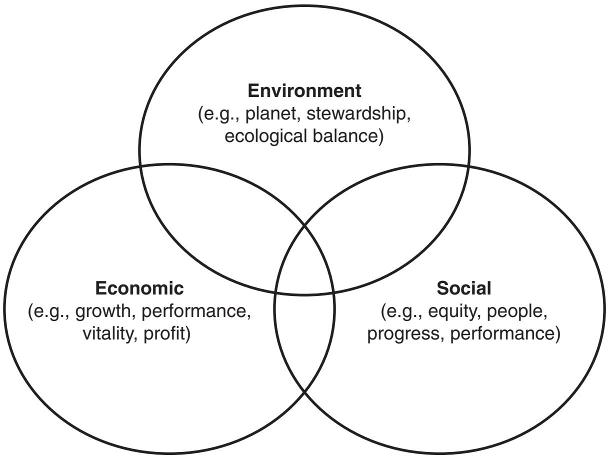
The effectiveness of LID will depend on the nature of the community and the magnitude of the rainfall event. For example, because the City of San Francisco is essentially built out, the impact of LID in terms of flowrate reduction has been relatively minimal

Figure 18–4

Typical examples of landscaping designed to limit the effects of wet weather flows: (a) swale, (b) around treatment unit, (c) open area at treatment plant, and (d) roadway runoff capture.

Figure 18–5

Relationship of the elements involved in the triple bottom line method of analysis.



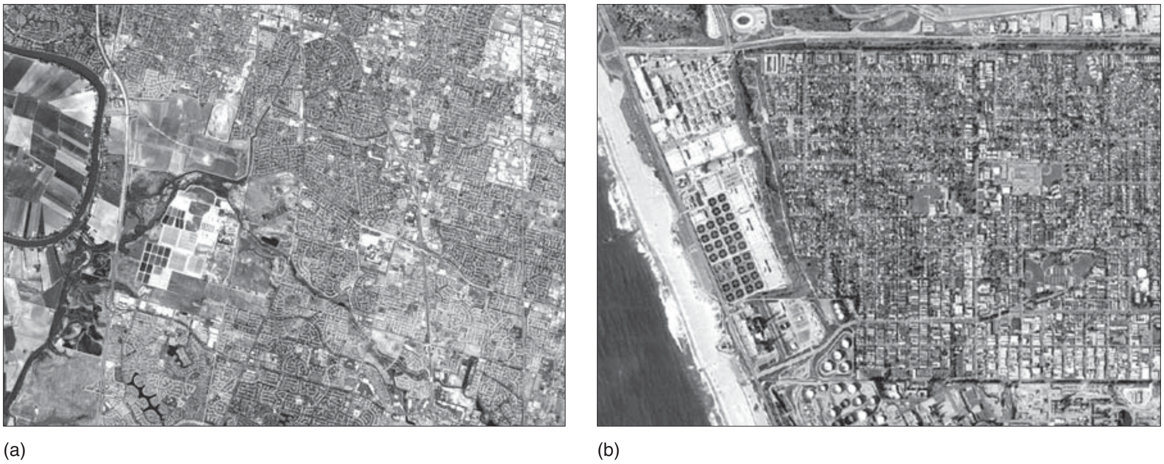
(e.g., on the order of two to five percent). Yet in other cities, flowrate reductions as high as 20 percent have been reported. With some of the recent record (extreme) rainfall events, the impact of LID has been difficult to assess. The challenge is how to integrate LID most effectively into the management of wastewater. Some notable examples in the form of case studies have been reviewed by the U.S. EPA (2010).

Triple Bottom Line

The *triple bottom line* refers to a method of analysis in which engineers are encouraged to consider social and environmental bottom lines in addition to the financial bottom line in arriving at the most sustainable solution (see Fig. 18–5). While the concept is laudable, in practice it has proven to be difficult to implement uniformly. Assessing the pluses and minuses of the financial aspects of a project has proven to be much easier than assessing the social and environmental pluses and minuses. In practice, to implement social and environmental bottom lines effectively, dollar values must be assigned to the corresponding benefits and drawbacks. If dollar values cannot be assigned, social and environmental concerns must be considered even though they will have little practical impact on project implementation beyond the normal concern for these issues incorporated into any project analysis. The challenge moving forward is how to best incorporate the concepts embodied in the triple bottom line analysis in project planning, design, and implementation.

18–2 IMPACT OF POPULATION DEMOGRAPHICS, CLIMATE CHANGE AND SEA LEVEL RISE, UNCONTROLLABLE EVENTS, AND UNINTENDED CONSEQUENCES

In addition to the identifiable causes of the variability observed in the treatment of wastewater as described in Chap. 3 and 4, a number of other global and local events now routinely impact the design and operation of wastewater treatment plants (WWTPs). Four such event categories are considered in the following discussion: (1) the impact of population demographics, (2) the impact of climate change and sea level rise, (3) the impact of uncontrollable events, and (4) the impact of the law of unintended consequences. Consideration of these topics is especially important in meeting the challenges and sustainability issues identified in the previous section.



(a)
(b)

Figure 18–6

Impact of urbanization on wastewater treatment plants: (a) inland location, Sacramento, CA (coordinates 38.439 N, 121.480 W, view at altitude 10 km) and (b) coastal location, Los Angeles (coordinates 33.923 N, 118.429 W, view at altitude 2.75 km).

Impact of Population Demographics

Population demographics will continue to impact existing and future of WWTPs in a variety of ways including the impact of urban spread and urbanization along coastal areas.

Impact of Urban Spread and Higher Density Housing. Since the early twentieth century, treatment plants have typically been located at some remote location, distant from the city they serve, where the wastewater would flow by gravity and near some water body that could be used as to receive the treated wastewater. In some cases, pumping was required. What has happened in the 50 to 100 intervening years is that urban spread has essentially encircled most of these early WWTPs (see Fig. 18–6). Urbanization, especially near the boundaries of the WWTPs, has often resulted in a number of diverse complaints about the WWTPs, including odors, noise, excess birds, unsightly vistas, and truck traffic, among others. As a result, a number of corrective measures have had to be implemented to deal with citizen complaints. Perhaps the most common intervention has been to cover open treatment tanks and to install odor management facilities (see Fig. 18–7). Scheduling truck deliveries in off hours has been used in a number of locations. Moving forward, care must be taken to identify and deal with citizens issues and concerns both in building new WWTPs and in upgrading existing WWTPs.

Along with urbanization, higher density housing will be necessary to accommodate anticipated population growth, especially along coastal areas as described below. Although, higher density housing poses a variety of infrastructure challenges, it also offers new opportunities to implement cost-effective decentralized wastewater treatment plants and localized reuse. As discussed previously, treatment plants located in high-density urban areas could be either of the interception or extraction type, as illustrated on Fig. 18–2. In many cases, it may make more sense to integrate extraction type treatment facilities in upscale apartment buildings, as now done in New York City (e.g., the apartment buildings in the Battery Park area of New York City are classic examples). The challenge is to develop a rational cost-effective plan for co-locating high-density housing and wastewater treatment plants.

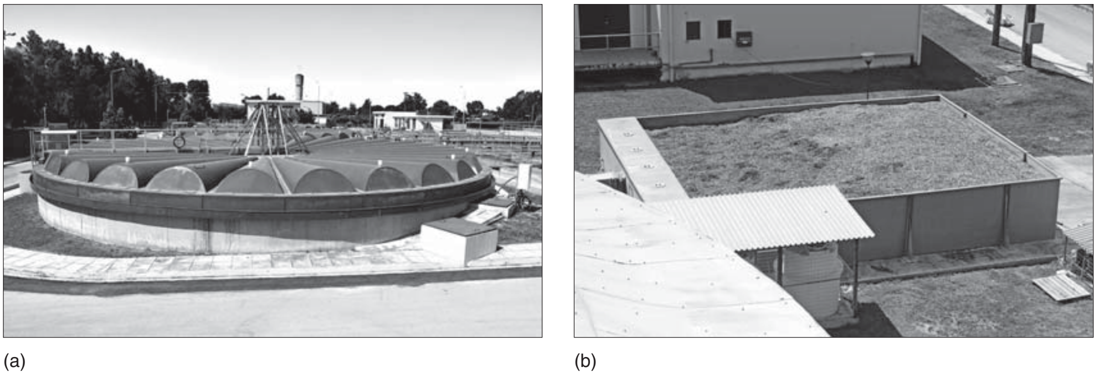


Figure 18–7

Typical odor control facilities for new and existing wastewater treatment plants: (a) covered primary sedimentation facilities (b) compost filter for odor control for odorous gases from covered primary sedimentation tanks.

Urbanization Along Coastal Areas. Currently, about 50 percent of the population of the United States lives within 80 km (50 mi.) of a coastal area; about the same ratio applies worldwide. Worldwide it is projected that up to 60 percent of the world's population will live near coastal areas by 2025 to 2030. The implications for water resources management of such a population shift from rural to coastal areas are significant. For example, withdrawing water from inland areas, transporting it to coastal population centers, treating and using it once, and then discharging it to coastal waters is, in the long run, unsustainable. Clearly, wastewater must be reused if the accumulation of large populations along coastal areas is to remain a viable option.

Although irrigation with treated wastewater has been occurring for decades, it is reaching logistical and economic constraints. In general, agricultural irrigation with reclaimed water is not feasible for most cities due to the long distance between the large sources of recycled water (e.g., coastal cities) and the major agricultural demand (rural areas). Further, the cost and disruption to construct a separate pipe system to convey recycled water back to agricultural areas and the need to provide winter water storage facilities are significant impediments for agricultural reuse. Thus, if significant amounts of wastewater are to be reused, the solution is to implement either IPR or the DPR of purified water in the existing water distribution system (see Fig. 18–8). In the future, because it is inevitable that DPR will become part of the water management portfolio, it is important that water and wastewater agencies begin to develop the necessary information that will allow DPR to become a reality (Haarhoff and van der Merwe, 1995; Leverenz et al., 2011; Tchobanoglous et al., 2011).

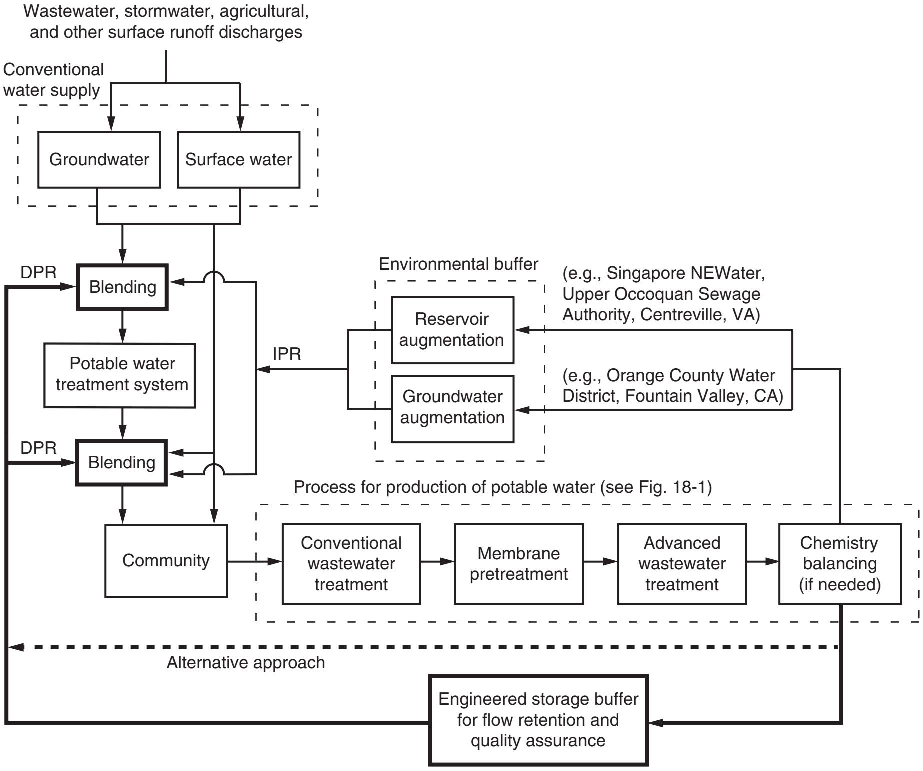
Impact of Climate Change and Sea Level Rise

Climate change and sea level rise have already had an impact on wastewater management facilities, but moving forward, even greater impacts should be anticipated and must be accounted for in the planning, design, and implementation of wastewater management facilities. Examples of the impacts of climate change and sea level rise that must be considered are reviewed in the following discussion.

Climate Change. The most immediate impacts of climate change are reflected in increased temperature, increased evaporation rates, earlier snowmelt, and reduced or increased

Figure 18–8

Definition sketch for direct and indirect potable reuse. The bold solid line corresponds to a system in which an engineered storage buffer is used to replace the environmental buffer used for indirect potable reuse. The bold dashed line corresponds to a DPR system in which an engineered storage buffer is not used. (Adapted from Tchobanoglous et al., 2011.)



rainfall events. Although the number of rainfall events has decreased in a number of locations, the intensity of rainfall events has increased. While the impacts of climate change on the water sector are perhaps most severe, the impacts of extreme rainfall events on wastewater management systems have also been significant, including (1) extreme flooding events, exceeding the capacity of the existing collection systems; (2) increased pumping costs; (3) the discharge of untreated stormwater runoff; (4) damage to collection system infrastructure; (5) flooding of wastewater treatment plants; (6) washout of biological treatment process at treatment plants with limited storage capacity in the collection system; and (7) flows beyond the capacity of the disinfection facilities. The impact of extreme increases in rainfall may necessitate significant increases in peak capacity and/or in system retention. Because such rainfall events can be expected to continue in the future, planning efforts must be undertaken to assess how to best adapt to these changes. Increasing temperatures are also of concern because as the wastewater in the collection system gets warmer, effluent temperature TMDL values may be exceeded. A discussion of the potential costs of adaptation of water and wastewater infrastructure to climate change may be found in NACWA (2009).

Sea Level Rise. Coupled with the effects of climate change, sea level rise has already impacted a number of facilities located on or near coastal areas. A significant impact of sea level rise is that it contributes to increased stormwater flooding along coasts and tidal rivers and estuaries. When tidal surges occur, the discharge from treatment plants located along the path of the surge is often blocked, leading to the release of untreated wastewater. Localized flooding in low lying areas is also exacerbated because stormwater tide-gates cannot open. Because sea level rise also increases the level of sea-water intrusion along with the hydrostatic pressure, the design of facilities for coastal areas must account for these occurrences. Corrective measures that have been considered include the construction of levees and sea walls, raising the elevation of equipment prone to flooding, relocating stormwater discharge locations, pumping effluent through existing gravity outfalls, improvements to the collection system to reduce extraneous flows and, in the extreme, relocating wastewater management facilities.

Impact of Uncontrollable Events

In addition to the future challenges identified in Sec. 18–1 and the impact of demographics, climate change, and sea level rise discussed previously, wastewater treatment plants are subject to the effects of uncontrollable events such as natural disasters and the price of chemicals and supplies.

Natural Disasters. Natural disasters are sudden events such as hurricanes, floods, cyclones, earthquakes, and brushfires caused by natural phenomena that result in the loss of life and extensive property damage. Natural disasters that come to mind readily with respect to their impact on wastewater management facilities are Hurricane Katrina, which occurred in 2005, and the resulting damage to the wastewater management facilities of the city of New Orleans, Louisiana; the string of earthquakes that struck New Zealand in 2011; and Superstorm Sandy that struck the East coast of the United States in 2012. The effects of Katrina were magnified by the tidal surge which breeched the levees that were supposed to protect against flooding. The lesson from Katrina and Superstorm Sandy is that when thinking about natural disasters with respect to the construction of new facilities or upgrading existing facilities, the unthinkable must be thought.

Chemical Costs. The impact of chemical costs that are difficult to control, especially for relatively small wastewater treatment plants, must be considered carefully. In many communities, treatment processes have been abandoned because of increases in the cost of chemicals. Because chemical costs are generally beyond the control of small municipalities, it is important to consider designs that will minimize the need for chemicals.

Impact of the Law of Unintended Consequences

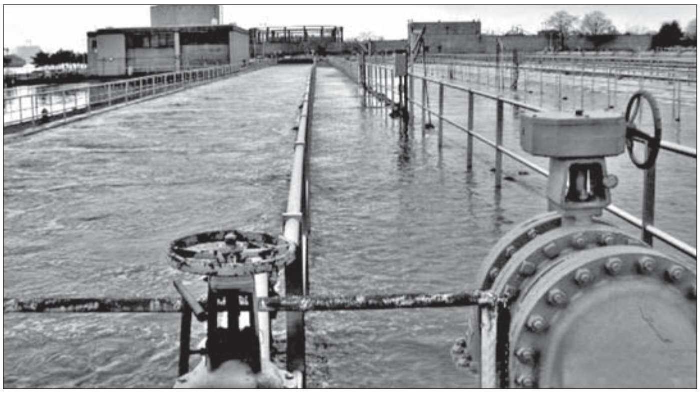
Unintended consequences are outcomes that are not anticipated or intended by a particular action. Even beyond all of the factors considered previously, unintended consequences must be anticipated, as resources and cost for wastewater management become more restrictive. The field of environmental engineering is littered with monuments to the law of unintended consequences. Some examples are considered below.

Treatment Plant Siting. The unintended consequences of locating treatment plants near coastal areas, as described previously, is a prime example of an unintended consequence. When the treatment plants were located originally, little or no thought was given to sea level rise or the subsequent development that would amplify the impact of tidal surges (see Fig. 18–9). To mitigate the unintended consequences will now require the construction of expensive levees or a sea wall and/or the installation of well points to depress the groundwater level or even the possibility of having to relocate one or more of the treatment plants, an unbelievably costly undertaking.

