About the Authors

George Tchobanoglous is Professor Emeritus in the Department of Civil and Environmental Engineering at the University of California, Davis. He received a B.S. degree in civil engineering from the University of the Pacific, an M.S. degree in sanitary engineering from the University of California at Berkeley, and a Ph.D. from Stanford University in 1969. Dr. Tchobanoglous' research interests are in the areas of wastewater treatment and reuse, wastewater filtration, UV disinfection, aquatic wastewater management systems, wastewater management for small and decentralized wastewater management systems, and solid waste management. He has authored or co-authored over 500 technical publications including 22 textbooks and 8 reference works. The textbooks are used in more than 225 colleges and universities, by practicing engineers, and in universities worldwide both in English and in translation. His books are famous for successfully bridging the gap between academia and the day-to-day world of the engineer. He is a Past President of the Association of Environmental Engineers and Science Professors. Among his many honors, in 2003 Professor Tchobanoglous received the Clarke Prize from the National Water Research Institute. In 2004, he received the Distinguished Service Award for Research and Education in Integrated Waste Management from the Waste-To-Energy Research and Technology Council. In 2004, he was also inducted into the National Academy of Engineering. In 2005, he was awarded an honorary Doctor of Engineering from the Colorado School of Mines. In 2007, he received the Frederick George Pohland Medal awarded by AAEE and AEESP. In 2012 he was made a WEF Fellow. He is a registered Civil Engineer in California.

H. David Stensel is a Professor in the Civil and Environmental Engineering Department at the University of Washington, Seattle, WA. Prior to his academic positions, he spent 10 years in practice developing and applying industrial and municipal wastewater treatment processes. He received a B.S. degree in civil engineering from Union College, Schenectady, NY, and M.E. and Ph.D. degrees in environmental engineering from Cornell University. His principal research interests are in the areas of wastewater treatment, biological nutrient removal, sludge processing methods, resource recovery, and biodegradation of micropollutants. He is a Past Chair of the Environmental Engineering Division of ASCE, has served on the board of the Association of Environmental Engineering Professors and on various committees for ASCE and the Water Environment Federation. He has authored or coauthored over 150 technical publications and a textbook on biological nutrient removal. Research recognition honors include the ASCE Rudolf Hering Medal, the Water Environment Federation Harrison Prescott Eddy Medal twice, and the Bradley Gascoigne Medal. In 2013, he received the Frederick George Pohland Medal awarded by AAEE and AEESP. He is a registered professional engineer, a diplomate in the American Academy of Environmental Engineers and a life member of the American Society of Civil Engineers and the Water Environment Federation.

Ryujiro Tsuchihashi is a technical leader with AECOM. He received his B.S. and M.S. in civil and environmental engineering from Kyoto University, Japan, and a Ph.D. in environmental engineering from the University of California, Davis. The areas of his expertise include wastewater/water reclamation process evaluation and design, evaluation and assessment of water reuse systems, biological nutrient removal, and evaluation of greenhouse gas emission reduction from wastewater treatment processes. He was a co-author of the textbook "Water Reuse: Issues, Technologies and Applications," a companion textbook to this textbook. He is a technical practice coordinator for AECOM's water reuse leadership team. Ryujiro Tsuchihashi is a member of the Water Environment Federation, American Society of Civil Engineer, and International Water Association, and has been an employee of AECOM for 10 years, during which he has worked on various projects in the United State, Australia, Jordan, and Canada.

Franklin Burton served as vice president and chief engineer of the western region of Metcalf & Eddy in Palo Alto, California for 30 years. He retired from Metcalf & Eddy in 1986 and has been in private practice in Los Altos, California, specializing in treatment technology evaluation, facilities design review, energy management, and value engineering. He received his B.S. in mechanical engineering from Lehigh University and an M.S. in civil engineering from the University of Michigan. He was co-author of the third and fourth editions of the Metcalf & Eddy textbook "Wastewater Engineering: Treatment and Reuse." He has authored over 30 publications on water and wastewater treatment and energy management in water and wastewater applications. He is a registered civil engineer in California and is a life member of the American Society of Civil Engineers, American Water Works Association, and Water Environment Federation.

Mohammad Abu-Orf is AECOM's North America biosolids practice leader and wastewater director. He received his B.S. in civil engineering from Birzeit University, West Bank, Palestine and received his M.S. and Ph.D. in civil and environmental engineering from the University of Delaware. He worked with Siemens Water Technology and Veolia Water as biosolids director of research and development. He is the main inventor on five patents and authored and co-authored more than 120 publications focusing on conditioning, dewatering, stabilization and energy recovery from biosolids. He was awarded first place for Ph.D. in the student paper competition by the Water Environment Federation for two consecutive years in 1993 and 1994. He coauthored manuals of practice and reports for the Water Environment Research Foundation. He served as an editor of the Specialty Group for Sludge Management of the International World Association for six years and served on the editorial board of the biosolids technical bulletin of the Water Environment Federation. Mohammad Abu-Orf has been an employee of AECOM for 6 years.

Gregory Bowden is a technical leader with AECOM. He received his B.S. in chemical engineering from Oklahoma State University and a Ph.D. in chemical engineering from the University of Texas at Austin. He worked for Hoechst Celanese (Celanese AG) for 10 years as a senior process engineer, supporting wastewater treatment facility operations at chemical production plants in North America. He also worked as a project manager in the US Filter/Veolia North American Technology Center. His areas of expertise include industrial wastewater treatment, biological and physical/chemical nutrient removal technologies and biological process modeling. Greg Bowden is a member of the Water Environment Federation and has been an AECOM employee for 9 years.

William Pfrang is a Vice-President of AECOM and Technical Director of their Metro-New York Water Division. He began his professional career with Metcalf & Eddy, Inc., as a civil engineer in 1968. During his career, he has specialized in municipal wastewater treatment plant design including master planning, alternative process assessments, conceptual, and detailed design. Globally, he has been the lead engineer for wastewater treatment projects in the United States, Southeast Asia, South America, and the Middle East. He received his B.S. and M.S. in civil engineering from Northeastern University. He is a registered professional engineer, a member of the American Academy of Environmental Engineers, and the Water Environment Federation. William Pfrang has been an employee of the firm for over 40 years.