Location of Stormwater Storage Basins. Another example of an unanticipated consequence is related to the stormwater storage basins, located around the periphery of the City of San Francisco. When the storage basins were designed and constructed, the storage basins were equipped with discharge weirs that were located so that they would

Figure 18–9

Flooding at the NYC DEP Bronx WPCP on March 2001. (Courtesy of CU-CCSR and NASA-GISS.)



only be breeched under an extreme rainfall event when the storage capacity of the basins was exceeded (see Fig. 18–10). However, with sea level rise and the subsequent development which channelized the slough to which the basins discharge, flow from tidal surges now overtops the weirs, allowing the seawater to enter the storage basins. The presence of sea water containing high sulfate concentrations has led to excessive hydrogen sulfide corrosion. To remedy the situation, the overflow weirs will have to be raised and pumps will be needed to pump the excess flow. Here again, the designers did not consider the potential impacts of sea level rise or that the subsequent development would amplify the impact of tidal surges.

Water Conservation. In the twenty-first century, water conservation has become a goal for most water and wastewater management agencies. Water conservation is an important element of Leadership in Energy and Environmental Design (LEED) certification. In simple terms LEED is a rating system for buildings. Points can be accumulated for features such as energy conservation, water conservation, water reuse, and mitigation of stormwater. The impact of water conservation, as discussed in Chap. 3, has been significant with respect to wastewater flowrates and constituent concentrations. In the past, per capita wastewater flowrates greater than 450 L/capita·d (120 gal/capita·d) were common. In the not-so-distant future, it is reasonable to assume the per capita flowrates could decrease to below 150 L/capita·d (40 gal/capita·d). Such a decrease would have a

Figure 18–10

Impact of sea level rise on the operation of stormwater storage basins in San Francisco, CA. (Courtesy of City of San Francisco, CA.)

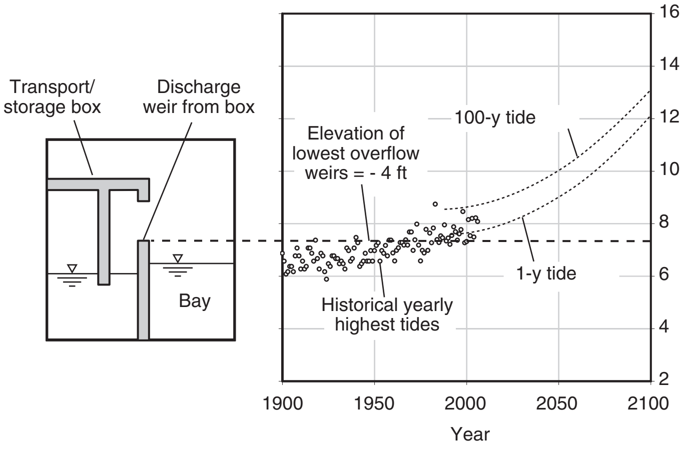


Figure 18–11

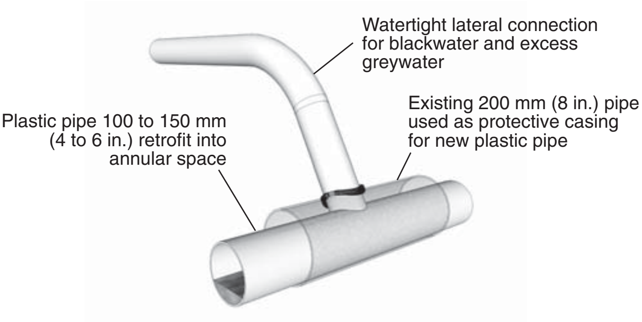
Use of a pipe within a pipe to accommodate reduced wastewater flows from residences.



significant impact on wastewater collection systems with respect to the release of odors, grease accumulations, and hydrogen sulfide corrosion.

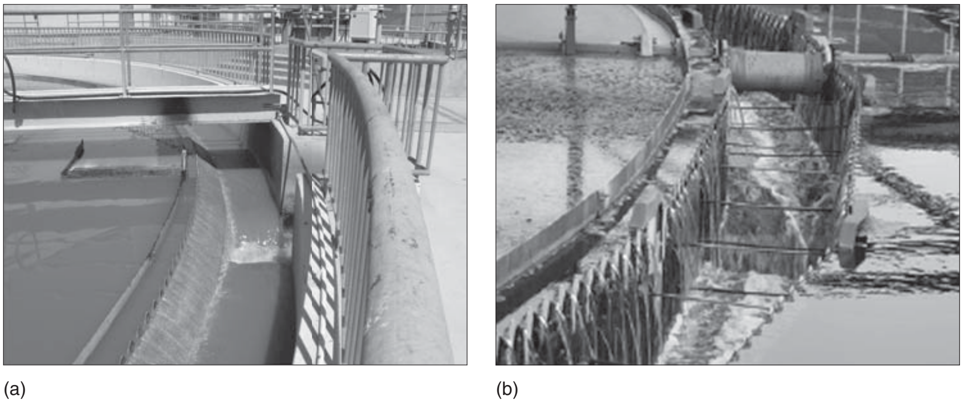
Most wastewater collection systems were designed to be self-cleaning at flowrates on the order of 380 to 450 L/capita·d (100 to 150 gal/capita·d). At reduced flowrates, wastewater solids and grease tend to accumulate and undergo anaerobic decomposition. In general, the release of odors locally has not been a significant problem. However, the transport of hydrogen sulfide by surface water friction has resulted in a significant increase in the rate of corrosion of downstream facilities. In some cities the rate of corrosion has increased by a factor of eight as compared to historic rates of corrosion. Grease accumulations resulting in flow blockages are another important issue associated with reduced wastewater flowrates.

In the future, with reduced rainfall and drought conditions associated with climate change, hydrogen sulfide corrosion and grease accumulation problems will continue to increase and exacerbate the problem of collection system maintenance. One mitigation measure that has been proposed is a pipe within a pipe (see Fig. 18–11). In such an arrangement, a smaller diameter plastic pipe would be placed within an existing collection system. Regardless of the mitigation measures, water conservation will continue to have a number of unintended consequences for the operation and maintenance of wastewater collection systems. Developing workable solutions will be a major change for wastewater management agencies.

Treatment Plant Hydraulics. In the past, when energy was $0.02–0.03/kWh, little attention or effort was devoted to minimizing treatment plant hydraulic headlosses. For example, as illustrated on Fig. 18–12, the water free-fall over the weirs in the primary

Figure 18–12

Examples of excessive headloss at a primary clarifier launder discharge box.



(a)

(b)

sedimentation tank to the collection box is more than 1 m (3.25 ft). Such a large loss of head results from the use of weir equations, based on having a free nappe. With a more nuanced analysis, the free-fall could probably be reduced by 50 percent, or more, resulting in a significant savings in energy when the cost for energy in many location is now approaching \$0.15/kW h, and higher during peak demand periods. In the future, it will be important to revisit all aspects of treatment plant hydraulics to achieve a effective utilization of energy.

18–3 UPGRADING TREATMENT PLANT PERFORMANCE THROUGH PROCESS OPTIMIZATION AND/OR OPERATIONAL CHANGES

Establishing proper control of treatment processes was always considered a primary duty of treatment plant operating personnel. In the past, the criterion of good control and operation was producing an effluent with water quality indicators that on the average did not exceed limits established by a regulatory authority, typically prescribed in a NPDES permit. In the twenty-first century, the operational challenge for existing WWTPs will be to improve treatment performance to meet more stringent discharge requirements, to meet new constituent discharge requirements as discussed in Sec 4–2 in Chap. 4, to minimize the use of resources, and to meet some of the challenges identified in Secs. 18–1 and 18–2.

In recent years, many secondary treatment plants were converted to biological nutrient removal and water reclamation facilities. Some plants are even required to produce an effluent suitable for the subsequent production of potable water. In a number of cases, because of funding limitations for plant expansion, plants operate in excess of their design capacity. At the same time, more emphasis is being placed on operational reliability, and, in some cases, plants are cited and fined for even the slightest violation of water quality standards. Finally, because of the need to improve plant efficiency and reduce capital and operating cost, privatization of facilities construction and operation has entered the wastewater field, resulting in cost competition between public and private operating entities.

Process Optimization

As a result of the social, economic, and technological changes discussed previously and throughout this book, the wastewater treatment plant operating staff is faced with many operational challenges. Often, these challenges can be addressed by optimizing process parameters and operational procedures, modernizing facilities, and retrofitting existing equipment and processes. Development of such improvements usually requires the use of sophisticated tools and protocols, rather than just intuitive approaches. Analysis of plant operating data is a first step in facility evaluation and performance optimization. Utilization of several methods can simplify this analysis including the use of (1) histograms, (2) linear correlation, (3) online process monitoring, (4) computer models, and (5) pilot scale testing. Each of these methods is described in Table 18–2 and expanded upon below. Plant optimization through process modification is considered in the following section.

Use of Histograms. A histogram is a graphical representation of the frequency with which an event occurs over a range of different values for the same variable. An example is the number of times in a year the TSS in the secondary effluent is from 0 to 9.99, 10 to 19.9, 20 to 29.9, and greater than 30 mg/L. Histograms are particularly useful if the

Table 18–2

Methods used to evaluate process performance

Method	Description
Histograms	Graphs displaying frequency of occurrence of parameters such as wastewater characteristics, flow, and cost of chemicals and electricity
Linear correlation	A statistical method used to evaluate data from historical records such as flowrates and water quality parameters
Online process monitoring	Instruments are used continuously or intermittently to record and track important operating parameters such as flowrates, dissolved oxygen concentrations, chlorine residual concentrations, and tank levels. Data from such monitoring can be used to identify trends in operation so that process changes can be implemented before a problem occurs
Computer models	Computer modeling is a useful tool to simulate existing process operations and the effects of possible changes such as modifications to operating strategies or the addition of new equipment or processes
Pilot scale testing	Pilot scale testing is useful in evaluating the performance of new or alternative technologies and in developing criteria that can be used for the design of full scale facilities

frequency of occurrence of undesirable values, such as effluent TSS, is high. Depending on the frequency of occurrence and critical nature of the parameter, significant changes may have to be made to the process operation or perhaps to the process unit infrastructure to achieve correction. Infrequent occurrences of undesirable values often mean that only minor adjustments to operation and maintenance practices may be necessary to achieve the desired results.

Another application of histograms is in establishing the priorities for the tasks that have to be performed to avoid an undesirable event. This type of histogram, called a Pareto chart, represents a graph displaying relative contribution of small problems causing one larger problem. The Pareto chart was named after Italian economist Vilfredo Pareto (1848–1923) who made the famous observation that 80 percent of the world wealth was owned by only 20 percent of people. This principle is valid in many situations and can be equated to process operations, as 80 percent of process problems are due to 20 percent of the causes. Pareto analysis is used to identify those 20 percent that led to majority of process troubles. Analysis includes following four steps:

1. Identifying the causes of a particular problem
2. Determining the frequency of each cause
3. Calculating the percentage of each cause of the total occurrences
4. Plotting the percentage in descending order

Use of a Pareto chart in analyzing the occurrence of tank overflows due to specific causes, such as instrumentation and electrical instrumentation failures, is illustrated on Fig. 18–13.

Use of Linear Correlation. If the relationship between two variables is linear, a linear *correlation* is said to exist. The strength of the relationship is defined by the correlation coefficient, which can vary between -1 to $+1$. Linear correlation is often used to evaluate relationship between a parameter that needs to be optimized and other variables

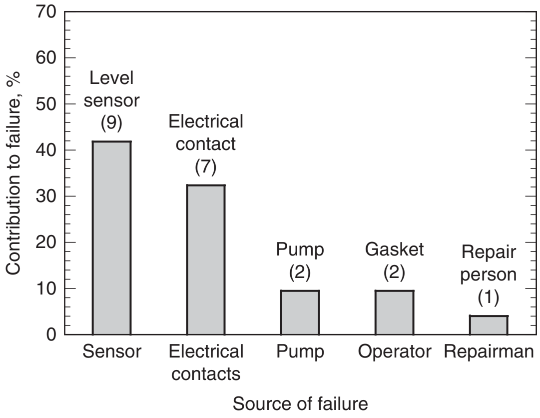


Figure 18–13

Pareto plot used to illustrate relative contribution of various causes to overall failure.

that may have some effect on that parameter. Many models used in process control are linear because they are well understood and are simple to analyze and solve. Usually, linear correlation is written as follows:

$$y = a_0 + a_1x_1 \tag{18–1}$$

where y = parameter to be optimized
a_0, a_1 = coefficients
x_1 = variable

The higher the probability that coefficient a_1 is not zero, the higher is the effect of the variable x_1 on the parameter y. This probability can be calculated using various statistical software packages. Usually, a 95 percent probability that a coefficient a_1 is not equal to zero is considered an indication that a variable x_1 has an effect on the optimized parameter y. The sign of the a_1 coefficient is used to determine in which direction the variable affects an optimized parameter. It is also important to note that lack of correlation between an optimized parameter and a variable does not necessarily mean that they are not related in general. In some cases, an appropriate relationship may be more complex than just a linear relationship (for example, the relationship may be log-normal as discussed in the Sec. 12–9 on UV disinfection), or the effect of their relationship was minimal within examined ranges.

Use of Online Process Monitoring. Since the 1950s, many industries have been using a variety of statistical analyses for making continuous process improvements. In the wastewater industry, statistical process control is not as popular because most effluent water quality characteristics are not distributed normally (i.e., bell-shaped). As a result, the methods required for implementation of statistical control for municipal wastewater treatment processes have to be more sophisticated than ones used in other industries.

Conventional analysis of historical data includes the analysis of data obtained through grab and composite sampling. Such data often do not reflect full dynamics of a treatment process. Online instrumentation, however, can be used to provide information that is more representative of the process dynamics. An example of online monitoring of dissolved oxygen (DO) for process control is shown on Fig. 18–14. The DO values vary significantly from the target value of 2 mg/L, indicating for much of the time the wastewater is overaerated. Installation of automatic DO control can prevent over- as well as underaeration resulting in savings in aeration energy and improved process control.

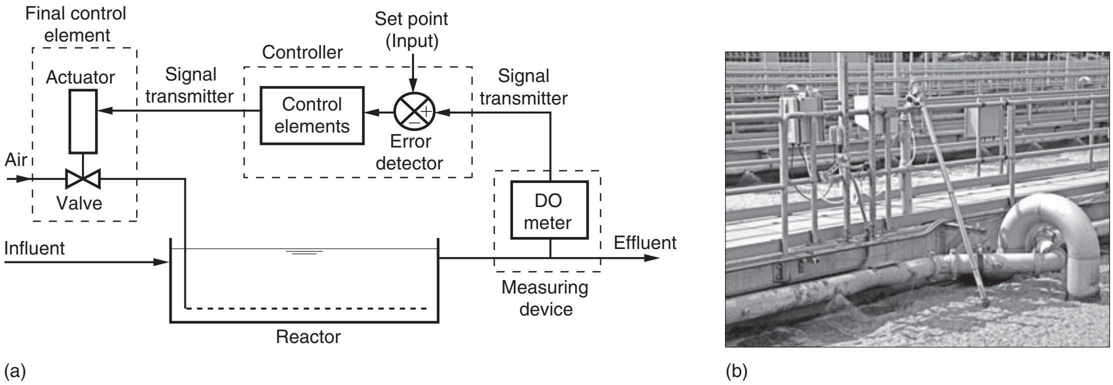

Figure 18–14

Dissolved oxygen (DO) control in an activated sludge biological treatment process: (a) general structure and components of an oxygen control loop and (b) typical installation of online meter used to monitor DO in activate sludge aeration tank.

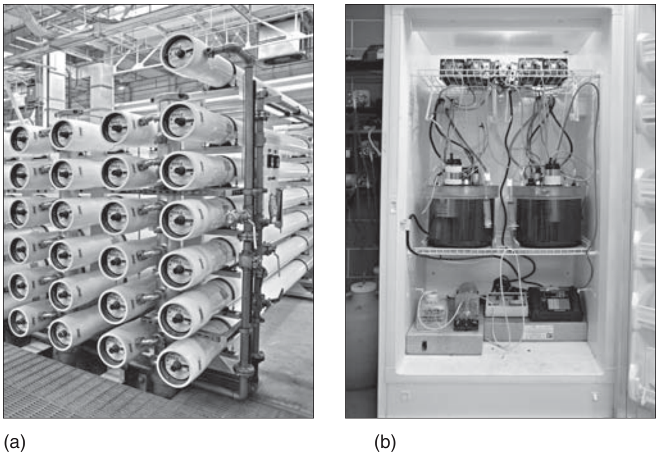
The use of online ammonium analyzers and nitrate analyzers have been increasing at the WWTPs with biological nutrient removal and addition of external carbon for denitrification. The analyzers are sometimes used to control the dosing of the external carbon in combination with the process control algorithm. In some treatment plants, online phosphorus analyzers have been used to control chemical dosing for the chemical phosphorus removal process.

Use of Computer Models. Computer modeling of treatment processes is an effective tool for development of facility improvements because it is now possible to understand the dynamics of treatment processes and to optimize operational parameters. The effect of changes in the operational modes on process performance can also be analyzed. For example, the results of computer modeling of the activated sludge process and the hydraulic modeling of clarifiers can be used to evaluate whether an existing activated sludge plant, designed for conventional treatment (i.e., BOD and TSS removal) can be modified to remove nutrients or/and to treat higher flow than it was designed for. Computer modeling is also very helpful in the evaluation of retrofit options, such as the installation of baffles in aeration tanks and clarifiers, changing of media size in filters, and so forth. In many cases, computer modeling can simplify physical modeling. The use of modeling in activated sludge design is discussed in Sec. 8–5 in Chap. 8.

To provide reliable results, a computer model requires calibration to verify the values that have been chosen for the coefficients included in the model. These coefficients often depend on wastewater characteristics and the design features of the particular process. Calibration involves modifying the coefficient values until model output matches the plant performance data collected using online water quality and flow monitors, composite samplers, and other data collection equipment. Sometimes to improve the quality of the model calibration, the process and equipment need to be operated under extreme conditions. Such experiments are called *stress testing* and require careful planning and execution to avoid threatening plant reliability. Poor planning of stress testing at the Chernobyl nuclear power station, for example, caused the worst nuclear disaster in the history of mankind.

Figure 18–15

Full and bench scale pilot plant facilities: (a) reverse osmosis module shown above the first row of modules is used to test different RO membranes in a side-by-side comparison with existing membrane modules and (b) laboratory scale reactors set up in the temperature control incubator at 25°C to study the anammox process.