Preface

Since completion of the fourth edition of this textbook, the field of wastewater engineering has evolved at a rapid pace. Some of the more significant changes include:

1. A new view of wastewater as a source of energy, nutrients, and potable water.
2. More stringent discharge requirements related to nitrogen and phosphorus;
3. Enhanced understanding of the fundamental microbiology and physiology of the microorganisms responsible for the removal of nitrogen and phosphorus and other constituents;
4. An appreciation of the importance of the separate treatment of return flows with respect to meeting more stringent standards for nitrogen removal and opportunities for nutrient recovery,
5. Increased emphasis on the treatment of sludge and the management of biosolids; and
6. Increased awareness of carbon footprint impacts and greenhouse gas emissions, and an emphasis on the development of energy-neutral or energy-positive wastewater plants through more efficient use of chemical and heat energy in wastewater.

The 5th edition of this textbook has been prepared to address the significant changes cited above. Increased understanding of the importance of pre-treatment processes is addressed in Chap. 5. Advances in biological treatment are addressed in Chaps. 7 through 10. New developments in disinfection are considered in Chap. 12. The management of sludge and biosolids is now covered in Chaps. 13 and 14. Return flow treatment is considered in Chap. 15. Energy management is considered in Chap. 17. An emphasis of this fifth edition is to present practical design and operational data, while maintaining a solid theoretical discussion of the technologies and applications. Input from AECOM's process engineers and outside reviewers was sought to provide the user with a source of real-world practical information, the likes of which is not available in any single source.

IMPORTANT FEATURES OF THIS BOOK

In the 4th edition of this book, a separate chapter was devoted to the fundamentals of process analysis, including an introduction to the preparation of mass balances and reaction kinetics. Because introductory courses on process analysis and modeling are now taught at most colleges and universities, the material on the fundamentals of process analysis from the 4th edition has been condensed and is now included in Secs. 1–7 through 1–11 in Chap. 1. The material on process analysis has been retained as a reference source for students that have already had a separate course on modeling and as an introduction to the subject for students who may not have had an introductory course.

Following the practice in the 4th edition, more than 150 example problems have been worked out in detail to enhance the readers' understanding of the basic concepts presented in the text. To aid in the planning, analysis, and design of wastewater management systems, design data and information are summarized and presented in more than 400 tables, most of which are new. To illustrate the principles and facilities involved in the field of wastewater management, over 850 individual illustrations, graphs, diagrams, and photographs are included. An additional 120 drawings are included in tables. More than 375 homework problems and discussion topics are included to help the readers of this textbook hone their analytical skills and enhance their mastery of the material. Extensive references are also provided for each chapter.

The International System (SI) of Units is used in the 5th edition. The use of SI units is consistent with teaching practice in most US universities and in most countries throughout the world. In general, dual sets of units (i.e., SI and US customary) have been used for the data tables. Where the use of double units was not possible, conversion factors are included as a footnote to the table.

To further increase the utility of this textbook, several appendixes have been included. Conversion factors from International System (SI) of Units to US Customary Units and the reverse are presented in Appendixes A–1 and A–2, respectively. Conversion factors used commonly for the analysis and design of wastewater management systems are presented in Appendix A–3. Abbreviations for SI and US customary units are presented in Appendixes A–4 and A–5, respectively. Physical characteristics of air and selected gases and water are presented in Appendixes B and C, respectively. The statistical analysis is reviewed in Appendix D. Dissolved oxygen concentrations in water as a function of temperature are presented in Appendix E. Carbonate equilibrium is considered in Appendix F. Moody diagrams for the analysis of flow in pipes are presented in Appendix G. The analysis of nonideal flow in reactors is considered in Appendix H. Modeling nonideal flow in reactors is addressed in Appendix I.

USE OF THIS BOOK

Enough material is presented in this textbook to support a variety of courses for one or two semesters, or three quarters at either the undergraduate or graduate level. The book can be used both as a class textbook or class reference to supplement instructors' notes. The specific topics to be covered will depend on the time available and the course objectives. Suggested course outlines are presented below.

For a one semester introductory course on wastewater treatment, the following material is suggested.

Topic	Chapter	Sections
Introduction to wastewater treatment	1	1–1 to1–6
Wastewater characteristics	2	All
Wastewater flowrates and constituent loadings	3	All
Physical unit processes	5	5–1 to 5–8
Chemical unit processes	6	6–1 to 6–3
Introduction to biological treatment of wastewater	7	All
Disinfection	12	12–1 to 12–5, 12–9
Biosolids management	13, 14	All
Process selection, design, and implementation	4	All
Advanced treatment processes (optional)	6, 11	6–7, 6–8, 11–5 to 11–7

For a two semester course on wastewater treatment, the following material is suggested.

Topic	Chapter	Sections
Introduction to wastewater treatment	1	1–1 to1–6
Wastewater characteristics	2	All
Wastewater flowrates and constituent loadings	3	All
Process selection, design, and implementation	4	4–1 to 4–5
Physical unit operations	5	All
Chemical unit operations	6	All
Introduction to biological treatment of wastewater	7	All
Suspended growth biological treatment processes	8	All
Attached growth and combined biological treatment processes	9	9–1 to 9–5
Anaerobic treatment processes	10	10–1 to 10–5
Disinfection	12	All
Sludge Management	13	All
Biosolids management	14	All
Treatment of return flows	15	All

For a one semester course on biological wastewater treatment, the following material is suggested.

Topic	Chapter	Sections
Introduction to wastewater treatment	1	1–1 to1–6
Wastewater characteristics	2	All
Process selection, design, and implementation	4	4–2, 4–4, 4–5
Introduction to biological treatment of wastewater	7	7–1 to 7–8
Suspended growth processes	8	8–1 to 8–3
Attached growth biological treatment processes	9	All
Anaerobic treatment processes	10	10–1 to 10–5
Anaerobic sludge treatment	13	13–9, 13–10

For a one semester course on physical and chemical unit processes, the following material is suggested. It should be noted that material listed below could be supplemented with additional examples from water treatment.

Topic	Chapter	Sections
Process selection, design, and implementation	4	4–1 to 4–4
Introduction to physical unit processes		
Mixing and flocculation	5	5–3
Sedimentation	5	5–4, 5–6, 5–7,
Gas transfer	5	5–10, 5–11
Filtration (conventional depth filtration)	11	11–3, 11–4, 11–6
Membrane filtration	11	11–7
Adsorption	11	11–9
Gas stripping	11	11–10
UV disinfection	12	12–9
Introduction to chemical unit processes		6–2
Coagulation	6	6–2
Chemical precipitation	6	6–3, 6–4, 6–6
Ion exchange	11	11–11
Water stabilization	6	6–10
Chemical oxidation (conventional)	6	6–7
Advanced oxidation processes	6	6–8
Photolysis	6	6–9

Acknowledgments

This textbook is a tribute to the engineers and scientists who continue to push forward the practice and technologies of the wastewater industry. These advances continue to offer the world cleaner water resources and sustainable water supplies. The book could not have been written without the efforts of numerous individuals including the primary writers, contributing authors, individuals with specialized skills, technical reviewers, outside reviewers, and practitioners who contributed real life experiences.

Contributing authors from AECOM included: Dr. Mohammad Abu-Orf who revised and updated Chaps. 13 and 14, Dr. Gregory Bowden who wrote Chap. 15, and Mr. William Pfrang who revised and updated Chap. 5. Their assistance is acknowledged gratefully. Dr. Harold Leverenz of the University of California at Davis, is singled out for special acknowledgment for extraordinary contributions to the development of the graphics used throughout the text, the revision of Chap. 6, and individual section write ups. Others deserving special acknowledgment, in alphabetical order, are: Mr. Russel Adams an environmental consultant provided comprehensive reviews of Chaps. 3, 11, and 12; Dr. Heidi Gough of the University of Washington wrote the molecular biology section of Chap. 7; Dr. April Gu of Northeastern University who helped write and provided material for Chap. 9; Ms. Emily Legault of HDR Engineers provided thoughtful and comprehensive reviews of Chaps. 2, 3, 7, 8, 11, and 12; Mr. Mladen Novakovic of AECOM contributed to the development of Chap. 5; Mr. Terry Goss of AECOM contributed extensively to the development of Chaps. 13 and 14; and Mr. Dennis Totzke of Applied Technologies had significant involvement in the development of Chap. 10.

The review of the manuscript was critical to maintain the quality of the text. Outside reviewers, arranged alphabetically, who provided critical reviews included: Dr. Onder Caliskaner of Kennedy/Jenks Consultants reviewed portions of Chap. 11; Dr. Robert Cooper of BioVir laboratories reviewed the section on microbiology in Chap. 2; Ms. Libia Diaz of the University of California at Davis reviewed the homework problems; Dr. Robert Emerick of Stantec Engineers, reviewed the section on UV disinfection in Chap. 12; Dr. David Hokanson of Trussell Technologies reviewed portions of Chap. 11; Ms. Amelia Holmes of University of California at Davis reviewed the homework problems; Dr. Kurt Ohlinger of Sacramento Regional County Sanitation District provided review for phosphorus recovery. Dr. Edward Schroeder professor emeritus of the University of California at Davis reviewed portions of Chaps. 1 and 2.

A number of current and former AECOM engineers contributed to the development of the manuscript by providing design information and by reviewing specific portions of the text. Listed in alphabetical order they are:

- Mr. Michael Adkins
- Mr. David Ammerman
- Ms. Jane Atkinson
- Mr. Simon Baker
- Dr. William Barber
- Mr. David Bingham
- Mr. Joerg Blischke
- Mr. Gary Breitwisch
- Dr. Dominique Brocard
- Mr. Nathan Cassity
- Mr. Chi Yun Chris Chen
- Mr. William Clunie
- Dr. Patrick Coleman
- Mr. Nicholas Cooper
- Mr. Grant Davies
- Mr. Daniel Donahue
- Mr. Ralph Eschborn
- Mr. Bryce Figdore

Mr. Steven Freedman
Mr. Lee Glueckstein
Mr. Terry Goss
Mr. Gary Hanson
Mr. Brian Harrington
Mr. Derek Hatanaka
Mr. Gregory Heath
Mr. Roger Hessel
Dr. Richard Irwin
Mr. Jay Kemp
Mr. King Fai Alex Kwan
Mr. Pertti Laitinen
Dr. Mark Laquidara
Dr. David Lycon
Mr. Jim Marx
Mr. Chris Macey
Mr. Bradley McClain
Mr. Alexander Mofidi
Mr. Paul Moulton
Mr. Mladen Novakovic
Mr. Kevin Oldfield
Mr. Ahmed Al-Omari
Mr. Robert Pape
Mr. Frederick Pope
Ms. Lucy Pugh
Mr. Jeffrey Reade
Mr. Dennis Sanchez
Mr. Ralph Schroedel
Dr. Keith Sears
Mr. Gerald Stevens
Dr. Beverley Stinson
Mr. Jean-Yves Urbain
Mr. Kevin Voit
Mr. Thomas Weber
Mr. Simon Wills

Finally, the production of this textbook could not have been completed without the guidance and assistance of the following individuals. Mr. William Stenquist, Executive Editor and Ms. Lorraine Buczek, Development Editor of the McGraw Hill Book Company. Ms. Rose Kernan and Ms. Erin McConnell of RPK Editorial Services, Inc. provided service above and beyond in working with the authors to produce the textbook. The collective efforts of these individuals were invaluable and greatly appreciated.

George Tchobanoglous
H. David Stensel
Ryujiro Tsuchihashi
Franklin Burton

Foreword

One hundred years have passed since the three-volume "American Sewerage Practice" treatise was published in 1914–1915 by Leonard Metcalf and Harrison P. Eddy. The initial publication quickly became the standard of care and established the foundation for modern wastewater treatment. The original concept of combining theory with a strong compliment of practical data and design guidance continues on in the fifth edition. The wealth of practical information continues to be a cornerstone of Metcalf & Eddy publications, and has led to its reputation as the number one wastewater practice textbook. In this fifth edition over 150 example problems and over 375 homework problems are provided.