Use of Pilot-Scale Testing. A full-scale treatment process is the ultimate tool for evaluation of proposed improvements [see Fig. 18–15(a)]. In recent years, more use has been made of laboratory (bench) and pilot-scale testing of proposed improvements before they are implemented at full scale. Pilot scale testing was discussed previously in Sec. 4–2 in Chap. 4; laboratory-scale biological test reactors are shown on Fig. 18–15(b). Pilot scale units can be operated under a variety of different conditions, and the quality of effluent and other parameters can be compared between old and new modes of operation. Such piloting not only provides the most accurate information about the benefits of proposed process improvements, but also provides an opportunity for training the operating staff in the operation of new processes.

Operational Changes to Improve Plant Performance

In some cases, process modifications can be made at little or no cost. Some of the common problems faced in the operation of treatment facilities relate to the changing nature of the wastewater to be treated, variations in flows and loads, utilizing and maintaining each process component to achieve its maximum capability, and maintaining quality control so that treated effluent and plant residuals meet exacting reuse or permit requirements. Examples of operational changes that can be used to resolve plant performance issues are presented in Table 18–3. An example would be the turndown of the aeration system in an activated sludge plant during low flow periods to reduce over-aeration and to save on energy costs.

Where a more comprehensive approach is needed, a capacity evaluation may be required to determine the capability of the critical elements in the treatment process. For example, short-circuiting may exist in the primary clarifiers resulting in the carryover of settleable material to the biological treatment units, thus causing overloading conditions and increasing the cost of treatment. Stress testing of the process components may be necessary to determine the limits of operating capability of the key components. In other cases, tracer testing to document hydraulic flow patterns (see Appendix H and I) or measuring dissolved oxygen transfer rates to determine aeration efficiency may be employed. These types of tests can also be used to determine if new physical facilities are required.

Table 18–3

Examples of operational changes that can be used to improve plant performance

Issue	Possible remedial action	See Sec. no.
General plant		
Odors from open tanks and channels	Reduce turbulence by controlling water levels to eliminate free falls and splashing	
	Add chemicals (such a chlorine, ferric chloride, or hydrogen peroxide) to influent wastewater	6–2, 6–3
	Modify process loading	
Wide influent flow variations	Conduct collection system I/I investigation to identify sources of extraneous flow	
Short circuiting in clarifiers and chlorine contact tanks	Conduct tracer tests	12–6
	Conduct stress tests	
Headworks		
Odorous grit	Adjust air flowrates in aerated grit chambers to obtain cleaner grit	
	Add lime to dewatered grit	
Odors and vectors in headworks	Cover grit and screenings receptacles	16–3
	Add lime to dewatered grit and screenings	
Inadequate grit removal	Analyze channel and grit chamber hydraulics	5–5
	Adjust flow distribution to grit chamber	
	Add temporary baffles to prevent short circuiting	
	Adjust airflowrate in aerated grit chambers	
Grit deposition in channels	Modify/adjust channel flow-through velocity	
Primary clarifiers		
Poor solids removal	Check for short circuiting/modify baffling	
	Improve flow distribution	5–6
	Add chemicals to influent	6–3
	Reduce return flows from other processes	15–2
Low solids concentration in primary sludge	Modify sludge pumping rate/install timers	
	Increase sludge blanket depth	
Aeration tanks		
Low DO	Determine DO profile in tank and adjust air flowrate	
	Conduct oxygen transfer test	5–11
	Assess diffuser fouling/clean fouled diffusers	
	Change conventional plug flow operation to step feed (if possible)	
	Check wastewater characteristics (rbCOD and nbVSS)	8–2
High DO	Turn off aeration equipment during low flow and loading periods	
	Install timers to control blower or mechanical aerator operation	
Filamentous organisms in mixed liquor	Examine mixed liquor microscopically to identify types of organisms	8–3
	Increase sludge wasting	
	Chlorinate return sludge	

(*continued*)

Table 18–3 (*Continued*)

Issue	Possible remedial action	See Sec. no.
Process is nitrifying	Check SRT	
Process is not nitrifying	Check SRT, alkalinity, and temperature	
Low pH	Check if nitrification is occurring	8–6
	Add alkalinity	8–6
Foaming	Identify nature of foam	8–3
	Change MLSS concentration	8–5
	Add defoaming agent to spray water	
Nocardia foaming	Use dilute chlorine solution spray on foam	
	Reduce oil and grease discharges to collection system	
Trickling filters		
Poor BOD removal	Reduce dosing rate	9–2
Solids washout at peak flows	Reduce recirculation rate	
Biological nitrogen removal process		
Inadequate removal	Check rbCOD, MLSS, and temperature/revise feed	
	Increase external carbon feed	
Final clarifiers		
Bulking sludge	Increase dissolved oxygen concentration	
	Increase F/M ratio	
	Modify return and waste activated sludge pumping rates	
	Chlorinate influent wastewater	
	Chlorinate return activated sludge	
Rising sludge	Increase return activated sludge pumping rate to reduce sludge blanket depth in clarifier	
	Conduct state point analysis of final clarifiers	8–10
Poor solids separation	Perform state point analysis	8–10
Disinfection		
High coliform count in effluent	Improve chlorine mixing	12–6
	Conduct tracer tests to determine short circuiting	12–6
	Check process for is partial nitrification	8–6
Solids processing		
Low solids concentration from dissolved air flotation thickener	Check air-solids ratio	
	Reduce solids loading rate	
	Add/increase polymer feed	
Poor anaerobic digester performance	Change frequency of solids feeding	13–9
	Increase concentration of feed solids	
	Check adequacy of mixing	
	Remove sludge and grit deposits	
	Increase SRT	

(*continued*)

Table 18–3 (*Continued*)

Issue	Possible remedial action	See Sec. no.
Poor aerobic digester performance	Check temperature/adjust SRT Increase concentration of feed solids Check adequacy of mixing Increase DO Check pH/adjust alkalinity	13–9
Odors from composting operations	Increase aeration by air addition or frequency of turning	14–5
Poor compost quality	Perform materials balance/adjust feed composition	14–5
Excessive moisture in compost mixture	Change compost mixture by adding amendment or bulking agent Improve sludge dewatering operations	14–5
Processing of return flows	Use flow equalization to input return flows more uniformly over the day or in the evening hours when excess aeration capacity is available	15–2
	Consider installation of separate treatment facilities for return flows.	15–3
	Consider the recovery of nutrients	15–4, 15–5

18–4 UPGRADING TREATMENT PLANT PERFORMANCE THROUGH PROCESS MODIFICATION

In many cases, to meet some of the many challenges identified in Secs. 18–1 and 18–2, it will be necessary to upgrade existing treatment plants. Upgrading of a wastewater treatment plant can encompass a large number or only a few factors. The scope of this text cannot include identifying and discussing all of the factors that may go into the decision to upgrade a facility; however, some common factors that necessitate upgrading existing treatment facilities include the need to:

1. Improve treatment plant performance
2. Reduce chemical, energy, and maintenance costs
3. Meet more stringent discharge requirements
4. Meet additional treatment capacity needs for population growth
5. Meet new constituent removal requirements for potable reuse
6. Meet new energy and resource recovery objectives

Because these factors have been discussed throughout this textbook, they are not discussed further, but are presented as a basis for understanding the material presented in this section. The various issues related to upgrading existing treatment plants are divided into two categories: (1) upgrading of physical facilities for liquid and solids treatment and (2) potential process modifications for meeting new requirements for constituent removal.

Upgrading Physical Facilities

Most treatment plants contain all of the essential elements necessary to meet treatment goals, but in some instances, the capacity of some of the components is underutilized or overloaded, hydraulic bottlenecks exist that constrain effective and efficient operation, and inadequacies in facilities design affect plant operations and maintenance. Some common issues related to upgrading liquid treatment and solids processing facilities are discussed below.

Upgrading Liquid Treatment Facilities. Upgrading existing facilities may be necessary to mitigate existing operating problems. An example might be the carryover of shredded screenings and hair from the screening process that is causing plugging of membrane filters. Replacement of coarse bar racks or comminutors may be necessary to reduce screenings pass-through and filter plugging. Covering primary sedimentation tanks to limit the release of odors and installing odor control facilities is a common plant upgrade (see Fig. 18–7). Another example is the installation of equalization basins or sidestream treatment processes to accommodate wet-weather flows. Examples of issues relating to the upgrading of physical facilities for the treatment of wastewater (liquid treatment facilities) are summarized in Table 18–4.

In some cases, a capacity evaluation is required in which a full-scale test program is required to determine the capability of the critical elements in the treatment process. For example, short-circuiting may exist in the primary clarifiers resulting in the carryover of settleable material to the biological treatment units, thus causing overloading conditions or increasing the cost of treatment. Stress testing of the process components may be necessary to determine the limits of operating capability of the key components. In other cases, tracer testing to document hydraulic flow patterns or measuring dissolved oxygen transfer rates to determine aeration efficiency may be employed.

Upgrading Solids Processing Facilities. Although a major focus of treatment plant design and operation is on the liquid treatment facilities because of the standards for treated effluent reuse and disposal, solids processing facilities are receiving increased attention because of the potential to recover energy and resources. Solids processing is often the most vexing problem for many plants because of operational difficulties, increasingly stringent requirements for reuse, and limited options for disposal. However, some of the new technologies described in this text can be used to upgrade the design and operation of solids processing facilities. Example upgrade options are described in Table 18–5. Frequent problems are often associated the return flows and loads from solids processing facilities such as thickening and dewatering. However, some of the new technologies described in this text can be used to upgrade the design and operation of solids processing facilities (see Chaps. 13 and 14). The separate treatment of return flows is considered in Chap. 15.

Upgrading to Meet New Constituent Removal Requirements

As discussed in Chaps. 1, 4, 8, 13, and 15 and in earlier sections of this chapter, standards for constituent removal have changed in recent years and will continue to change as more scientific information is developed and as the reuse of treated wastewater and biosolids becomes increasingly important. Examples of many of the current and future issues and upgrade options in resolving these issues are summarized in Table 18–6.

18–5 MANAGEMENT OF WET-WEATHER FLOWS

Although the management of wet-weather flows has, to date, received considerable attention, it is anticipated that even greater attention will be devoted to this aspect of wastewater management in the future. Sanitary sewer overflows (SSOs) are currently regulated under the Clean Water Act, with the U.S. EPA taking the position that all SSOs are illegal discharges and must be eliminated. It is widely recognized, however, that no matter how well a sanitary sewer collection system is operated and maintained, occasional unintentional discharges occur from almost every system. To date, efforts to develop and implement a national policy to regulate the control of SSOs have not been successful.

Table 18–4

Examples of upgrading of physical liquid treatment facilities to improve plant performance

Issue	Remedial action/upgrade option	See sec. no.
General plant		
Odors	Cover structures	16–3
	Add odor collection and treatment system	
	Reduce turbulence by eliminating free falls and sharp bends	
	Add chemical feed facilities	
Wide influent flow variations	Add upstream flow equalization	3–7
	Install variable speed drives on pumps	
	Install small capacity pumps for low flows	
Flow control/ distribution	Improve flow splitting	
	Add metering	
Return flows from sludge processing facilities upset biological process	Provide flow storage/equalization	15–2
	Provide sidestream treatment of return flows	15–3
	Modify operations/upgrade solids processing facilities to reduce load	
Headworks		
Inadequate screenings removal	Modify/replace screens to prevent screenings carryover	5–1
	Install fine screens	
	Replace comminutors	
Odorous, wet screenings	Install screenings press	5–2
	Replace screens with macerators	
	Enclose and ventilate screening equipment	16–3
Odorous grit	Install grit washer	
	Enclose and ventilate grit equipment	16–3
Inadequate grit removal	Add permanent baffles to prevent short circuiting	
	Replace/upgrade grit removal equipment	5–5
Primary clarifiers		
Inadequate solids removal in primary clarifiers	Add chemical treatment and flocculation	6–2, 6–3
	Add high rate clarification	5–7
	Install baffles at effluent weirs	
Aeration tanks		
Low DO	Install DO probes for DO monitoring	
	Replace coarse bubble with fine pore diffusers	5–11
	Change diffuser placement to a grid pattern	
High DO	Install variable speed drives on centrifugal blowers to provide turndown capability	5–11
	Install inlet guides vanes on centrifugal blowers to provide turndown capability	
	Install variable speed drives on positive displacement blowers	
	Install timers and two-speed motors on mechanical aerators	
	Install automatic DO control system	

(*continued*)

Table 18–4 (*Continued*)

Issue	Remedial action/upgrade option	See sec. no.
Unbalanced DO profile in plug flow aeration tanks	Change to step feed process	8–9
	Add DO control system	
Solids deposition	Increase mixing capacity	5–3
Nocardia foaming	Add selector	8–4
Trickling filter		
Plugging and ponding of rock filters	Install plastic packing	9–2
Odors and poor BOD removal	Increase airflow by improving natural draft or adding ventilation system	9–2
Biological treatment system		
Insufficient reactor and solids separation capacity	Add chemical treatment	6–2, 6–3
	Add high rate clarification to reduce loading on biological treatment system	5–7
	Add membrane bioreactor	8–12
Solids washout from high flow-rates	Add flow equalization	3–7
	Add high rate clarification process for excess flows	5–7
	Use contact stabilization process	
Secondary clarifiers		
Inadequate solids separation in secondary clarifiers	Modify flow distribution	8–11
	Modify circular clarifier center feedwell	8–11
	Add flocculating center feedwell	8–11
	Install baffles at effluent weirs	
	Add tube or plate settlers	5–4
	Modify effluent weir configuration	
	Modify sludge collector to improve solids withdrawal	
Disinfection		
Inadequate chlorine disinfection	Add/replace chlorine mixers	12–6
	Add/modify baffles to reduce short circuiting in chlorine contact tank	
	Add chlorine residual control system	
TSS in effluent	Add depth filters before disinfection	
Excessive chlorine residual	Add chlorine residual analyzer and automatic control system	12–6
	Add dechlorination facilities	
	Replace chlorination system with UV	

SSO Policy Issues

In 1994, a stakeholder process was initiated to consider technical and policy issues pertaining to SSOs. An SSO Subcommittee was formed to evaluate the need for national consistency in regulating SSOs, and defining public policy issues related to collection system operation and maintenance as well as public health and environmental impacts related to SSOs. SSO Subcommittee efforts continued until 1999 and several basic principles were identified as suggested NPDES Permit requirements. In 2001, a Notice of Proposed Rulemaking (NPRM)

Table 18–5

Examples of upgrading physical solids treatment facilities to improve plant performance

Issue	Remedial action/upgrade option	See sec. no.
Thickening		13–6
Low solids concentration in primary sludge	Add gravity thickening Add co-settling thickening	
Insufficient gravity thickening of waste activated sludge	Use alternative thickeners (dissolved air flotation, or centrifuge)	
Alkaline stabilization		13–8
Odor and vector problems in dewatered sludge	Add post-lime stabilization	
Anaerobic digesters		13–9
Excessive hydraulic loading	Add sludge thickening prior to digestion	
Inadequate mixing	Upgrade digester mixing system Install egg-shaped digester	
Poor digestion of mixed primary and biological sludge	Install separate digesters	
Inadequate solids destruction	Install two-phased anaerobic digestion process	
Aerobic digestion		13–10
Insufficient pathogen removal	Increase SRT by adding thickening or additional aerobic digester capacity Add ATAD process	
Inadequate mixing	Increase mixing energy	
Composting		
Excessive plastics and inert material in product to be reused	Install fine screens in plant influent Install sludge screens	5–1 13–5
Dewatering and Drying		14–2, 14–3
Excessive water in dewatered sludge cake	Add sludge thickeners Install high solids centrifuge dewatering Install filter press Add solar drying beds Add heat dryers	
Sludge Lagoons and drying beds		
Odors	Construct turbulence inducing structures	16–3
Land application of biosolids		14–10
Excessive attraction of vectors	Modify preapplication treatment methods or method of biosolids application	
Excessive pathogen levels	For Class A biosolids, use one of the six prescribed alternative treatment alternatives For Class B biosolids, use of three prescribed alternative monitoring or treatment alternatives	

Table 18–6

Potential process modifications for meeting new standards for constituent removal

Issue	Remedial action/upgrade option	See Sec. no.
TSS discharge standards	Investigate alternative solids separation facilities	5–9

	Composting	14–5
	Air drying	14–3

intended to further development of these basic principles was signed by the EPA Administrator but rulemaking efforts never advanced.

SSO Guidance

In 2005 EPA issued a guidance document that contains most of what was intended to be in the original rule relative to these basic principles, which have become known as CMOM – Capacity, Management, Operations, and Maintenance. Individual EPA Regional offices have required implementation of CMOM principles through the NPDES Permit process. During 2010, a series of listening sessions were held by EPA to obtain public input for use by EPA in considering whether and how to modify NPDES Regulations as they pertain to municipal sanitary sewer systems and SSOs. EPA is currently preparing a summary of the input received.