The textbook has become a widely used teaching resource for universities and colleges and a reference for engineering firms throughout the world and is now published in Chinese, Greek, Italian, Japanese, Korean, and Spanish.

New advances in technology continue to occur at a record pace in all fields including wastewater treatment. As a result this fifth edition includes numerous advances and represents the current state of the art information. AECOM takes great pride in presenting this Metcalf & Eddy textbook, a comprehensive compilation of the best wastewater practices in use today.

The manuscript was developed by a team of primary writers including Dr. George Tchobanoglous, Dr. H. David Stensel, Dr. Ryujiro Tsuchihashi, Dr. Mohammad Abu-Orf, Mr. William Pfrang and Dr. Gregory Bowden. In addition to our primary authors, over 55 AECOM employees and outside technical specialists contributed in reviews and provided practical data and guidance.

I would also like to acknowledge Mr. Bill Stenquist, Executive Editor, McGraw-Hill, who was instrumental in bringing the resources of McGraw-Hill to this project.

The fifth edition textbook could not have been developed without the enthusiastic support of AECOM. I thank Mr. John M. Dionisio, Chairman and Chief Executive Officer, Mr. Robert Andrews, Chief Executive, Water, and Mr. James T. Kunz, Senior Vice President—Program Director.

Jekabs P. Vittands
Senior Vice President
AECOM

1

Introduction to Wastewater Treatment and Process Analysis

WORKING TERMINOLOGY

Term	**Definition**
Batch reactor	A vessel in which flow is neither entering nor leaving during the reaction time.
Biosolids	Sludge from wastewater treatment processes that has been stabilized to meet the criteria in the U.S. EPA's 40 CFR 503 regulations and, therefore, can be used beneficially.
Complete-mix reactor (CMR)	A reactor in which complete mixing occurs instantaneously and uniformly throughout the reactor as fluid particles enter the reactor.
Characteristics, wastewater	General classes of wastewater constituents such as physical, chemical, and biological constituents.
Homogeneous reaction	Reactions that occur uniformly throughout the fluid so that the potential for reaction at any point within the fluid is the same.
Heterogeneous reaction	Reactions that occur between one or more constituents that can be identified with specific sites.
Ideal flow	A flow regime in which all fluid particles are retained in a reactor for a time period equivalent to the theoretical detention time.
Mass-balance analysis	An accounting of mass within a defined boundary before and after reactions and conversions have taken place.
Molecular diffusion, coefficient of	The movement of molecules from a region of higher concentration to a region of lower concentration.
Nonideal flow	A flow regime in which a portion of the fluid particles are held in a reactor for a time other than the theoretical detention time.
Plug-flow reactor (PFR)	A vessel intended to transport fluid particles such that they leave in the same sequence as they entered.
Reaction rate	The rate of change (decrease or increase) in the number of moles of a reactive substance per unit volume per unit time (for homogeneous reactions), or per unit surface area or mass per unit time (for heterogeneous reactions).

Term	Definition
Reaction order	An empirical coefficient used to describe the relationship between reaction rate and concentration for a compound in a given reaction.
Reactor	A vessel or tank in which physical, chemical, or biological reactions occur.
Sludge	Any material (i.e., sludge) produced during primary, secondary, or advanced wastewater treatment that has not undergone any process to reduce pathogens or vector attraction (see also Biosolids).
Steady-state	The condition that occurs when the concentration of a constituent does not change with time.
Temperature coefficient	A coefficient used to correct reaction rate constants for the effect of temperature.
Stoichiometry	The proportions in which chemical elements combine or are produced and the weight relations in any chemical reaction.
Stormwater	Part of the precipitation that appears in surface streams. It is the same as streamflow unaffected by artificial diversions, storage, or other works of man in or on the stream channels.
Wastewater	Used water discharged from homes, businesses, cities, industry, and agriculture. Various synonymous uses such as municipal wastewater (sewage), industrial wastewater, and stormwater.
Wastewater treatment	The removal of constituents so the treated effluent can be returned to the environment or reused safely.
Water reuse	The use of treated wastewater for a beneficial use such as agricultural and landscape irrigation and for indirect and direct potable use.
Unit process	A subset of a complete treatment process in which constituent conversion or removal is accomplished by physical forces (such as gravity sedimentation) or by chemical or biological reactions.

Wastewater is essentially the water supply of the community after it has been used in a variety of applications and which now contains constituents that render it unsuitable for most uses without treatment. When untreated wastewater accumulates and is allowed to go septic, the decomposition of the organic matter it contains will lead to nuisance conditions, including the production of malodorous gases. In addition, untreated wastewater contains numerous pathogenic microorganisms that dwell in the human intestinal tract. Wastewater also contains nutrients, which can stimulate the growth of aquatic plants, and may contain toxic compounds or compounds that potentially may be mutagenic or carcinogenic. For these reasons, the immediate and nuisance-free removal of wastewater from its sources of generation (see Fig. 1–1), followed by treatment, reuse, or dispersal (disposal) into the environment, is necessary to protect public health and the environment.

Wastewater engineering is that branch of environmental engineering in which the basic principles of science and engineering are applied to solving the issues associated with the collection, treatment, and reuse of wastewater. The ultimate goal of wastewater engineering is the protection of public and environmental health in a manner commensurate with economic, social, and political concerns. The objective of this chapter is twofold. The first objective is to introduce and briefly discuss (1) the evolution of wastewater treatment, (2) the evolution of regulations pertaining to wastewater management, (3) the general characteristics of wastewater, (4) the classification of wastewater treatment methods, (5) the application of treatment methods, and (6) the status of wastewater

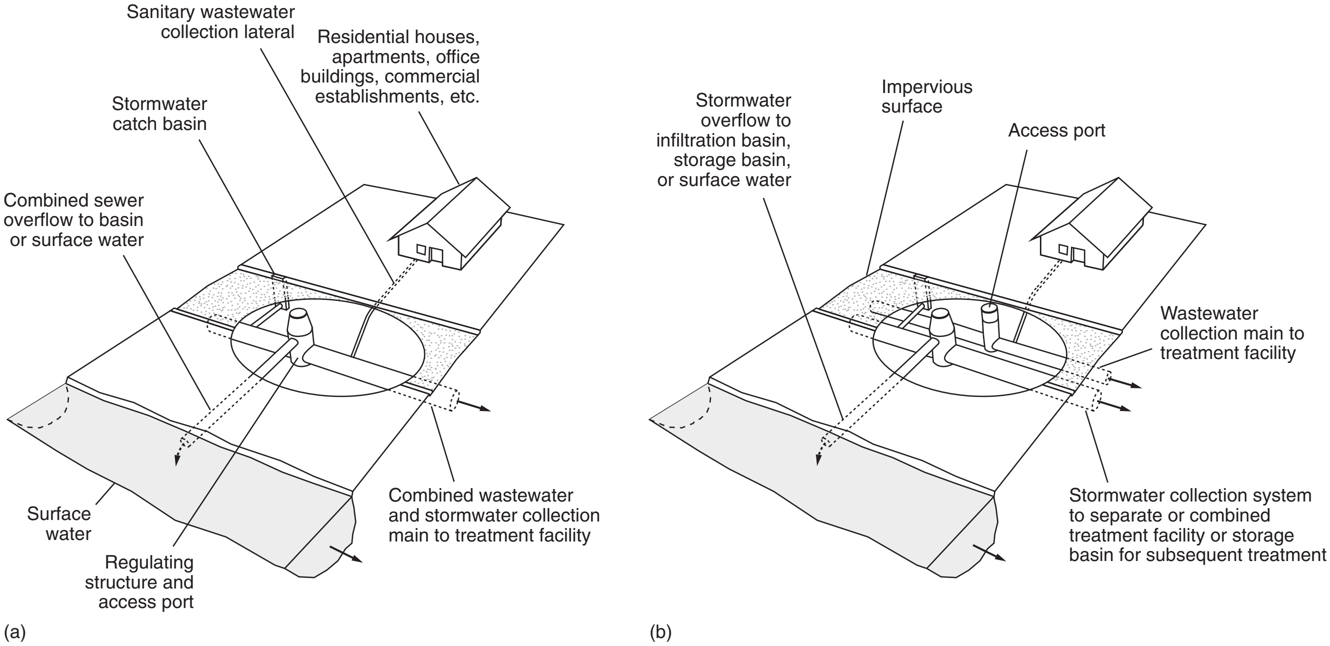

Figure 1–1

Schematic diagram of wastewater collection system infrastructure: (a) combined (wastewater and stormwater) collection system and (b) separate wastewater and stormwater collection systems. (Courtesy of H. Leverenz.)

treatment in the United States. The material presented in the first five sections of this chapter is intended to serve as an introduction to the subject of wastewater treatment and to provide a basis for the analysis of the unit processes that will be presented in subsequent chapters.

The second objective of this chapter is to present a review of and introduction to (1) the fundamentals of process analysis, (2) the reactors used in wastewater treatment, (3) the modeling of ideal flow reactors, (4) process kinetics, and (5) treatment process modeling. The material presented in the last five sections of this chapter is meant to serve as a review for those readers who have already taken courses in process analysis and to provide an introduction to the subject for those who are new to process analysis. By dealing with the basic concepts (e.g., mass balance and reactor analysis) first, it will be possible to apply them (without repeating the details) in the remaining chapters.

1–1 EVOLUTION OF WASTEWATER TREATMENT

The evolution of the field of wastewater treatment is the story of health and environmental concerns, especially as the size of cities increased. Methods of wastewater treatment were first developed in response to the concern for public health and the adverse conditions caused by the discharge of wastewater to the environment. Also important, as cities became larger, the land required for wastewater treatment and disposal, principally by irrigation and intermittent filtration (methods used commonly in the early 1900s) was no longer available. Thus, it became necessary to develop other methods of treatment that could be used to accelerate the forces of nature, under controlled conditions, in engineered treatment facilities that required less land (i.e., a smaller footprint).

Treatment Objectives

In general, from about 1900 to the early 1970s, treatment objectives were concerned with (1) the removal of suspended and floatable material, (2) the treatment of biodegradable organics, and (3) the elimination of pathogenic organisms. Unfortunately, these objectives were not uniformly met throughout the United States, as is evidenced by the many plants that were discharging partially treated wastewater well into the 1980s.

Since 1980, the water-quality improvement objectives of the 1970s have continued, but the emphasis has shifted to the definition and removal of constituents that may cause long-term health effects and environmental impacts. Consequently, while the early treatment objectives remain valid today, the required degree of treatment has increased significantly, and additional treatment objectives and goals have been added. Therefore, treatment process design must go hand-in-hand with the water quality objectives or standards established by the federal, state, and regional regulatory authorities.

Current Health and Environmental Concerns

As research into the characteristics of wastewater has become more extensive and as the techniques for analyzing specific constituents and their potential health and environmental effects have become more comprehensive, the body of scientific knowledge has expanded significantly. Many of the new treatment methods being developed are designed to deal with health and environmental concerns associated with constituents found as a result of advanced detection methods. However, the advancement in treatment technology effectiveness has not kept pace with the enhanced constituent detection capability. Constituents can be detected at lower concentrations than can be attained by available treatment technology. Therefore, careful assessment of health and environmental effects and community concerns has become increasingly important in wastewater management. The need to establish a dialog with the community is important to assure that health and environmental issues are being addressed.

Sustainability Considerations

The need to be more efficient with the use of resources and the dispersal of anthropogenic constituents in the environment has become a central issue in nearly all aspects of society. Some important considerations include the rapid extraction of remaining fossil carbon supplies and subsequent transfer of this carbon to the atmosphere, the consumption of nonrenewable resources, and the release of gases to the atmosphere, which may have an influence on climate. Some notable examples of problematic current and past practices with respect to wastewater treatment include the discharge of nutrients and trace constituents, excessive headloss and pumping as a result of poor hydraulic design, inefficient aeration system design, lack of consideration for the importance of primary treatment systems, limited use of anaerobic processes for BOD removal and energy recovery, limitations in sludge reuse and ultimate disposal options, placement of wastewater treatment facilities without regard to water reuse, life cycle pumping energy implications, and the potential impacts of sea level rise.