Wet-Weather Management Options

Wet weather treatment systems and processes are designed similar to conventional wastewater treatment processes in many respects. The key difference between wet-weather treatment and conventional wastewater treatment is the highly variable, intermittent nature of wet weather flow as compared to the continuous (24 h/d, 365 d/y) operation of a conventional wastewater treatment process. To withstand the rigors of constant ON/OFF, wet-dry cycles and widely varying flows and loads, wet weather treatment processes must be designed to be simple, rugged, and reliable. In assessing the applicability of any technology, system, or process for wet weather treatment, the designer must be assured that it can withstand the highly variable operating conditions outlined previously. A number of treatment technologies are identified and discussed in Table 18–7. Each of the processes

Table 18–7

Representative wet-weather treatment processes in various combinations

Unit processes	Description
Screening and disinfection  	Screening and disinfection facilities combine these two unit processes to control the two most prevalent constituents in CSOs in terms of contribution to water quality impacts—floatable debris and pathogens. Screening equipment must be selected to withstand repeated wet-dry cycles, and screens that avoid moving parts below the water surface are preferred. Screen opening sizes can range from approximately 12 to 20 mm (0.5 to 0.75 in.) down to 3 to 4 mm (0.1 to 0.15 in.). Screenings are normally containerized for disposal following each storm event but, in some cases, can also be macerated and introduced into a sewer tributary to a downstream WWTP. Disinfection is normally accomplished using sodium hypochlorite due to the proven nature of high-rate hypochlorite disinfection and the ability of the equipment to start and stop automatically in response to storm events. Hypochlorite contact times of 15 min are common, but times as short as five min have been used in combination with high-intensity, induction mixers to introduce the hypochlorite into the screened flow. When required, dechlorination is accomplished by applying liquid sodium bisulfite following disinfection
Detention/treatment  	Detention/treatment facilities employ gravity sedimentation (see Chap. 5) in combination with offline storage to reduce impacts of CSOs. Unit processes typically include: influent screening (to capture floating pollutants and remove large objects), gravity sedimentation, sodium hypochlorite disinfection, and de-chlorination using liquid sodium bisulfite (when required). High-rate disinfection practices, using induction mixers, are customarily used. High-rate disinfection practices improve disinfection efficiency, which is important as disinfection takes place concurrent with sedimentation. Ancillary processes typically include detention basin dewatering and flushing systems, and odor control. Dewatering and flushing systems are automated typically to reduce staffing requirements, with flushing gates and tipping buckets are used commonly to scour settled solids from the tank bottom following each storm event. Side water depths ranging from 3 to 6 m (10 to 20 ft), and surface overflowrates (SORs) on the order of 180 to 240 m/d (4500 to 6000 gal/ft^2·d) are used in conjunction with the peak design flow to size detention basins. These high SORs take into account the transient nature of wet weather flows, meaning that the peak design flow may occur for only minutes during each storm event that causes the facility to activate, and that for much of the storm the actual SOR is much lower. In addition to pollutant removal achieved by gravity sedimentation, a portion of the influent flow remains in the basin following each storm event. On an annual basis, the percent removal achieved by this captured volume is significant due to the prevalence of small storms that can be largely captured in the detention basin. Chemically-enhanced detention treatment is an emerging wet weather treatment process that involves the addition of a coagulant (typically a metal salt) and flocculent (polymer) to improve solids removal efficiency. When chemically-enhanced detention treatment is used, high-rate disinfection follows in a separate contact basin.

(*continued*)

Table 18–7 (*Continued*)

Unit processes	**Description**
Swirl/vortex 	Swirl/vortex treatment uses a combination of gravitational and rotational forces to enhance liquid-solids separation. Flow is introduced tangentially into a circular basin with specific geometry to direct the flow on a long spiral path. While some rotational motion occurs, gravitational forces acting on the solids as they travel along the spiral flow path are primarily responsible for solids separation. Solids that settle are concentrated at the bottom of the unit and from there are conveyed as a slurry to a sewer or interceptor and on to the WWTP. Swirl/vortex units are equipped with integral screens and/or baffles to capture floating pollutants. For configurations that do not include an integral screen, a separate screening process is provided typically upstream of the swirl/vortex unit. High-rate disinfection, using sodium hypochlorite, is often performed concurrent with swirl/vortex treatment, followed by de-chlorination using liquid sodium bisulfite (when required). Provisions to dewater the unit following each storm event are normally provided, but automated flushing mechanisms and odor control systems are uncommon. There are three specific geometric configurations commonly used for swirl/vortex treatment units: one developed by the U.S. EPA, which is in the public domain, and two proprietary configurations. Details on the geometry of the U.S. EPA design are found in EPA-R2—72-008. Each swirl/vortex unit operates on the basic principles outlined above. It is imperative to characterize the particle settling velocity specific to the wet weather flow to be treated using swirl/vortex technology. The use of settling column tests is highly recommended as a basis for establishing an appropriate surface overflowrate (SOR). For removals that approach a primary sedimentation level of efficiency (TSS removals of 50 percent or more) SORs on the order of 300 to 400 m/d (7500 to 10,000 gal/ft^2·d) are typical. Higher SORs, on the order of 600 to 1200 m/d (15,000 to 30,000 gal/ft^2·d), can be used with recognition that a swirl/vortex unit sized at those SORs will generally only remove floatable pollutants and heavier solids (grit). Chemically-enhanced swirl/vortex treatment is an emerging wet weather treatment process that involves the addition of a coagulant (typically a metal salt) and flocculent (polymer) to improve solids removal efficiency. When chemically-enhanced swirl/vortex treatment is used, high-rate disinfection follows in a separate contact basin.

(*continued*)

Table 18–7 (*Continued*)

Unit processes	Description
Ballasted flocculation 	Ballasted flocculation is a physical-chemical treatment process that uses a recycled media and chemical addition to improve the settling characteristics of solids. By agglomerating and increasing the specific gravity of the solids particles, effective solids separation can be accomplished at surface overflowrates (SORs) many times higher than with conventional sedimentation, ranging from 0.80 to 3.25 m/min (20 to 80 $\text{gal/ft}^2\cdot\text{min}$). Appurtenant unit processes include fine screening (screens with clear openings of 6 mm (0.25 in.) or smaller are generally required), and may include grit removal. A separate grit removal process is typically included for wet weather applications with higher activation frequencies and volumes to mitigate contamination of the ballast with grit particles. Because coagulant (typically a metal salt) and flocculent (polymer) are added to enhance solids separation, disinfection and de-chlorination (if necessary) are provided downstream of ballasted flocculation. Because ballasted flocculation produces a high-quality effluent, UV disinfection provides an alternative to sodium hypochlorite disinfection. When used for wet weather treatment the ballasted flocculation process train incorporates an automated shut-down procedure to partially drain the system and recycle the ballast to the influent end of the process. There are two ballasted flocculation process systems that have been used successfully for wet weather treatment. One uses recycled sludge from the process as ballast and the other uses a fine "microsand," which is recovered using hydrocyclones. Both processes involve dosing the influent flow with coagulant upstream of initial rapid mixing, then adding polymer and ballast to increase the size and specific gravity of solids in the flow. As the flow passes through a series of mixing compartments the mixing intensity decreases, allowing the particles to agglomerate. Solids separation usually takes place in a circular clarifier equipped with plate or tube settlers to provide a greater effective surface area for settling. While there are many functional similarities between the two processes, both have specific advantages and disadvantages which must be carefully weighed relative to each unique application.
Storage basins 	Storage basins are used to hold excess wet weather flow temporarily during and shortly after storm events, and can be installed at the WWTP or at satellite locations. These basins fill during periods when conveyance and/or treatment capacity is not available and are drained when capacity is available. Basin volume is generally determined by defining the excess (or overflow) volume corresponding to a design storm event and annual performance is checked using a collection system model. Ancillary processes typically include detention basin dewatering and flushing systems, and odor control. Influent screens are normally provided to prevent large objects (sticks, bricks, etc) from entering the basin. Because the purpose of these screens is protection from overflows rather than treatment, screen openings are relatively large 25 to 75 mm (1 to 3 in.), which mitigates the quantities of screenings to be handled at satellite locations.

(*continued*)

Table 18–7 (*Continued*)

Unit processes	Description
Tunnel storage 	Tunnel storage is used to temporarily hold excess wet weather flow during and shortly after storm events in the same manner as storage basins. While tunnel storage often mitigates peak flows to be handled at a WWTP, it is typically implemented in the collection system. Tunnel volume is generally determined by defining the excess (or overflow) volume corresponding to a design storm event and annual performance is checked using a collection system model. Ancillary processes typically include a tunnel dewatering system and odor control. Storage tunnels are normally designed to be self-cleansing but, if low velocities are expected, flushing systems can be included. A means of preventing large objects from entering the tunnel, such as a coarse bar rack or baffle arrangement can be devised, and screens sized with 25 to 75 mm (1 to 3 in.) clear openings to prevent large objects (sticks, bricks, etc) from entering the dewatering pump station at the downstream end of the tunnel are normally provided.

described in Table 18–7 has performed satisfactorily under various wet-weather operating conditions. The challenge moving forward is how to integrate the technologies identified and others into existing wastewater management programs.

DISCUSSION TOPICS

18–1 Review three articles on asset management for wastewater treatment facilities and discuss the benefits and potential risks in implementing asset management as discussed in the articles.

18–2 A large development is planned at the outskirt of a city with 60,000 population, and population is expected to increase by 20,000 in the next 10 y. Currently the city has one wastewater treatment facility, which is nearing its plant capacity. Discuss the potential advantages and/or disadvantages of considering decentralized wastewater management based on the geographic and climatic characteristics of your location.

18–3 Assuming that the intensity of wet-weather events has continued to increase, what measures would you propose investigate to alleviate the potential washout of solids at a treatment plant with shallow secondary clarifiers [3 m (10 ft) side water depth].

18–4 Discuss advantages and disadvantages of converting a combined wastewater collection system into separate wastewater and stormwater collection systems.

18–5 Discuss advantages and disadvantages of converting separate wastewater and stormwater collection systems into a combined wastewater collection system.

18–6 Discuss the benefits and drawbacks of either of the actions proposed in Problems 18–4 and 18–5 with respect to the management of stormwater.

Physical Properties of Selected Gases and the Composition of Air

Appendix B

B–1 PHYSICAL PROPERTIES OF SELECTED GASES

Table B–1

Molecular weight, specific weight, and density of gases found in wastewater at standard conditions (0°C, 1 atm)[a]

Gas	Formula	Molecular weight	Specific weight, lb/ft³	Density, g/L,
Air	–	28.97	0.0808	1.2928
Ammonia	NH_3	17.03	0.0482	0.7708
Carbon dioxide	CO_2	44.00	0.1235	1.9768
Carbon monoxide	CO	28.00	0.0781	1.2501
Hydrogen	H_2	2.016	0.0056	0.0898
Hydrogen sulfide	H_2S	34.08	0.0961	1.5392
Methane	CH_4	16.03	0.0448	0.7167
Nitrogen	N_2	28.02	0.0782	1.2507
Oxygen	O_2	32.00	0.0892	1.4289

[a] Adapted from Perry, R. H., D. W. Green, and J. O. Maloney: Perry's (eds) (1984) *Chemical Engineers' Handbook*, 6th ed., McGraw-Hill Book Company, New York.

B–2 COMPOSITION OF DRY AIR

Table B–2

Composition of dry air at 0°C and 1.0 atmosphere[a]

Gas	Formula	Percent by volume[b,c]	Percent by weight
Nitrogen	N_2	78.03	75.47
Oxygen	O_2	20.99	23.18
Argon	Ar	0.94	1.30
Carbon dioxide	CO_2	0.03	0.05
Other[d]	–	0.01	–

[a] Note: Values reported in the literature vary depending on the standard conditions.

[b] Adapted from North American Combustion Handbook, 2nd ed., North American Mfg., Co., Cleveland, OH.

[c] For ordinary purposes air is assumed to be composed of 79 percent N_2 and 21 percent O_2 by volume.

[d] Hydrogen, Neon, Helium, Krypton, Xenon.

Note: Molecular weight of air = $(0.7803 \times 28.02) + (0.2099 \times 32.00) + (0.0094 \times 39.95) + (0.0003 \times 44.00) = 28.97$ (see Table B–1 above).

B–3 DENSITY OF AIR AT OTHER TEMPERATURES

In SI units

The following relationship can be used to compute the density of air, ρ_a, at other temperatures at atmospheric pressure.

$$\rho_a = \frac{PM}{RT}$$

where P = atmospheric pressure, $1.0132^5 \times 10^5\ \text{N/m}^2$
M = molecular weight of air (see Table B-1), 28.97 g/ g mole
R = universal gas constant, 8314 N · m/ (mole air · K)
T = temperature, K (273.15 + °C)

For example, at 20°C, the density of air is:

$$\rho_{a,20°C} = \frac{(1.01325 \times 10^5\ \text{N/m}^2)(28.97\ \text{g/ mole air})}{[8314\ \text{N}\cdot\text{m/(mole air}\cdot\text{K)}][(273.15 + 20)\text{K}]}$$

$$= 1.204 \times 10^3\ \text{g/m}^3 = 1.204\ \text{kg/m}^3$$

In U.S. customary units

The following relationship can be used to compute the specific weight of air, γ_a, at other temperatures at atmospheric pressure.

$$\gamma_a = \frac{P\,(144\ \text{in}^2/\text{ft}^2)M}{RT}$$

where P = atmospheric pressure, 14.7 lb/in^2
M = molecular weight of air (see Table B–1), 28.97 lb/ lb mole air
R = universal gas constant, 1544 ft · lb/(lb mole air · °R)
T = temperature, °R (460 + °F)

For example, at 68°F, the specific weight of air is:

$$\gamma_a = \frac{(14.7\ \text{lb/in}^2)(144\ \text{in}^2/\text{ft}^2)(28.97\ \text{lb/lb mole air})}{[1544\ \text{ft}\cdot\text{lb/(lb mole air}\cdot°\text{R)}][(460 + 68)°\text{R}]} = 0.0752\ \text{lb/ft}^3$$

B–4 CHANGE IN ATMOSPHERIC PRESSURE WITH ELEVATION

In SI units

The following relationship can be used to compute the change in atmospheric pressure with elevation.

$$\frac{P_b}{P_s} = \exp\left[-\frac{gM(z_b - z_a)}{RT}\right]$$

where P_b = pressure at elevation z_b, N/m^2
P_s = atmospheric pressure at sea level, $1.01325 \times 10^5\ \text{N/m}^2$
g = acceleration due to gravity, 9.81 m/s^2
M = molecular weight of air (see Table B-1), 28.97 g/mole air
z_b = elevation b, m

z_a = elevation b, ft
R = universal gas constant, 8314 N · m/(mole air · K)
T = temperature, K (273.15 + °C)

In U.S. customary units

The following relationship can be used to compute the change in atmospheric pressure with elevation.

$$\frac{P_b}{P_s} = \exp\left[-\frac{gM(z_b - z_a)}{g_c RT}\right]$$

where P_b = pressure at elevation z_b, lb/in^2
P_s = atmospheric pressure at sea level, lb/in^2
g = acceleration due to gravity, 32.2 ft/s^2
M = molecular weight of air (see Table B–1), 28.97 lb$_m$/lb mole air
z_b = elevation b, ft
z_a = elevation b, ft
g_c = 32.2 ft · lb$_m$/lb · s^2
R = universal gas constant, 1544 ft · lb/(lb mole air · °R)
T = temperature, °R (460 + °F)

Physical Properties of Water **Appendix** C

The principal physical properties of water are summarized in SI units in Table C–1 and in U.S. customary units in Table C–2. They are described briefly below (Vennard and Street, 1975; Webber, 1971).

C–1 SPECIFIC WEIGHT

The specific weight of a fluid, γ, is its weight per unit volume. In SI units, specific weight is expressed in kilonewtons per cubic meter (kN/m^3). The relationship between γ, ρ, and the acceleration due to gravity g is $\gamma = \rho g$.

C–2 DENSITY

The density of a fluid, ρ, is its mass per unit volume. In SI units density is expressed in kilograms per cubic meter (kg/m^3). For water, ρ is 1000 kg/m^3 at 4°C. There is a slight decrease in density with increasing temperature.

C–3 MODULUS OF ELASTICITY

For most practical purposes, liquids may be regarded as incompressible. The bulk modulus of elasticity, E, is given by

$$E = \frac{\Delta p}{(\Delta V/V)}$$

where Δp is the increase in pressure, which when applied to a volume V, results in a decrease in volume ΔV. In SI units, the modulus of elasticity is expressed in kilonewtons per meter squared (kN/m^2).

C–4 DYNAMIC VISCOSITY

The viscosity of a fluid, μ, is a measure of its resistance to tangential or shear stress. In SI units, the dynamic viscosity is expressed in Newton seconds per square meter (N·s/m^2).

C–5 KINEMATIC VISCOSITY

In many problems concerning fluid motion, the viscosity appears with the density in the form μ/ρ, and it is convenient to use a single term, ν, known as the kinematic viscosity. In SI units, the kinematic viscosity is expressed in meters squared per second (m^2/s). The kinematic viscosity of a liquid diminishes with increasing temperature.

C–6 SURFACE TENSION

The surface tension of a fluid, σ, is the physical property that enables a drop of water to be held in suspension at a tap, a glass to be filled with liquid slightly above the brim and yet not spill, or a needle to float on the surface of a liquid. The surface-tension force across any imaginary line at a free surface is proportional to the length of the line and acts in a direction perpendicular to it. In SI units, surface tension per unit length is expressed in Newtons per meter (N/m). There is a slight decrease in surface tension with increasing temperature.

C–7 VAPOR PRESSURE

Liquid molecules that possess sufficient kinetic energy are projected out of the main body of a liquid at its free surface and become vapor. In a system open to the atmosphere, the vapor pressure, p_v, is the partial pressure exerted by the liquid vapor in the atmosphere. In a closed system, the vapor molecules are in equilibrium with the liquid; the pressure exerted by the vapor molecules is known as the saturated vapor pressure. In SI units, vapor pressure is expressed in kilonewtons per square meter (kN/m^2).

Statistical Analysis of Data **Appendix** D

The statistical analysis of wastewater flowrate and constituent concentration data involves the determination of statistical parameters used to quantify a series of measurements. Commonly used statistical parameters and graphical techniques for the analysis of wastewater management data are reviewed below.

D–1 COMMON STATISTICAL PARAMETERS

Commonly used statistical measures include the mean, median, mode, standard deviation, and coefficient of variation, based on the assumption that the data are distributed normally. Although the terms just cited are the most commonly used statistical measures, two additional statistical measures are needed to quantify the nature of a given distribution. The two additional measures are the coefficient of skewness, and coefficient of kurtosis. If a distribution is highly skewed, as determined by the coefficient of skewness, normal statistics cannot be used. For most wastewater data that are skewed, it has been found that the log of the value is normally distributed. Where the log of the values is normally distributed, the distribution is said to be log normal. The common statistical measures used for the analysis of wastewater management data (Eqs. D–1 through D–9) are summarized in Table D–1.