Sustainability issues such as the overall energy balance, process-related greenhouse gas emissions, total chemical usage and carbon footprint associated with those chemicals, and the fate of the constituents present in effluent and process byproducts are now of critical importance in the design, construction, and operation of wastewater management facilities. A number of developments have taken place recently that have made the prospect of sustainability a reality, including the development of new or improved technologies for the recovery of heat and chemical energy from wastewater, advanced processes capable of full-scale water purification, new technologies for satellite and decentralized wastewater management infrastructure, and process models that also compute resource consumption and greenhouse gas emissions. The refinement and optimization of existing processes, along with the implementation of new approaches and technologies, will create the foundation for a sustainable approach to wastewater management.

1–2 EVOLUTION OF REGULATIONS OF SIGNIFICANCE TO WASTEWATER ENGINEERING

The establishment of the U.S. Environmental Protection Agency (U.S. EPA) and the enactment of federal regulations have brought about significant changes in the planning and design of wastewater treatment facilities in the United States. The creation of the U.S. EPA and the important regulations that govern the management of wastewater are considered briefly in the following text.

Establishment of Environmental Protection Agency

The U.S. EPA was established on December 2, 1970. The objective was to consolidate in one agency a variety of federal research, monitoring, standard-setting, and enforcement activities to ensure environmental protection. Although examples of pollution were visible for decades prior to 1970, the seminal event in coalescing concerns about the environment and public opinion was the publication of *Silent Spring* by Rachael Carson in 1962. The book appeared first in serial form in *The New Yorker* in June 1962 and in book form later that year. The impacts resulting from the indiscriminate use of pesticides as documented by Carson helped rally public support for the federal government to take action. The pesticide DDT was banned in 1972.

Important Federal Regulations

Following the formation of the U.S. EPA, a number of enabling federal regulations brought about changes in planning and design of wastewater treatment facilities in the United States. The principal regulations are summarized in Table 1–1 and discussed below.

Public Law 92-500. Clearly, the most significant event in the field of wastewater management in the last 100 y was the passage of the Federal Water Pollution Control Act Amendments of 1972 (Public Law 92-500), often referred to as the Clean Water Act (CWA). Before that date, there were no specific national water pollution control goals or objectives. The CWA not only established national goals and objectives—“to restore and maintain the chemical, physical, and biological integrity of the Nation’s waters”—but also marked a change in water pollution control philosophy. No longer was the classification of the receiving stream of ultimate importance, as it had been before.

National Pollution Elimination Discharge System (NPDES). The CWA law decreed that the quality of the nation’s waters was to be improved by the imposition of specific effluent limitations. A National Pollution Elimination Discharge System (NPDES) program was established based on uniform technological minimums with which each point source discharger had to comply. It is interesting to note that the Clean Air Acts of 1970 and 1990 have also had a significant impact on industrial and municipal wastewater programs, primarily through the implementation of treatment facilities for the control of emissions.

Table 1–1

Summary of significant U.S. Federal regulations that affect wastewater management

Regulation	Description
The Federal Water Pollution Control Act (FWPCA) (P.L. 80-845, 62 Stat. 1155) of 1948	The first major law enacted by Congress to address the problems of water pollution in the United States.
Clean Water Act (CWA)(P.L. 92-500, Federal Water Pollution Control Act Amendments of 1972)	Establishes the National Pollution Discharge Elimination System (NPDES), a permitting program based on uniform technological minimum standards for each discharger.
Water Quality Act of 1987 (WQA) (Amendment of the CWA)	Strengthens federal water quality regulations by providing changes in permitting and adds substantial penalties for permit violations. Amends solids control program by emphasizing identification and regulation of toxic pollutants in sewage sludge.
40 CFR Part 503 (1993) (Sewage Sludge Regulations)	Regulates the use and disposal of biosolids from wastewater treatment plants. Limitations are established for items such as contaminants (mainly metals), pathogen content, and vector attraction.
National Combined Sewer Overflow (CSO) Policy (1994)	Coordinates planning, selection, design and implementation of CSO management practices and controls to meet requirements of CWA. Nine minimum controls and development of long term CSO control plans are required to be implemented immediately .
Clean Air Act of 1970 and 1990 Amendments	Establishes limitations for specific air pollutants and institutes prevention of significant deterioration in air quality. Maximum achievable control technology is required for any of 189 listed chemicals from "major sources," i.e., plants emitting at least 60 kg/d.
40 CFR Part 60	Establishes air emission limits for sludge incinerators with capacities larger than 1000 kg/d (2200 lb/d) dry basis.
Total Maximum Daily Load (TMDL) (2000) Section 303(d) of the CWA	Requires states to develop prioritized lists of polluted or threatened waterbodies and to establish the maximum amount of pollutant (TMDL) that a waterbody can receive and still meet water quality standards (U.S. EPA, 2000).

Standards for Secondary Treatment. Pursuant to Section 304(d) of Public Law 92-500 (see Table 1–1), the U.S. EPA published its definition of minimum standards for secondary treatment. The definition of secondary treatment is reported in Table 1–2 and includes three major effluent parameters: biodegradable organics, expressed in terms of five-day biochemical oxygen demand (5-d BOD); total suspended solids (TSS); and the hydrogen ion concentration expressed as pH. These standards provided the basis for the design and operation of most wastewater treatment plants. The secondary treatment regulations were amended further in 1989 to clarify the percent removal requirements during dry periods for treatment facilities served by combined sewers.

Water Quality Act of 1987. In 1987, Congress enacted the Water Quality Act of 1987 (WQA), the first major revision of the CWA. Important provisions of the WQA were (1) the strengthening federal water quality regulations by providing changes in permitting and adding substantial penalties for permit violations, (2) significantly amending the CWA's formal solids control program by emphasizing the identification and regulation of toxic pollutants in the solids (sludge), (3) providing funding for state and U.S. EPA studies for defining nonpoint and toxic sources of pollution, (4) establishing new deadlines for compliance including priorities and permit requirements for stormwater, and (5) phasing out the construction grants program as a method of financing publicly owned treatment works (POTWs).