D–2 GRAPHICAL ANALYSIS OF DATA

Graphical analysis of wastewater management data is used to determine the nature of the distribution. For most practical purposes, the type of the distribution can be determined by plotting the data on both arithmetic- and logarithmic-probability paper and noting whether the data can be fitted with a straight line. The three steps involved in the use of arithmetic, and logarithmic-probability paper are as follows.

1. Arrange the measurements in a data set in order of increasing magnitude and assign a rank serial number.
2. Compute a corresponding plotting position for each data point using Eqs. (D–10) and (D–11).

   $$\text{Plotting position (\%)} = \left(\frac{m}{n+1}\right) \times 100 \qquad \text{(D–10)}$$

   where m = rank serial number
   n = number of observations

   The term $(n + 1)$ is used to correct for a-small-sample bias. The plotting position represents the percent or frequency of observations that are equal to or less than the indicated value. Another expression often used to define the plotting position is known as Blom's transformation:

   $$\text{Plotting position (\%)} = \frac{m - 3/8}{n + 1/4} \times 100 \qquad \text{(D–11)}$$

3. Plot the data on arithmetic- and logarithmic-probability paper. The probability scale is labeled "Percent of values equal to or less than the indicated value."

Table D–1

Statistical parameters used for the analysis of wastewater management data[a]

Parameter		Definition
Mean value $\bar{x} = \frac{\sum f_i x_i}{n}$	(D–1)	**Terms** $\bar{x}$ = mean value f_i = frequency (for ungrouped data $f_i = 1$) x_i = the mid-point of the ith data range (For ungrouped data x_i = the *i*th observation)
Standard Deviation $s = \sqrt{\frac{\sum f_i (x_i - \bar{x})^2}{n - 1}}$	(D–2)	n = number of observations (Note $\sum f_i = n$) s = standard deviation
Coefficient of variation $C_v = \frac{100\, s}{\bar{x}}$	(D–3)	C_v = coefficient of variation, percent α_3 = coefficient of skewness α_4 = coefficient of kurtosis M_g = geometric mean s_g = geometric standard deviation
Coefficient of skewness $\alpha_3 = \frac{\sum f_i (x_i - \bar{x})^3/(n-1)}{s^3}$	(D–4)	$P_{15.9}$ and $P_{84.1}$ = values from arithmetic or logarithmic probability plots at indicated percent values, corresponding to one standard deviation
Coefficient of kurtosis $\alpha_4 = \frac{\sum f_i (x_i - \bar{x})^4/(n-1)}{s^4}$	(D–5)	**Median value** If a series of observations are arranged in order of increasing value, the middlemost observation, or the arithmetic mean of the two middlemost observations, in a series is known as the median.
Geometric mean $\log M_g = \frac{\sum f_i (\log x_i)}{n}$	(D–6)	**Mode** The value occurring with the greatest frequency in a set of observations is known as the mode. If a continuous graph of the frequency distribution is drawn, the mode is the value of the high point, or hump, of the curve. In a symmetrical set of observations, the mean, median, and mode will be the same value. The mode can be estimated with the following expression. Mode = 3(median) − 2($\bar{x}$).
Geometric standard deviation $\log s_g = \sqrt{\frac{\sum f_i (\log^2 x_g)}{n - 1}}$	(D–7)	**Coefficient of skewness** When a frequency distribution is asymmetrical, it is usually defined as being a skewed distribution.
Using probability paper $s = P_{84.1} - \bar{x}$ or $P_{15.9} + \bar{x}$	(D–8)	
$s_g = \frac{P_{84.1}}{M_g} = \frac{M_g}{P_{15.9}}$	(D–9)	**Coefficient of kurtosis** Used to define the peakedness of the distribution. The value of the kurtosis for a normal distribution is 3. A peaked curve will have a value greater than 3 whereas a flatter curve it will have a value less than 3.

[a] Adapted from Metcalf & Eddy (1991) and Crites and Tchobanoglous (1998).

If the data, plotted on arithmetic-probability paper, can be fit with a straight line, then the data are assumed to be normally distributed. Significant departure from a straight line can be taken as an indication of skewness. If the data are skewed, logarithmic probability paper can be used. The implication here is that the logarithm of the observed values is normally distributed. On logarithmic-probability paper, the straight line of best fit passes through the geometric mean, M_g, and through the intersection of $M_g \times s_g$ at a value of 84.1 percent and M_g/s_g at a value of 15.9 percent. The geometric standard deviation, s_g, can be determined using Eq. D–9 given in Table D–1. The use of arithmetic- and logarithmic-probability paper is illustrated in Example D–1.

EXAMPLE D–1 **Statistical Analysis of Wastewater Flowrate Data.** Using the following weekly flowrate data obtained from an industrial discharger for a calendar quarter of operation, determine the statistical characteristics and predict the maximum weekly flowrate that will occur during a full year's operation.

Week No.	Flowrate, m^3/wk	Week No.	Flowrate, m^3/wk
1	2900	8	3675
2	3040	9	3810
3	3540	10	3450
4	3360	11	3265
5	3770	12	3180
6	4080	13	3135
7	4015		

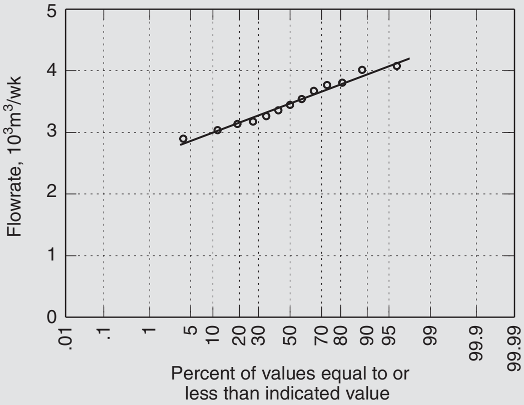
Solution

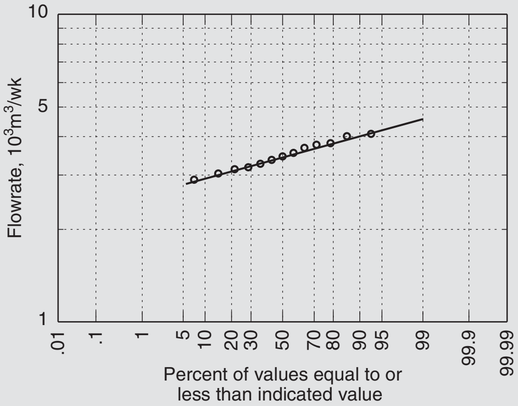
1. Plot the flowrate data using the log/probability method.
   a. Set up a data analysis table with three columns as described below.
      i. In column 1, enter the rank serial number starting with number 1
      ii. In column 2, arrange the flowrate data in ascending order
      iii. In column 3, enter the probability plotting position

Rank serial no., m	Flowrate, m^3/wk	Plotting position,[a] %
1	2900	7.1
2	3040	14.3
3	3135	21.4
4	3180	28.6
5	3265	35.7
6	3360	42.9
7	3450	50.0
8	3540	57.1
9	3675	64.3
10	3770	71.4
11	3810	78.6
12	4015	85.7
13	4080	92.9

[a] Plotting position = $[m/(n + 1)]100$.

b. Plot the weekly flowrates expressed in m^3/wk versus the plotting position. The resulting plots are presented below. Because the data fall on a straight line on both plots, the flowrate data can be described adequately by either distribution. This fact can be taken as indication that the distribution is not skewed significantly and that normal statistics can be applied.





2. Determine the statistical characteristics of the flowrate data.

a. Set up a data analysis table to obtain the quantities needed to determine the statistical characteristics.

Flowrate, m^3/wk	$(x - \bar{x})$	$(x - \bar{x})^2$	$(x - \bar{x})^3$ 10^{-6}	$(x - \bar{x})^4$ 10^{-9}
2900	−578	334,084	−193	11,161
3040	−438	191,844	−84	3680
3135	−343	117,649	−40	1384
3180	−298	88,804	−26	789
3265	−213	45,369	−9.6	206
3360	−118	13,924	−1.6	19.4
3450	−28	784	−0.02	0.06
3540	62	3844	0.24	1.48
3675	197	38,809	7.6	151
3770	292	85,264	25	727
3810	332	110,224	37	1215
4015	537	288,369	155	8316
4080	602	362,404	218	13,134
45,220		1,681,372	88.62	40,784

b. Determine the statistical characteristics using the parameters given in Table D–1.

i. Mean

$$\bar{x} = \frac{\sum x}{n}$$

$$\bar{x} = \frac{45{,}220}{13} = 3478 \text{ m}^3/\text{wk}$$

ii. Median (the middle-most value)
Median = 3450 m^3/wk (see data table above)

iii. Mode
Mode = 3(Median) − 2($\bar{x}$) = 3(3450) − 2(3478) = 3394 m^3/wk

iv. Standard deviation

$$s = \sqrt{\frac{\sum(x - \bar{x})^2}{n - 1}}$$

$$s = \sqrt{\frac{1{,}681{,}372}{12}} = 374.3 \text{ m}^3\text{/wk}$$

v. Coefficient of variation

$$C_V = \frac{100s}{\bar{x}}$$

$$C_V = \frac{100(374.3)}{3478} = 10.8\%$$

vi. Coefficient of skewness

$$\alpha_3 = \frac{[\sum(x - \bar{x})^3/(n - 1)]}{s^3}$$

$$\alpha_3 = \frac{(88.62 \times 10^6/12)}{(374.3)^3} = 0.141$$

vii. Coefficient of kurtosis

$$\alpha_4 = \frac{[\sum(x - \bar{x})^4/(n - 1)]}{s^4}$$

$$\alpha_4 = \frac{(40{,}784 \times 10^9/12)}{(374.3)^4} = 1.73$$

Reviewing the statistical characteristics, it can be seen that the distribution is somewhat skewed (α_3 = 0.141 versus 0 for a normal distribution) and is considerably flatter than a normal distribution would be (α_4 = 1.73 versus 3.0 for a normal distribution).

3. Determine the probable annual maximum weekly flowrate.
   a. Determine the probability factor:

$$\text{Peak week} = \frac{m}{n + 1} = \frac{52}{52 + 1} = 0.981$$

   b. Determine the flowrate from the figure given in Step 1b at the 98.1 percentile:

Peak weekly flowrate = 4500 m^3/wk

Comment The statistical analysis of data is important in establishing the design conditions for wastewater treatment plants. The application of statistical analysis to the selection of design flowrates and mass loadings rates is considered in the Sec. 3–6 in Chap. 3.

Dissolved Oxygen Concentration in Water as a Function of Temperature, Salinity, and Barometric Pressure

Appendix E

Table E–1

The air solubility of oxygen in mglL as functions of temperature and elevation in meters for 0–1800 m[a]

Carbonate Equilibrium

Appendix F

The chemical species that comprise the carbonate system include gaseous carbon dioxide [$(CO_2)_g$], aqueous carbon dioxide [$(CO_2)_{aq}$], carbonic acid [H_2CO_3], bicarbonate [HCO_3^-], carbonate [CO_2^{-2}], and solids containing carbonates. In waters exposed to the atmosphere, the equilibrium concentration of dissolved CO_2 is a function of the liquid phase CO_2 mole fraction and the partial pressure of CO_2 in the atmosphere. Henry's law (see Chap. 2) is applicable to the CO_2 equilibrium between air and water; thus

$$x_g = \frac{P_T}{H} p_g \tag{F–1}$$

where x_g = mole fraction of gas in water, mole gas/mole water

$$= \frac{\text{mole gas}\,(n_g)}{\text{mole gas}\,(n_g) + \text{mole water}\,(n_w)}$$

P_T = total pressure, usually 1.0 atm

H = Henry's law constant, $\dfrac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}$

p_g = mole fraction of gas in air, mole gas/mole of air (Note: The mole fraction of a gas is proportional to the volume fraction.)

The concentration of aqueous carbon dioxide is determined using Eq (F–1). At sea level, where the average atmospheric pressure is 1 atm, or 101.325 kPa, carbon dioxide comprises approximately 0.03 percent of the atmosphere by volume (see Appendix B). Values of the Henry's law constant for CO_2 as a function of temperature are given in Table F–1. The values in Table F–1 were computed using Eq. (2–48) and the data given in Table 2–7 in Chap. 2.

Table F–1

Henry's Law constant for CO_2 as a function of temperature

T, °C	H, atm
0	794
10	1073
20	1420
30	1847
40	2361
50	2972
60	3691

Aqueous carbon dioxide [$(CO_2)_{aq}$] reacts reversibly with water to form carbonic acid.

$$(CO_2)_{aq} + H_2O \rightleftarrows H_2CO_3 \tag{F–2}$$

The corresponding equilibrium expression is

$$\frac{[H_2CO_3]}{[CO_2]} = K_m \tag{F–3}$$

The value of K_m at 25°C is 1.58×10^{-3}. Note that K_m is unitless. Because of the difficulty of differentiating between $(CO_2)_{aq}$ and H_2CO_3 in solution and the observation that very little H_2CO_3 is ever present in natural waters, an effective carbonic acid value ($H_2CO_3^*$) is used which is defined as:

$$H_2CO_3^* \rightleftarrows (CO_2)_{aq} + H_2CO_3 \tag{F–4}$$

Because carbonic acid is a diprotic acid it will dissociate in two steps - first to bicarbonate and then to carbonate. The first dissociation of carbonic acid to bicarbonate can be represented as

$$H_2CO_3^* \rightleftarrows H^+ + HCO_3^- \tag{F–5}$$

The corresponding equilibrium relationship is defined as

$$\frac{[H^+][HCO_3^-]}{[H_2CO_3^*]} = K_{a1} \tag{F–6}$$

The value of first acid dissociation constant K_{a1} at 25°C is 4.467×10^{-7} mole/L. Values of K_{a1} at other temperatures are given in Table F–2, which is repeated here from Table 6–16 in Chap. 6.

The second dissociation of carbonic acid is from bicarbonate to carbonate as given below

$$HCO_3^- \rightleftarrows H^+ + CO_3^{2-} \tag{F–7}$$

The corresponding equilibrium relationship is defined as:

$$\frac{[H^+][CO_3^{2-}]}{[HCO_3^-]} = K_{a2} \tag{F–8}$$

The value of the second acid dissociation constant K_{a2} at 25°C is 4.477×10^{-11} mole/L. Values of K_{a2} at other temperatures are given in Table F–2.

Table F–2

Carbonate equilibrium constants as function of temperature[a]

Temperature, °C	Equilibrium constant[b]	
	$K_{a1} \times 10^7$	$K_{a2} \times 10^{11}$
5	3.020	2.754
10	3.467	3.236
15	3.802	3.715
20	4.169	4.169
25	4.467	4.477
30	4.677	5.129
40	5.012	6.026

[a] Adapted from Table 6–20 in Chap. 6.

[b] The reported values have been multiplied by the indicated exponents.

Thus, the value K_{a2} at 20°C is equal to 4.169×10^{-11}.

The distribution of carbonate species as function of pH is illustrated on Fig. F–1.

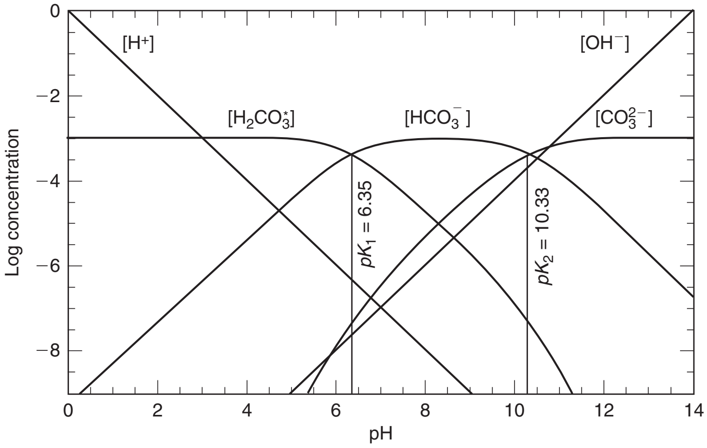

Figure F–1

Log concentration versus pH diagram for a 10^{-3} molar solution of carbonate at 25°C. By sliding the constituent curves up or down, pH values can be obtained at different concentration values. (LD)

To illustrate the use of the data presented in Tables F–1 and F–2, it will be helpful to estimate the pH of a water, assuming the atmosphere above the water contains 0.03 percent CO_2 by volume (see Appendix B), the bicarbonate (HCO_3^-) concentration in the water is 610 mg/L, and the temperature of the water is 20°C.

1. Use Eq. (F–1) to determine concentration of H_2CO_3 in the water. The value of Henry's constant from Table F–1 is 1420 atm, thus

   $$x_{H_2CO_3} = \frac{P_T}{H} p_g = \frac{(1\text{ atm})(0.00030)}{1420\text{ atm}} = 2.113 \times 10^{-7}$$

   Because one liter of water contains 55.6 mole [1000 g/(18 g/mole)], the mole fraction of H_2CO_3 is equal to:

   $$x_{H_2CO_3} = \frac{\text{mole gas}\,(\text{n}_\text{g})}{\text{mole gas}\,(\text{n}_\text{g}) + \text{mole water}\,(\text{n}_\text{w})}$$

   $$2.113 \times 10^{-7} = \frac{[H_2CO_3]}{[H_2CO_3] + 55.6\text{ mole/L}}$$

   Because the number of moles of dissolved gas in a liter of water is much less than the number of moles of water,

   $$[H_2CO_3] \approx (2.113 \times 10^{-7})(55.6\text{ mole/L}) \approx 11.75 \times 10^{-6}\text{ mole/L}$$

2. Use Eq. (F–6) to determine the pH of the water. The value of K_{a1} at 20°C from Table F–2 is 4.169×10^{-7}, thus

   $$[H^+] = \frac{K_{a1}[H_2CO_3^*]}{[HCO_3^-]}$$

   Substitute known values and solve for $[H^+]$

   $$[H^+] = \frac{(4.169 \times 10^{-7})(11.75 \times 10^{-6}\text{ mole/L})}{[(610\text{ mg/L})/61{,}000\text{ mg/mole})]} = 4.90 \times 10^{-10}$$

   $$\text{pH} = -\log[H^+] = -\log[4.90 \times 10^{-10}] = 9.31$$

   From Fig. F–1, the amount of carbonate present is essentially non-measurable.

Analysis of Nonideal Flow in Reactors using Tracers

Appendix H

The analysis of reactor hydraulic performance using tracers is considered in this appendix. Important applications of tracer studies include the assessment of: (1) short circuiting in sedimentation tanks and biological reactors, (2) the effective contact time in chlorine contact basins, (3) hydraulic approach conditions in UV reactors, and (4) patterns in constructed wetlands and other natural treatment systems. Tracer studies are also of critical importance in assessing the degree of success that has been achieved with corrective measures. Topics considered in this appendix include: (1) factors leading to nonideal flow in reactors, (2) important characteristics of tracers, (3) analysis of tracer response curves, and (4) practical interpretation of tracer measurements. The types of tracers used and the conduct of tracer tests are discussed in Sec. 12-3 in Chap. 12. The discussion of nonideal flow in this section will also serve as an introduction to the modeling of nonideal flow considered in Appendix I.

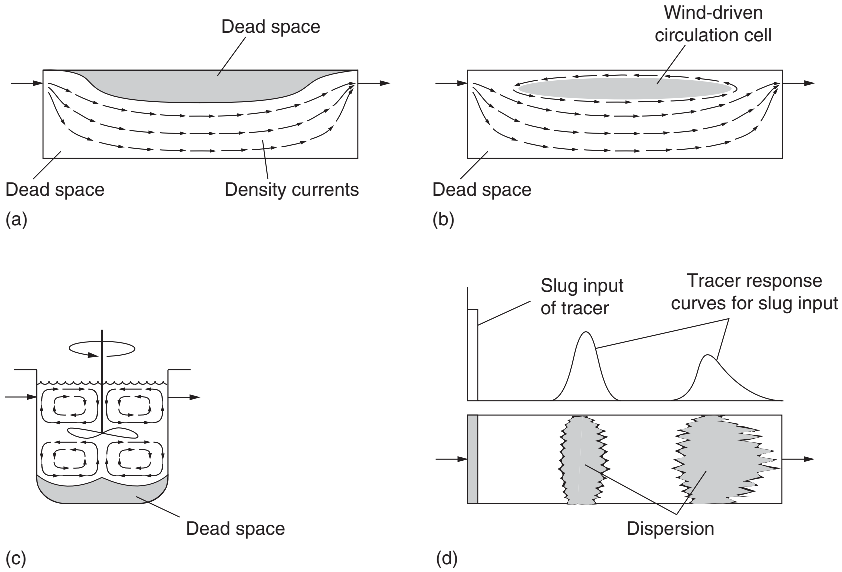
H–1 FACTORS LEADING TO NONIDEAL FLOW IN REACTORS

Nonideal flow occurs when a portion of the flow which enters the reactor during a given time period arrives at the outlet, in less than the theoretical detention time, ahead of the bulk flow which entered the reactor during the same time period. The theoretical detention time, τ, is defined as V/Q, where V is the volume and Q is the flowrate in consistent units. Nonideal flow is often identified as short circuiting. Factors leading to nonideal flow in reactors include:

1. Temperature differences. In complete-mix and plug-flow reactors, nonideal flow (short circuiting) can be caused by density currents due to temperature differences. When the water entering the reactor is colder or warmer than the water in the tank, a portion of the water can travel to the outlet along the bottom of or across the top of the reactor without mixing completely [see Fig. H–1(a)].
2. Wind driven circulation patterns. In shallow reactors, wind circulation patterns can be set up that will transport a portion of the incoming water to the outlet in a fraction of the actual detention time [see Fig. H–1(b)].
3. Inadequate mixing. Without sufficient energy input, portions of the reactor contents may not mix with the incoming water [see Fig. H–1(c)].
4. Poor design. Depending on the design of the inlet and outlet of the reactor relative to the reactor aspect ratio, dead zones may develop within the reactor which will not mix with the incoming water.
5. Axial dispersion in plug-flow reactors [see Fig. H–1(d)]. In plug-flow reactors the forward movement of the tracer is due to advection and dispersion. *Advection* is the term used to describe the movement of dissolved or colloidal material with the current velocity. For example, in a tubular plug-flow reactor (e.g., a pipeline), the early arrival of the tracer at the outlet can be reasoned partially by remembering that the velocity distribution in the pipeline will be parabolic. *Dispersion* is the term used to describe the axial and longitudinal transport of material brought about by velocity differences and dispersion. The distinction between molecular diffusion and dispersion is considered further in Appendix I.

Figure H–1

Definition sketch for short circuiting caused by (a) density currents caused by temperature differences, (b) wind circulation patterns, (c) inadequate mixing, (d) fluid advection and dispersion.



Ultimately, the inefficient use of the reactor volume due to short circuiting resulting from any of the factors described above, can result in reduced treatment performance. The subject of short circuiting in a series of complete-mix reactors was examined extensively in an early paper by MacMullin and Weber (1935); Fitch (1956) and Morrill (1932) examined the effects of short circuiting on the performance of sedimentation tanks.

H–2 TYPES OF TRACERS

Over the years, a number of tracers have been used to evaluate the hydraulic performance of reactors. Important characteristics for a tracer include (adapted in part from Denbigh and Turner, 1984):

1. The tracer should not affect the flow (should have essentially the same density as water when diluted).
2. The tracer must be conservative so that a mass balance can be performed.
3. It must be possible to inject the tracer over a short time period.
4. The tracer should be able to be analyzed conveniently.
5. The molecular diffusivity of the tracer should be low.
6. The tracer should not be adsorbed onto or react with the exposed reactor surfaces.
7. The tracer should not be adsorbed onto or react with the particles in wastewater.

Dyes and chemicals that have been used successfully in tracer studies at wastewater treatment plants are discussed in Sec. 12–6 in Chap. 12. In addition to the tracers considered in Sec. 12-3, lithium chloride is used commonly for the study of natural systems. Sodium chloride, used extensively in the past, has a tendency to form density currents unless mixed completely. Sulfur hexafluoride gas (SF_6) is used most commonly for tracing the movement of groundwater.

H–3 ANALYSIS OF TRACER RESPONSE CURVES

Because of the complexity of the hydraulic response of full-scale reactors, tracer response curves are used to analyze the hydraulics of reactors. Typical examples of tracer response curves are shown on Fig. H–2. Tracer response curves, measured using a short-term and continuous injection of tracer, are known as C (concentration versus time) and F (fraction of tracer remaining in the reactor versus time) curves, respectively. The fraction remaining is based on the volume of water displaced from the reactor by the step input of tracer. The terms used to characterize tracer response curves, the analysis of concentration versus time, and the development of residence time distribution (RTD) curves are described below.

Terms Used to Characterize Tracer Response Curves

Over the years, a number of different symbols and numerical values, as reported in Table H–1, have been used to characterize output tracer curves. The relationship of the terms in Table H–1 and a typical tracer response curve are illustrated on Fig. H–3.

Concentration Versus Time Tracer Response Curves

As noted previously, tracer response curves measured using a short-term or continuous injection of tracer are known as "C" curves (concentration versus time). To characterize C curves, such as those shown on Fig. H–3, the mean value is given by the centroid of the distribution. For C curves, the theoretical mean residence time is determined as follows.

$$\bar{t}_c = \frac{\int_0^\infty tC(t)dt}{\int_0^\infty C(t)dt} \tag{H–1}$$

where $\bar{t}_c$ = mean residence time derived from tracer curve, T

t = time, T

$C(t)$ = tracer concentration at time t, ML^{-3}

The variance, σ_c^2 used to define the spread of the distribution, is defined as

$$\sigma_c^2 = \frac{\int_0^\infty (t - \bar{t})^2 C(t)dt}{\int_0^\infty C(t)dt} = \frac{\int_0^\infty t^2 C(t)dt}{\int_0^\infty C(t)dt} - (\bar{t}_c)^2 \tag{H–2}$$

Figure H–2

Typical tracer response curves: (a) two different types of circular clarifiers (adapted from Dague and Baumann, 1961) and (b) open channel UV disinfection system (courtesy of Andy Salveson).

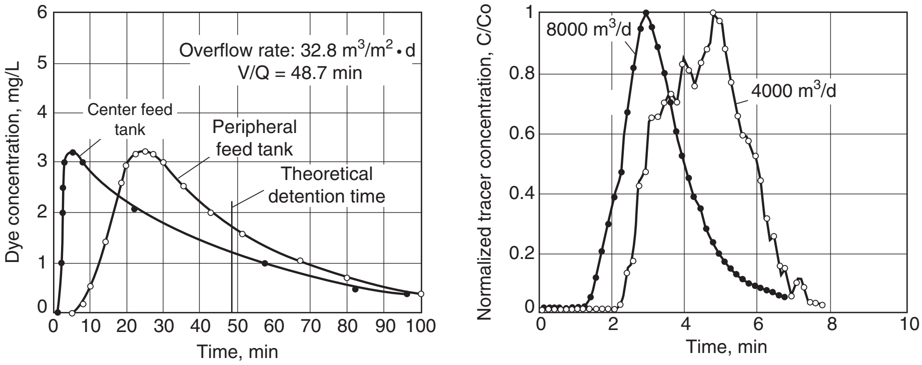


Table H–1

Various terms used to describe the hydraulic performance of reactors used for wastewater treatment[a]

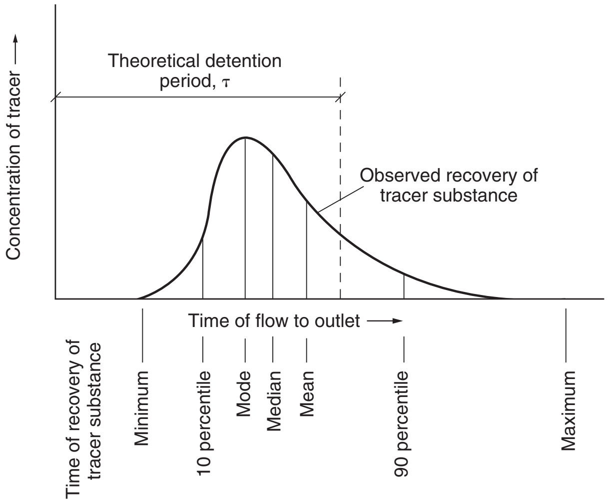
Term	Definition
τ	Theoretical hydraulic residence time (V, volume/Q, flowrate)
t_i	Time at which tracer first appears
t_p	Time at which the peak concentration of the tracer is observed (mode)
t_g	Mean time to reach centroid of the RTD curve
t_{10}, t_{50}, t_{90}	Time at which 10, 50, and 90 percent of the tracer had passed through the reactor
t_{90}/t_{10}	Morrill Dispersion Index, MDI
1/MDI	Volumetric efficiency as defined by Morrill (1932)
t_i/τ	Index of short circuiting. In an ideal plug-flow reactor, the ratio is one, and approaches zero with increased mixing
t_p/τ	Index of modal retention time. Ratio will approach 1 in a plug-flow reactor, and 0 in a complete-mix reactor. For values of the ratio greater than or less than 1.0 the flow distribution in the reactor is not uniform
t_g/τ	Index of average retention time. A value of one would indicate that full use is being made of the volume. A value of the ratio greater than or less than 1.0 indicates the flow distribution is not uniform
t_{50}/τ	Index of mean retention time. The ratio t_{50}/τ, is a measure of the skew of the RTD curve. In an effective plug-flow reactor, the RTD curve is very similar to a normal or Gaussian distribution (U.S. EPA, 1986). A value of t_{50}/τ, less than 1.0 corresponds to an RTD curve that is skewed to the left. Similarly, for values greater than 1.0 the RTD curve is skewed to the right
$t/\tau = \theta$	Normalized time, used in the development of the normalized RTD curve

[a] Adapted,in part, from Morrill (1932) and U.S. EPA (1986).

It will be recognized that the integral term in the denominator in Eqs. (H–1) and (H–2) corresponds to the area under the concentration versus time curve. It will also be recognized that the mean and variance are equal to the *first* and *second moments* of the distribution about the y axis.

Figure H–3

Definition sketch for the parameters used in the analysis of concentration versus time tracer response curves.



If the concentration versus time tracer response curve is defined by a series of discrete time step measurements, the theoretical mean residence time is typically approximated as

$$\bar{t}_{\Delta c} \approx \frac{\sum t_i C_i \Delta t_i}{\sum C_i \Delta t_i} \tag{H–3}$$

where $\bar{t}_{\Delta c}$ = mean detention time based on discrete time step measurements
t_i = time at *i*th measurement, T
C_i = concentration at ith measurement, ML^{-3}
Δt_i = time increment about C_i, T

The variance for a concentration versus time tracer response curve, defined by a series of discrete time step measurements, is defined as

$$\sigma^2_{\Delta c} \approx \frac{\sum t_i^2 C_i \Delta t_i}{\sum C_i \Delta t_i} - (\bar{t}_{\Delta c})^2 \tag{H–4}$$

Where $\sigma^2_{\Delta C}$ = variance based on discrete time measurements, T^2. The application of Eqs. (H–3) and (H–4) is illustrated in Example 12–8 in Chap. 12. Additional details on the analysis of tracer response curves may be found in Levenspiel (1998).

Residence Time Distribution (RTD) Curves

To standardize the analysis of output concentration versus time curves a single reactor for a pulse input of tracer, such as shown on Figs. H–2 and H–3, the output concentration measurements are often normalized by dividing the measured concentration values by an appropriate function such that the area under the normalized curve is equal to one. The normalized curves are known, more formally, as *residence time distribution (RTD) curves* (see Fig. H–4). When a pulse addition of tracer is used, the area under the normalized curve is known as an E curve (also known as the exit age curve). The most important characteristic of an E curve is that the area under the curve is equal to one, as defined by the following integral.

$$\int_0^\infty E(\bar{t}_{\Delta c})\, dt = 1 \tag{H–5}$$

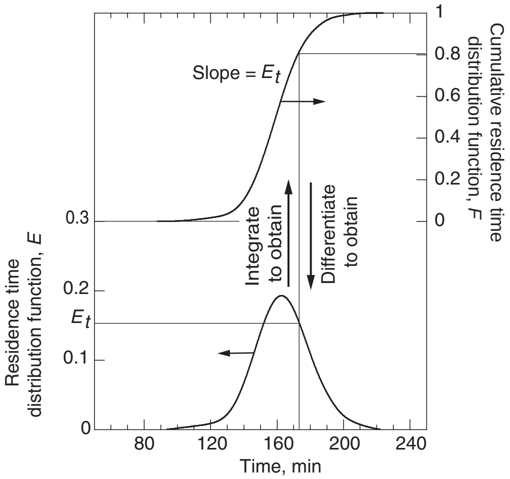


Figure H–4

Normalized residence time distribution curves. The curve on the bottom is known as the exit age curve, identified as the "*E* curve." The curve on top is the cumulative residence time curve, identified as the "*F* curve."

where $E(t)$ is the residence time distribution function. The $E(t)$ value is related to the $C(t)$ value as follows:

$$E(t) = \frac{C(t)}{\displaystyle\int_0^\infty C(t)dt} \tag{H–6}$$

As in Eqs. (H–1) and (H–2), the integral term in the denominator in Eqs. (H–6) corresponds to the area under the concentration versus time curve. Applying Eq. (H–6) to the expression, obtained previously, for the complete-mix reactor, the exit age curve $E(t)$ for a complete-mix reactor is obtained as follows:

$$E(t) = \frac{C(t)}{\displaystyle\int_0^\infty C(t)\,dt} = \frac{C_o e^{-t/\tau}}{\displaystyle\int_0^\infty C_o e^{-t/\tau}\,dt} = \frac{e^{-t/\tau}}{\tau} \tag{H–7}$$

and the corresponding value based on normalized time, $\theta = t/\tau$, is

$$E(\theta) = \tau E(t) = e^{-\theta} \tag{H–8}$$

The mean residence time for the $E(t)$ curve, given by Eq. (H–8), can be derived by applying Eq. (H–23); the resulting expression is given by

$$t_m = \frac{\displaystyle\int_0^\infty tE(t)dt}{\displaystyle\int_0^\infty E(t)dt} = \int_0^\infty tE(t)dt \tag{H–9}$$

In a similar manner when a step input is used, the normalized concentration curve is known as the cumulative residence time distribution curve and is designated as the F curve. The F curve is defined as

$$F(t) = \int_0^t E(t)dt = 1 - e^{-t/\tau} \tag{H–10}$$

where $F(t)$ is the cumulative residence time distribution function. As shown on Fig. H–4, the $F(t)$ curve is the integral of the $E(t)$ curve while the $E(t)$ curve is the derivative of the $F(t)$ curve. In effect, $F(t)$ represents the amount of tracer that has been in the reactor for less than the time t. The development of E and F RTD curves is illustrated in Example H–1. Additional details on the analysis of E and F curves may be found in Denbigh and Turner (1984), Fogler (2005), Levenspiel (1998), and in the chemical engineering literature.

EXAMPLE H–1 **Development of Residence Time Distribution (RTD) Curves from Concentration versus Time Tracer Curves** Use the concentration versus time tracer data given in Example 12–8 in Chap. 12 to develop E and F residence time distribution (RTD) curves for the chlorine contact basin. Using the E curve, compute the residence time and compare to the value obtained in Example 12–8. Plot the resulting E and F curves.

Solution

1. Using the values for time and concentration from Example 12–8, set up a computation table to calculate $E(t)$ values. The computation table is shown below. The $E(t)$ values are calculated by finding the sum of the $C \times \Delta t$ values, which corresponds to

the area under the C (concentration) curve, and dividing the original concentrations by the sum as illustrated below.