Table 1–2

Minimum national standards for secondary treatment[a, b]

Characteristic of discharge	Unit of measurement	Average 30-d concentration[c]	Average 7-d concentration[c]
BOD_5	mg/L	30[d]	45
Total suspended solids	mg/L	30[d]	45
Hydrogen-ion concentration	pH units	Within the range of 6.0 to 9.0 at all times[e]	
$CBOD_5$[f,g]	mg/L	25	40

[a] Federal Register (1988, 1989).

[b] Present standards allow stabilization ponds and trickling filters to have higher 30-d average concentrations (45 mg/L) and 7-d average concentrations (65 mg/L) BOD/suspended solids performance levels as long as the water quality of the receiving water is not adversely affected. Exceptions are also permitted for combined sewers, certain industrial categories, and less concentrated wastewater from separate sewers. For precise requirements of exceptions, Federal Register (1988) should be consulted.

[c] Not to be exceeded.

[d] Average removal shall not be less than 85 percent.

[e] Only enforced if caused by industrial wastewater or by in-plant inorganic chemical addition.

[f] Carbonaceous 5-d biochemical oxygen demand.

[g] May be substituted for BOD_5 at the option of the permitting authority.

Biosolids Regulations. Regulations that affect wastewater facilities design include those for the treatment, disposal, and beneficial use of biosolids (40 CFR Part 503). In the biosolids regulation promulgated in 1993, national standards were set for pathogen and heavy metal content and for the safe handling and use of biosolids. The standards are designed to protect human health and the environment where biosolids are applied beneficially to land. The rule also promotes the development of a "clean sludge" (U.S. EPA, 1992). The regulations describing the reuse and disposal of solids are found in Chap. 13.

Total Maximum Daily Load. The total maximum daily load (TMDL) program was promulgated in 2000 but did not take effect until 2002. The TMDL rule is designed to protect ambient water quality. A TMDL represents the maximum amount of a pollutant that a water body can receive and still meet water quality standards. A TMDL is the sum of (1) the individual waste load allocations for point sources, (2) load allocations for nonpoint sources, (3) natural background levels, and (4) a margin of safety (U.S. EPA, 2000). To implement the rule, a comprehensive watershed-based water quality management program must be undertaken to find and control nonpoint sources in addition to conventional point source discharges. With implementation of the TMDL rule, the focus on water quality shifts from technology-based controls to preservation of ambient water quality. The end result is an integrated planning approach that transcends jurisdictional boundaries and forces different sectors, such as agriculture, water, and wastewater utilities and urban runoff managers, to cooperate. Implementation of the TMDL rule will vary depending on the specific water quality objectives established for of each watershed and, in some cases, will require the installation of advanced levels of treatment.

Air Emissions. Wastewater treatment facilities are potential sources of odors and other air emissions. Volatile organic compounds (VOCs) are of a particular concern because many of them are believed to be carcinogenic. Regulations have been developed for hazardous air pollutants (HAPs), a set of 188 chemicals regulated specifically by the U.S. EPA that are known or thought to cause human health effects in excess of specified levels. The regulations are defined in 40 CFR61.

Other Federal Regulations

In addition to the requirements established under the 1987 Water Quality Act and enforced by the U.S. EPA, other federal, state, and local regulations have to be considered in the planning, design, construction, and operation of wastewater treatment plants. Significant federal regulations include those prescribed by the Occupational Safety and Health Act (OSHA), which deals with safety provisions to be included in the facility's design. State, regional, and local regulations may include water quality standards for the protection of public health and the beneficial uses of the receiving waters, air quality standards for the regulation of air emissions (including odor) from treatment facilities, and regulations for the disposal and reuse of solids and biosolids.

State and Regional Regulations

Many of the state and regional regulatory agencies not only establish the permit requirements for wastewater discharges but also issue design guidelines for specific processes. Well-known design standards include the so-called "Ten States Standards" published by the Great Lakes-Upper Mississippi River Board of State Sanitary Engineers (2004) and the "Manual TR-16, Guides for the Design of Wastewater Treatment Works" published by the New England Interstate Water Pollution Control Commission (1998). For each state, the requirements of the regulatory agencies, including those having jurisdiction for public health, air quality, and solid waste management, have to be investigated carefully.

1–3 CHARACTERISTICS OF WASTEWATER

An understanding of the nature of wastewater is essential in the design and operation of collection, treatment, and reuse facilities and in the management of environmental quality. The sources of wastewater and the constituents and their sources that are found in wastewater are introduced in this section. These subjects are discussed in greater detail in Chaps. 2 and 3.

Sources of Wastewater

As received at the wastewater treatment facility, the characteristics of wastewater from a community depend on the components that make up the wastewater flow and changes occurring in the collection system used. Common sources of wastewater may include:

Domestic wastewater. Wastewater discharged from residences and from commercial, institutional, and public facilities. Domestic wastewater is also known as *sanitary wastewater.*

Industrial wastewater. Wastewater in which industrial wastes predominate.

Infiltration/inflow (I/I). Water that enters the collection system through indirect and direct means. Infiltration is extraneous water that enters the collection system through leaking joints, cracks and breaks. Inflow is stormwater that enters the collection system from storm drain connections (catch basins), roof leaders, foundation and basement drains, or through access port (manhole) covers.

Stormwater. Runoff resulting from rainfall and snowmelt.

Types of Collection Systems

Three types of collection systems are used for the removal of wastewater and stormwater: (1) sanitary wastewater collection systems, (2) combined wastewater and stormwater collection systems, and (3) stormwater collection systems (see Fig. 1–1). Where separate sanitary wastewater collection systems are used, the wastewater flow is composed of domestic wastewater, industrial wastewater, and infiltration/inflow. Where a combined collection system is used, the wastewater flow is composed of domestic wastewater, industrial wastewater, and infiltration/inflow plus stormwater and the constituents carried in the stormwater. In both cases, the percentage of the wastewater components will vary with local conditions and the time of the year. Where separate stormwater collection systems are used, it has been found that varying amounts of wastewater may be present in the stormwater, depending on local conditions.