Area under C curve $= \Sigma C\Delta t$

$$E(t) = \frac{C}{\Sigma C\Delta t}$$

a. For each time interval, multiply the concentration by the time step ($t = 8$ min) and obtain the sum of the multiplied values. As shown in the computation table, the sum (which is the approximate area under the curve) is 817.778 μg/L-min.

b. Calculate the $E(t)$ values by dividing the original concentration values by the area under the curve.

c. Confirm that the $E(t)$ values are correct by multiplying each one by the time step, and calculating the sum. According to Eq. (H–6) written in summation form, the sum should be 1.00.

$$\Sigma E(t)\,\Delta t = \Sigma\left(\frac{C\Delta t}{\Sigma C\Delta t}\right) = \Sigma\left(\frac{C}{\Sigma C}\right) = 1$$

Time, t, min	Conc., C, μg/L	$C \times \Delta t$ μg/L·min	$E(t)$, min^{-1}	$E(t) \times \Delta t$, unitless	$t \times E(t) \times \Delta t$, min

Total	102.222	817.778	-	1.0000	163.616

[a] ppb = parts per billion

2. Determine the mean residence time using the following summation form of Eq. (H–28).

$$\bar{t} = \Sigma(t)E(t)\,\Delta t$$

The required computation is presented in the final column of the computation table given above. As shown, the computed mean residence time (163.6 min) is essentially the same as the value (163.4 min) determined in Example 12–8 in Chap.12.

3. Develop the F RTD curve. The values for plotting the F curve are obtained by summing cumulatively the $E(t)\Delta t$ values to obtain the coordinates of the F curve.

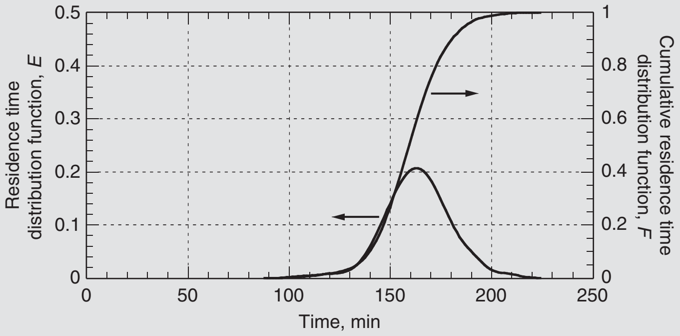
Total		1.0000	

4. Plot the resulting E and F curves. The plot of the E (column 3) and F (column 4) curves using the values determined above is shown below:



Comment The use of normalized RTD curves to obtain coefficients of dispersion is included in the discussion of the Hydraulic Characteristics of Nonideal Reactors. Additional details may be found in Denbigh and Turner (1984) and Levenspiel (1998).

Practical Interpretation of Tracer Measurements

In 1932, based on his studies of sedimentation basins, Morrill (1932) suggested that the ratio of the 90 percentile to the 10 percentile value from the cumulative tracer curve could be used as a measure of the dispersion index, and that the inverse of the dispersion index is a measure of the volumetric efficiency (Morrill, 1932). The dispersion index as proposed by Morrill is given by

$$\text{Morrill Dispersion Index, MDI} = \frac{P_{90}}{P_{10}} \tag{H–11}$$

where P_{90} = 90 percentile value from log-probability plot

P_{10} = 10 percentile value from log-probability plot

The percentile values are obtained from a log-probability plot of the time (log scale) versus the cumulative percentage of the total tracer which has passed out of the basin (on probability scale). The value of the MDI for an ideal plug-flow reactor is 1.0 and about 22 for a complete-mix reactor. A plug-flow reactor with an MDI value of 2.0 or less is considered by the U.S. EPA to be an effective plug-flow reactor (U.S. EPA, 1986). The volumetric efficiency is given by the following expression:

$$\text{Volumetric efficiency, \%} = \frac{1}{\text{MDI}} \times 100 \tag{H–12}$$

The determination of the Morrill dispersion index and the volumetric efficiency for the analysis of the flow pattern in a chlorine contact basin is illustrated in Example 12–8 in Chap. 12.

Modeling Nonideal Flow in Reactors

Appendix I

The hydraulic characteristics of nonideal reactors can be modeled by taking dispersion into consideration. For example, if dispersion becomes infinite, the plug-flow reactor with axial dispersion is equivalent to a complete-mix reactor. Both the plug-flow reactor with axial dispersion and complete-mix reactors in series are considered in the following discussion. However, before considering nonideal flow in reactors it will be helpful to examine the distinction between the diffusion and dispersion as applied to the analysis of reactors used for wastewater treatment.

I–1 THE DISTINCTION BETWEEN MOLECULAR DIFFUSION AND DISPERSION

In addition to short-circuiting caused by the use of improper design of reactor inlets and outlets, inadequate mixing, thermal and density currents, and diffusion and dispersion can also result in nonideal flow. The distinction between the diffusion and dispersion is as follows.

DIFFUSION

Under quiescent flow conditions (i.e., no flow), the mass transfer of material is brought about by *molecular diffusion*, in which dissolved constituents and/or small particles move randomly. This random motion is known as *Brownian Motion*. Further, it should be noted that molecular diffusion can occur under either laminar of turbulent flow conditions, as it does not depend on the bulk movement of a liquid. The transfer of mass by molecular diffusion in stationary systems can be represented by the following expression, known as Fick's first law:

$$r = -D_m \frac{\partial C}{\partial x} \tag{I–1}$$

where r = rate of mass transfer per unit area per unit time, $ML^{-2}T^{-1}$

D_m = coefficient of molecular diffusion in the x direction, L^2T^{-1}

C = concentration of constituent being transferred, ML^{-3}

In the chemical engineering literature the symbol "J" is used to denote mass transfer in concentration units whereas the symbol "N" is used to denote the transfer of mass expressed as moles. The negative sign in Eq. (I–1) is used to denote the fact that diffusion takes place in the direction of decreasing concentration (Shaw, 1966). Adolf Fick (1829–1901), a physician and physiologist, derived the first, and second, laws of diffusion in the 1850s by direct analogy to the equations used to describe the conduction of heat in solids as proposed by Fourier (Crank, 1957). Determination of numerical values for the coefficient of molecular diffusion is illustrated in Sec. 1–10 in Chap. 1.

DISPERSION

The transfer of a constituent from a higher concentration to a lower concentration (e.g., blending) brought about by eddies formed by turbulent flow or by the shearing forces between fluid layers is termed *dispersion.* Under this definition eddies can vary in size from microscale to macroscale to large circulation patterns in the oceans. While microscale transport can only be brought about by molecular diffusion, macroscale transport is brought about by both molecular diffusion and dispersion (Crittenden et al., 2012). Under turbulent flow conditions, the longitudinal spreading of a tracer is caused by dispersion, in which case the coefficient of molecular diffusion term, D_m, in Eq. (I–1) is replaced by the "coefficient of dispersion", D.

While the magnitude of the molecular diffusion depends primarily on the chemical and fluid properties, turbulent or eddy diffusion and dispersion depend primarily on the flow regime. Typical observed ranges for the coefficient of molecular diffusion and dispersion are reported in Table I–1. In all cases, it is important to remember that regardless of whether the coefficient of molecular diffusion or the coefficient of turbulent or eddy diffusion, or dispersion is operative, the driving force for mass transfer is the concentration gradient.

I–2 PLUG-FLOW REACTOR WITH AXIAL DISPERSION

In the following analysis only the one-dimensional problem is considered. However, it should be noted that all dispersion problems are three dimensional, with the dispersion coefficient varying with direction and the degree of turbulence. Using the relationship given above [Eq. (I–1)] and referring to Fig. I–1(c), the one-dimensional materials mass balance for the transport of a conservative dye tracer by advection and dispersion is:

Accumulation = inflow − outflow

$$\frac{\partial C}{\partial t}A\Delta x = \left(\upsilon AC - AD\frac{\Delta C}{\Delta x}\right)\bigg|_{x} - \left(\upsilon AC - AD\frac{\Delta C}{\Delta x}\right)\bigg|_{x+\Delta x} \tag{I–3}$$

where $\partial C/\partial t$ = change in concentration with time, $ML^{-3}T^{-1}$, (g/m$^3\cdot$s)

A = cross-sectional area in x direction, L^2, (m^2)

Δx = differential distance, L, m

C = constituent concentration, ML^{-3}, (g/m^3)

D = coefficient of axial dispersion, L^2T^{-1}, (m^2/s)

υ = average velocity in x direction, LT^{-1}, (m/s)

In Eq. (I–3) the term υAC represents the transport of mass due to advection and the term $AD(\Delta C/\Delta x)$ represents the transport brought about by dispersion. Taking the limit of Eq. (I–3) as Δx approaches zero results in the following two expressions:

$$\frac{\partial C}{\partial t} = -D\frac{\partial^2 C}{\partial x^2} - \upsilon\frac{\partial C}{\partial x} \tag{I–4}$$

Table I–1

Typical range of values for molecular diffusion and dispersion[a]

Coefficient	Symbol	Range of values, cm²/s
Molecular diffusion	D_m	$10^{-10} - 10^{-7}$
Dispersion	D	$10^{-3} - 10^{0}$

[a] Adapted from Schnoor (1996), Shaw (1966), and Thibodeaux et al. (2012).

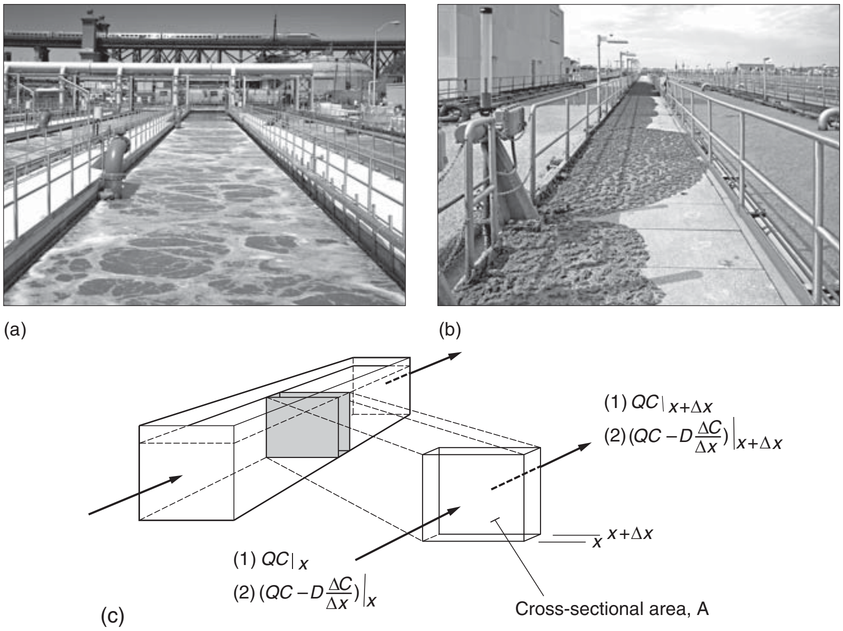

Figure I–1

Views of plug-flow reactors and definition sketch: (a) and (b) views of plug-flow activated sludge process reactors and (c) definition sketch for the hydraulic analysis of a plug-flow reactor with (1) advection only and (2) with advection and axial dispersion.

$$\frac{\partial C}{\partial t} = -D\frac{\partial^2 C}{\partial x^2} - \frac{\partial C}{\partial \tau} \tag{I–5}$$

In Eq. (I–5) the hydraulic detention time $\partial\tau$ has been substituted for the term $\partial x/\upsilon$. Equation (I–5) has been solved for small amounts of axial dispersion (see below). The solution for a unit pulse input leading to symmetrical output tracer response curves for small amounts of axial dispersion is given by Levenspiel (1998):

$$C_\theta = \frac{1}{2\sqrt{\pi(D/\upsilon L)}} \exp\left[-\frac{(1 - \theta)^2}{4(D/\upsilon L)}\right] \tag{I–6}$$

where C_θ = normalized tracer response, C/C_o, unitless
θ = normalized time, t/τ, unitless
t = time, T, (s)
τ = theoretical detention time, V/Q, T, (s)
D = coefficient of axial dispersion, L^2T^{-1}, (m^2/s)
υ = fluid velocity, LT^{-1}, (m/s)
L = characteristic length, L, (m)

The solution given by Eq. (I–6) is for what is known as a *closed system* in which it is assumed that there is no dispersion upstream or downstream of the boundaries of the reactor (e.g., a reactor with inlet and outlet weirs). A large reactor, such as a rectangular sedimentation basin, fed by a small diameter pipe, is an example of a closed system. If a tracer were added to the flow in the small diameter pipe, the tracer would be transported by advection with little or no dispersion. The same situation exists in the discharge pipe from the reactor. Nevertheless, for small amounts of dispersion, Eq. (I–6) can be used to approximate the performance of an open or closed reactor, regardless of the boundary conditions.

It will be noted that Eq. (I–6) has the same general form as the equation for the normal probability distribution. Thus, the corresponding mean and variance are

$$\bar{\theta} = \frac{\bar{t}_c}{\tau} = 1 \tag{I–7}$$

$$\sigma_\theta^2 = \frac{\sigma_c^2}{\tau^2} = 2\frac{D}{\upsilon L} \tag{I–8}$$

where $\bar{\theta}$ = normalized mean detention time, $\bar{t}_c/\tau$, unitless
$\bar{t}_c$ = mean detention (or residence) time derived from C curve [see Eq. (H–1), Appendix H], T, (s)
τ = theoretical detention (or residence) time, T, (s)
σ_θ^2 = variance of normalized tracer response C curve, T^2, (s^2)
σ_c^2 = variance derived from C curve [see Eq. (H–2), Appendix H], T^2, (s^2)

Defining the exact extent of axial dispersion is difficult. To provide an estimate of dispersion, the following unitless dispersion number has been defined:

$$d = \frac{D}{\upsilon L} = \frac{Dt}{L^2} \tag{I–9}$$

where d = dispersion number, unitless
D = coefficient of axial dispersion, L^2T^{-1}, (m^2/s)
υ = fluid velocity, LT^{-1}, (m/s)
L = characteristic length, L, (m)
t = travel time (L/υ), T, (s)

Normalized effluent concentration versus time curves, obtained using Eq. (I–6), for a plug-flow reactor with limited axial dispersion for various values of the dispersion number are shown on Fig. I–2.

When dispersion is large, the output curve becomes increasingly nonsymmetrical, and the problem becomes sensitive to the boundary conditions. In environmental problems, a wide variety of entrance and exit conditions are encountered, but most can be considered approximately open; that is, the flow characteristics do not change greatly as the boundaries are crossed. The solution to Eq. (I–5) for a unit pulse input in an *open system* with larger amounts of dispersion is as follows (Fogler, 2005; Levenspiel, 1998):

$$C_\theta = \frac{1}{2\sqrt{\pi\theta(D/\upsilon L)}} \exp\left[-\frac{(1-\theta)^2}{4\theta\,(D/\upsilon L)}\right] \tag{I–10}$$

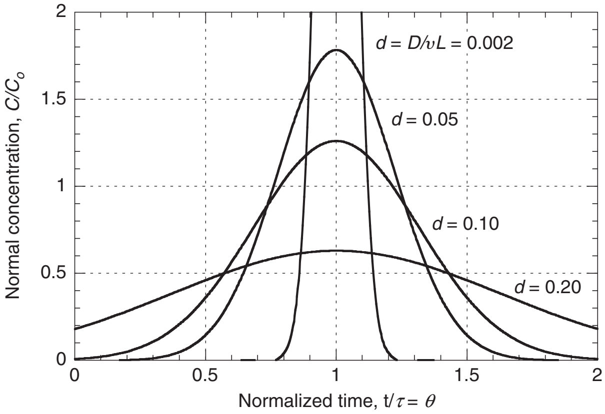

Figure I–2

Typical concentration versus time tracer response curves for a plug flow reactor with small amounts of axial dispersion subject to a pulse (slug) input of tracer.

The corresponding mean and variance are:

$$\bar{\theta} = \frac{\bar{t}_c}{\tau} = 1 + 2\frac{D}{\upsilon L} \tag{I–11}$$

$$\sigma_\theta^2 = \frac{\sigma_c^2}{\tau^2} = 2\frac{D}{\upsilon L} + 8\left(\frac{D}{\upsilon L}\right)^2 \tag{I–12}$$

where the terms are as defined previously for Eqs. (I–7), (I–8) and (I–9).

The mean as given by Eq. (I–11) is greater than the hydraulic detention time because of the forward movement of the tracer due to dispersion. Effluent concentration versus time curves, obtained using Eq. (I–12), for a plug-flow reactor with significant axial dispersion for various dispersion factors are shown on Fig. I–3. A more detailed discussion of closed and open reactors may be found in Fogler (2005) and Levenspiel (1998).

In the literature, the inverse of Eq (I–9), as given below, is often identified as the Peclet number of longitudinal dispersion (Kramer and Westererp, 1963).

$$P_e = \frac{\upsilon L}{D} = \frac{1}{d} \tag{I–13}$$

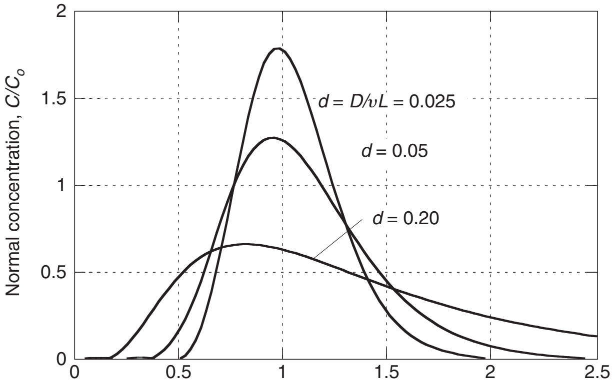
In effect, the Peclet number represents the ratio of the mass transport brought about by advection and dispersion. If the Peclet number is significantly greater than one, advection is the dominant factor in mass transport. If the Peclet number is significantly less than one, dispersion is the dominant factor in mass transport. Although beyond the scope of this presentation, it can also be shown that the number of complete-mix reactors in series required to simulate a plug-flow reactor with axial dispersion is approximately equal to the Peclet number divided by 2. Thus, for a dispersion factor of 0.025, the Peclet number is equal to 40 and the corresponding number of reactors in series needed to simulate the dispersion in a plug-flow reactor is equal to 20. This relationship will be illustrated in the following discussion dealing with complete-mix reactors in series. The Peclet number is also used to define transverse diffusion in packed bed plug-flow reactors (Denbigh and Turner, 1984).

For practical purposes, the following dispersion values can be used to assess the degree of axial dispersion in wastewater treatment facilities.

No dispersion	$d = 0$ (ideal plug-flow)
Low dispersion	$d = <0.05$
Moderate dispersion	$d = 0.05$ to 0.25
High dispersion	$d = >0.25$
	$d \to \infty$ (complete-mix)

Figure I–3

Typical concentration versus time tracer response curves for a plug flow reactor with large amounts of axial dispersion subject to a pulse (slug) input of tracer.



Typical dispersion numbers determined for actual treatment facilities are given in Table I–2. The considerable range in the dispersion numbers reported in Table I–2 for individual treatment processes is due, most often, to one or more of the following factors (Arceivala and Asolekar, 2007):

1. The scale of the mixing phenomenon
2. Geometry (i.e., aspect ratio) of the unit
3. Power input per unit volume (i.e., mechanical and pneumatic)
4. Type and disposition of the inlets and outlets of the treatment units
5. Inflow velocity and its fluctuations
6. Density and temperature differences between the inflow and the contents of the reactor.

Because of the wide range of dispersion numbers that can result for individual treatment processes, special attention must be devoted to the factors cited above in the design of treatment facilities. Determination of the dispersion number and the coefficient of dispersion using the tracer response curves is illustrated in Example I–1.

Evaluation of the coefficient of axial dispersion D for existing facilities is done experimentally using the results of tracer tests, as discussed previously. Because the systems encountered in wastewater treatment are large, experimental work is often difficult and expensive, and is, unfortunately, usually after the fact. To take into account axial dispersion in the design of treatment facilities both scaled models and empirical relationships have been developed for a variety of treatment units including oxidation ponds (Polprasert and Bhattasrai, 1992) and chlorine contact basins (Crittenden et al., 2012). An approximate value of D for water for large Reynolds numbers is (Davies, 1972)

$$D = 1.01\nu \mathrm{N_R}^{0.875} \tag{I–14}$$

where D = coefficient of dispersion, L^2T^{-1}, (m^2/s)
ν = kinematic viscosity, L^2T^{-1}, m^2/s (see Appendix C)
N_R = Reynolds number, unitless
$= 4\upsilon R/\nu$
υ = velocity in open channel, LT^{-1}, (m/s)
R = hydraulic radius = area/wetted perimeter, L, (m)

Table I–2

Typical dispersion numbers for various wastewater treatment facilities [a]

Treatment facility	Range of values for dispersion number
Rectangular sedimentation tanks	0.2–2.0
Activated sludge aeration reactors	
Long plug-flow	0.1–1.0
Complete-mix	3.0–4.0+
Oxidation ditch activated sludge process	3.0–4.0+
Waste stabilization ponds	
Single ponds	1.0–4.0+
Multiple cells in series	0.1–1.0
Mechanically aerated lagoons	
Long rectangular shaped	1.0–4.0+
Square shaped	3.0–4.0+
Chlorine contact basins	0.02–0.004

[a] Adapted from Arceivala and Asolekar (2007).

Values for N_R found in open channel flow in wastewater treatment plants are typically in the range from 10^3 to 10^4. The corresponding values for D range from 0.0004 to 0.003 m^2/s (4 to 30 cm^2/s).

EXAMPLE I–1 **Determination of the Dispersion Number and the Coefficient of Dispersion from Concentration versus Time Tracer Response Curves** Use the concentration versus time tracer data given in Example 12-8 in Chap. 12 to determine the dispersion number and the coefficient of dispersion for the chlorine contact basin described in Example 12–8. Compare the value of the coefficient of dispersion computed, using the tracer data, to the value computed using Eq. (I–14). Assume the following data are applicable:

1. The flowrate at the time when the tracer test was conducted = 240,000 m^3/d
2. Number of chlorine contact basin = 4
3. Number of channels per contact basins = 13
4. Channel dimensions
   a. Length = 36.6 m
   b. Width = 3.0 m
   c. Depth = 4.9 m
5. Temperature = 20°C

Solution

1. From Example 12-8, the mean value and variance for the tracer response C curve are:
   a. Mean, $\tau_{\Delta c} = 2.7$ h
   b. Variance, $\sigma^2_{\Delta c} = 280.5\ \text{min}^2$
2. Determine the theoretical detention time for the chlorine contact basin using the given data.

$$\tau = \frac{4 \times 13 \times (36.6\ \text{m} \times 3.0\ \text{m} \times 4.9\ \text{m})}{(240{,}000\ \text{m}^3/\text{d})}$$

3. Determine the normalized mean detention time using Eq. (I–7). Use the approximate value of $\bar{t}_{\Delta c}$ for $\bar{t}_c$.

$$\bar{\theta}_{\Delta c} = \frac{\bar{t}_{\Delta c}}{\tau} \approx \frac{2.7}{2.8} \approx 0.96 \approx 1.0$$

4. Determine the dispersion number using Eq. (I–8). Use the approximate value of $\sigma^2_{\Delta c}$ for σ^2_c.

$$\sigma^2_{\Delta c} = \frac{\sigma^2_{\Delta c}}{\tau^2} \approx 2\frac{D}{\upsilon L} = 2\text{d}$$

$$d \approx \frac{1}{2}\frac{\sigma^2_{\Delta c}}{\tau^2} \approx \frac{1}{2}\frac{280.5\ \text{min}^2}{(167.9\ \text{min})^2} = 0.00498$$

5. Using Eq. (I–9), determine the coefficient of dispersion.

$$D = d \times \upsilon \times L$$

$$\upsilon = \frac{Q}{A} = \frac{(240{,}000\ \text{m}^3/\text{d})}{(4 \times 13 \times 3.0\ \text{m} \ \times 4.9\ \text{m})} = 314.0\ \text{m/d} \ = 0.00363\ \text{m/s}$$

$$D = (0.00498)(0.00363\ \text{m/s})(36.6\ \text{m}) = 6.62 \times 10^{-4}\ \text{m}^2/\text{s}$$

6. Compare the value of the coefficient of dispersion computed in Step 5 with the value computed using Eq. (I–14).

   $$D = 1.01\nu N_R^{0.875}$$

   a. Compute the Reynolds number

   $$N_R = 4vR/\nu$$
   $$\nu = 1.002 \times 10^{-6}\ \text{m}^2/\text{s}$$
   $$N_R = \frac{(4)(0.00363\ \text{m/s})\ [(3.0\ \text{m} \times 4.9\ \text{m})/(2 \times 4.9\ \text{m} + 3.0\ \text{m})]}{(1.002 \times 10^{-6}\ \text{m}^2/\text{s})} = 1664$$

   b. Compute the coefficient of dispersion

   $$D = (1.01)(1.002 \times 10^{-6})\,(1664)^{0.875} = 6.66 \times 10^{-4}\ \text{m}^2/\text{s}$$

Comment Based on the computed value of the dispersion number (0.00498), the chlorine contact basin would be classified as having low dispersion (i.e., $d = < 0.05$). The coefficient of dispersion determined using the results of the tracer study and Eq. (I–14) are remarkably close, given the nature of such measurements.

I–3 COMPLETE-MIX REACTORS IN SERIES

When varying amounts of axial dispersion are encountered, the flow is sometimes identified as *arbitrary flow*. The output from a plug-flow reactor with axial dispersion (arbitrary flow) is often modeled using a number of complete-mix reactors in series, as outlined below. In some situations, the use of a series of complete-mix reactors may have certain advantages with respect to treatment. To understand the hydraulic characteristics of reactors in series (see Fig. I–4), assume that a pulse input (i.e., a slug) of tracer is injected into the first reactor in a series of equally sized reactors so that the resulting instantaneous concentration of tracer in the first reactor is C_o. The total volume of all the reactors is V, the volume of an individual reactor is V_i, and the hydraulic residence time V_i/Q is τ_i. The effluent concentration from the first reactor as is given by the following equation [see Eq. (1–13) in Chap. 1].

$$C_1 = C_o e^{-t/\tau_i} \tag{I–15}$$

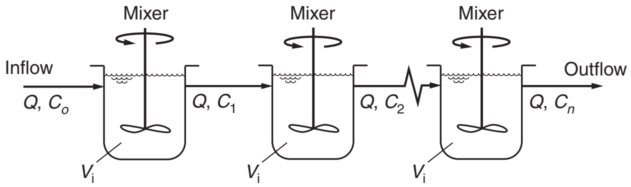
Writing a materials balance for the second reactor results in the following:

Accumulation = inflow − outflow

$$\frac{dC_2}{dt} = \frac{1}{\tau_i}C_1 - \frac{1}{\tau_i}C_2 \tag{I–16}$$

Figure I–4

Definition sketch for the analysis of complete-reactors in series.



Rearranging the terms in Eq. (I–16) and substituting Eq. (I–15) for C_1 results in

$$\frac{dC_2}{dt} + \frac{C_2}{\tau_i} = \frac{C_o}{\tau_i} e^{-t/\tau_i} \tag{I–17}$$

The general non-steady-state solution for Eq. (I–17) is obtained by first noting that Eq. (I–17) has the form of the standard first-order linear differential equation. The solution procedure outlined in Eqs. (I–18) through (I–23) involves the use of an integrating factor. It should be noted that Eq. (I–17) can also be solved using the separation of variables method. The solution to Eq. (I–17) is included here because these types of equations are encountered frequently in the field of environmental engineering and in this text. The first step in the solution is to rewrite Eq. (I–17) in the form

$$C_2' + \frac{C_2}{\tau_i} = \frac{C_o}{\tau_i} e^{-t/\tau_i} \tag{I–18}$$

where C_2' is used to denote the derivative dC_2/dt. In the next step, both sides of the expression are multiplied by the integrating factor $e^{\beta t}$, where $\beta = (1/\tau_i)$.

$$e^{\beta t}(C_2' + \beta C_2) = e^{\beta t}(\beta C_o e^{-\beta t}) = \beta C_o \tag{I–19}$$

The left hand side of the above expression can be written as a differential as follows:

$$(C_2 e^{\beta t})' = \beta C_o \tag{I–20}$$

The differential sign is removed by integrating the above expression

$$C_2 e^{\beta t} = \beta C_o \int dt \tag{I–21}$$

Integration of Eq. (I–21) yields

$$C_2 e^{\beta t} = \beta C_o t + \mathrm{K}\ \text{(constant of integration)} \tag{I–22}$$

Dividing by $e^{\beta t}$ yields

$$C_2 = \beta \mathrm{C}_o t e^{-\beta t} + \mathrm{K} e^{-\beta \mathrm{t}} \tag{I–23}$$

But when $t = 0$, $C_2 = 0$ and K is equal to 0. Thus,

$$C_2 = C_o \frac{t}{\tau_i} e^{-t/\tau_i} \tag{I–24}$$

Following the same solution procedure, the generalized expression for the effluent concentration for the ith reactor is

$$C_i = \frac{C_o}{(i-1)!} \left(\frac{t}{\tau_i}\right)^{i-1} e^{-t/\tau_i} \tag{I–25}$$

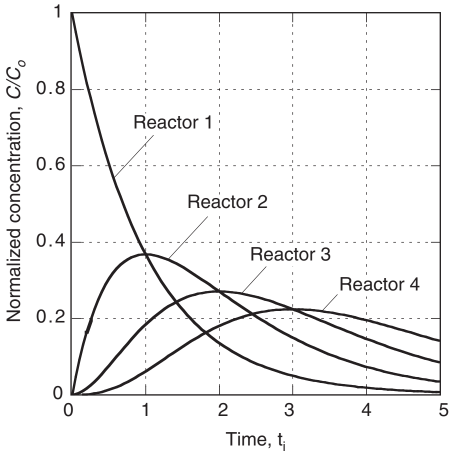
The effluent concentration from each of four complete-mix reactors in series is shown on Fig. I–5.

The corresponding expression based on the overall hydraulic residence time τ, where τ is equal to $n\tau_i$ is

$$C_i = \frac{C_o}{(i-1)!} \left(\frac{nt}{\tau}\right)^{i-1} e^{-nt/\tau} \tag{I–26}$$

Figure I–5

Effluent concentration curves for each of four complete-mix reactors in series subject to a slug input of tracer into the first reactor of the series.



Fraction Remaining

Equation (I–25) can also be used to obtain the fraction of tracer remaining in a series of complete-mix reactors at any time *t*. The fraction of tracer remaining, *F*, at time *t*, is equal to

$$F = \frac{C_1 + C_2 + \cdots + C_n}{C_o} \tag{I–27}$$

Using Eq. (I–25) to obtain the individual effluent concentrations, the fraction remaining in four equal sized reactors in series is given by

$$F_{4R} = \frac{C_o e^{-4t/\tau} + C_o(4t/\tau)\,\mathrm{e}^{-4t/\tau} + (C_o/2)\,(4t/\tau)^2 e^{-4t/\tau} + (C_o/6)\,(4t/\tau)^3 e^{-4t/\tau}}{C_o}$$

$$F_{4R} = \left[1 + (4t/\tau) + \frac{(4t/\tau)^2}{2} + \frac{(4t/\tau)^3}{6}\right] e^{-4t/\tau} \tag{I–28}$$

The fraction of a tracer remaining in a series of 2, 4, 6 and 75 complete-mix reactors in series is given on Fig. I–6.

Comparison of Nonideal Plug-Flow Reactor and Complete-Mix Reactors in Series

In many cases it will be useful to model the performance of plug-flow reactors with axial dispersion, as discussed previously, with a series of complete-mix reactors in series. To obtain

Figure I–6

Fraction of tracer remaining in a system comprised of reactors in series.

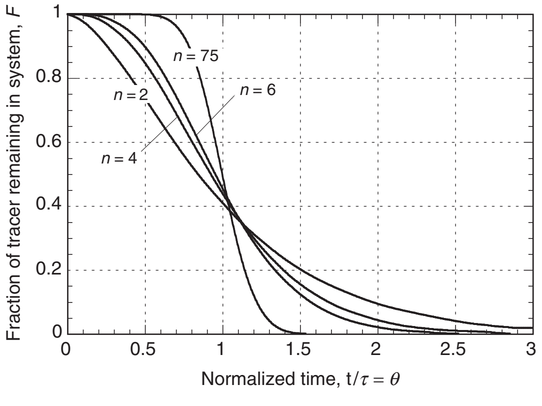


Figure I–7

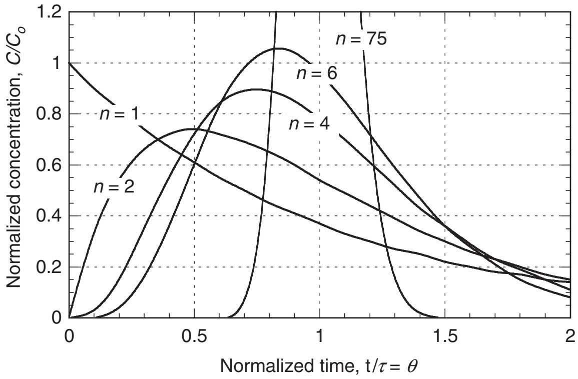
Effluent tracer concentration curves for reactors in series, subject to a slug input of tracer into the first reactor of the series. Concentration values greater than one occur because the same amount of tracer is placed in the first reactor in each series of reactors.



the normalized residence time distribution (RTD) curve for n reactors in series, Eq. (I–26) can be written as follows by noting that the total volume is nV_i and $\tau = n\tau_i$:

$$E(\theta) = \frac{C_n}{C_o/n} = \frac{n}{(n-1)!}(n\theta)^{n-1}e^{-n\theta} \tag{I–29}$$

In effect, in Eq. (I–29) it is assumed that the same amount of tracer is always added to the first reactor in series. Effluent residence time distribution curves, obtained using Eq. (I–57), for 1, 2, 4, 6, and 75 reactors in series are shown on Fig. I–7. It is interesting to note that a model comprised of four complete-mix reactors in series is often used to describe the hydraulic characteristics of constructed wetlands. As shown on Fig. I–7, the concentration increases as the number of reactors in series increases because the same amount of tracer is used regardless of the number of reactors in series. It should also be noted that the F curves shown on Fig. I–6 can also be obtained by integrating the E curves given on Fig. I–7.

A comparison of the residence time distribution curves obtained for a plug-flow reactor, with a dispersion number of 0.05, and to the residence time distribution curves obtained for six, eight and ten complete-mix reactors in series is shown on Fig. I–8. As shown, all three of the complete-mix reactors in series can be used, for practical purposes, to simulate a plug-flow reactor with a dispersion factor of 0.05. As noted previously, the number of reactors in series needed to simulate a plug-flow reactor with dispersion is approximately equal to the Peclet number divided by 2. Thus, for a dispersion factor of 0.05, the Peclet number is equal to 20 and the corresponding number of reactors in series needed to simulate the dispersion in a plug-flow reactor is equal to 10. As shown on Fig. I–8, the response curves computed using ten reactors in series and Eq. (I–10) with a dispersion number, $d = 0.05$ are essentially the same.

Figure I–8

Comparison of effluent response curves for a plug-flow reactor with a dispersion factor of 0.05 and reactor systems comprised of six, eight, and ten reactors in series subject to a pulse input of tracer.

Name Index

Subject Index

Because a number of the subjects covered in this text can be referenced (i.e., indexed) under different alphabetical listings, it has been necessary to develop an approach to limit the degree of duplication, yet not affect the utility of the index. The approach used is as follows. Each subject with multiple subentries is indexed in detail under one letter of the alphabet. Where the same subject is indexed under another letter of the alphabet, inclusive page numbers are given and a *See also* citation is given to the location where the subject is indexed in detail. For example, Activated carbon adsorption, 1138–1162, is followed by (*See also* Adsorption). Where a subject is indexed in detail (e.g., Biochemical oxygen demand) and a commonly used abbreviation (e.g., BOD) is also cited under the same letter of the alphabet, the abbreviated entry is followed by a *See* citation. For example, the index entry BOD is followed by (*see* Biochemical oxygen demand). Where an abbreviation occurs under a different letter of the alphabet than where the detailed citation is given, inclusive page numbers are given followed by the *See also* citation. For older or unused terms, the *see* citation is used to direct the reader to the appropriate term used.

To access the number of data tables in the textbook more easily, an index entry followed by the capital letter T in parenthesis [e.g., (T)] is used to denote a data table related to the subject matter.