Wastewater Constituents

The constituents in wastewater can be characterized in terms of their physical, chemical, and biological properties. The principal constituents of wastewater, and their sources, are reported in Table 1–3. It should be noted that many of the physical properties and chemical and biological constituents listed in Table 1–3 are interrelated. For example, temperature, a physical property, affects both the amounts of gases dissolved in the wastewater as well as the biological activity in the wastewater.

Constituents of Concern. Although the list of constituents presented in Table 1–3 is extensive, secondary treatment standards for wastewater, as reported in Table 1–2, are based on the removal of biodegradable organics, total suspended solids, and pH. More stringent standards may apply, depending on the use that will be made of the treated wastewater. For example, when wastewater is to be reused as a potable water supply, it may be necessary to remove nutrients, heavy metals, pathogens, and priority pollutants to significantly lower levels than would normally be required. Depending on local conditions, it may even be necessary to remove dissolved inorganic solids.

Recoverable Resources in Wastewater. As noted previously, the focus of the developments in wastewater treatment in the twentieth century was on the removal of constituents considered to be contaminants when discharged to the environment. In the twenty first century, there has been a paradigm shift in the view of wastewater. Wastewater is now considered a *renewable recoverable source of energy, resources, and water* (Tchobanoglous, 2011). In this new view of wastewater, the focus of wastewater treatment is changing. New processes are being developed that will make it possible to recover energy, resources, and water more effectively. In fact, it is reasonable to assume that in the not-so-distant future, wastewater treatment plants could become net exporters as opposed to consumers of energy. The heat and chemical energy in wastewater are considered in Chap. 2.

1–4 CLASSIFICATION OF WASTEWATER TREATMENT METHODS

The constituents found in wastewater are removed by physical, chemical, and biological means. The individual methods usually are classified as physical, chemical, and biological unit processes. Although these processes occur in a variety of combinations in treatment systems, it has been found advantageous to study their scientific basis separately because the principles involved do not change.

Physical Unit Processes

Treatment methods in which the application of physical forces predominate are known as physical unit processes. Because most of these methods evolved directly from man's

Table 1–3

Physical, chemical, and biological characteristics of wastewater and their sources

Characteristic	Sources
Physical properties:	
Color	Domestic and industrial wastes, natural decay of organic materials
Odor	Decomposing wastewater, industrial wastes
Solids	Domestic water supply, domestic and industrial wastes, soil erosion, inflow/infiltration
Temperature	Domestic and industrial wastes
Chemical constituents	
Organic	
Carbohydrates	Domestic, commercial, and industrial wastes
Fats, oils, and grease	Domestic, commercial, and industrial wastes
Pesticides	Agricultural wastes
Phenols	Industrial wastes
Proteins	Domestic, commercial, and industrial wastes
Priority pollutants	Domestic, commercial, and industrial wastes
Surfactant	Domestic, commercial, and industrial wastes
Volatile organic compounds	Domestic, commercial, and industrial wastes
Other	Natural decay of organic materials
Inorganic:	
Alkalinity	Domestic wastes, domestic water supply, groundwater infiltration
Chlorides	Domestic wastes, domestic water supply, groundwater infiltration
Heavy metals	Industrial wastes
Nitrogen	Domestic and agricultural wastes
Potassium	Domestic, commercial, and industrial wastes
pH	Domestic wastes, domestic water supply, groundwater infiltration
Phosphorus	Domestic, commercial, and industrial wastes; natural runoff
Priority pollutants	Domestic, commercial, and industrial wastes
Sulfur	Domestic water supply; domestic, commercial, and industrial wastes
Gases	
Hydrogen sulfide	Decomposition of domestic wastes
Methane	Decomposition of domestic wastes
Oxygen	Domestic water supply, surface-water infiltration
Biological constitutes	
Animals	Open watercourses and treatment plants .
Helminths (worms)	Domestic wastes
Plants	Open watercourses and treatment plants
Protists	
Eubacteria	Domestic wastes, surface-water infiltration, treatment plants
Archaebacteria	Domestic wastes, surface-water infiltration, treatment plants
Viruses	Domestic wastes

direct observations of nature, they were the first to be used for wastewater treatment. Screening, mixing, flocculation, sedimentation, flotation, filtration, and adsorption are typical physical unit process. For example, adsorption involves the removal of specific compounds from the wastewater on solid surfaces using the forces of attraction between bodies.

Chemical Unit Processes

Treatment methods in which the removal of constituents is brought about by the addition of chemicals or by other chemical reactions are known as chemical unit processes. Precipitation, gas transfer, adsorption, and disinfection are the most common examples used in wastewater treatment. In chemical precipitation, treatment is accomplished by producing a chemical precipitate that can be removed by settling, filtration, or membrane processes. In most cases, the separated precipitate will contain both the constituents that may have reacted with the added chemicals and the constituents that were swept out of the wastewater as the precipitate settled. The addition of oxygen to water to support aerobic reactions is the most common example of gas transfer. Another common chemical unit process is the use of chlorine for wastewater disinfection, which has been practiced for more than a century.

Biological Unit Processes

Treatment methods in which the removal of constituents is brought about by biological activity are known as biological unit processes. Biological treatment is used primarily to remove the colloidal or dissolved biodegradable organic substances found in wastewater. Basically, these substances are converted into (a) gases that can escape to the atmosphere and (b) biological cell tissue that can be removed by settling or another solid's separation process. Biological treatment is also used to remove the nitrogen and phosphorus from wastewater. With proper environmental control, wastewater can be treated biologically in most cases. Therefore, it is the responsibility of the engineer to ensure that the proper environment is produced and controlled effectively to achieve all treatment objectives.

1–5 APPLICATION OF TREATMENT METHODS

The principal methods now used for the treatment of wastewater and process residuals are identified in this section. Detailed descriptions of each method are not presented because the purpose here is only to introduce the many different ways in which treatment can be accomplished. The detailed descriptions are presented throughout the remainder of this book.

Wastewater Processing

To achieve the removal of constituents, a number of unit processes are grouped together to provide what is known as primary, secondary, tertiary, and advanced treatment (see Table 1–4). In general, the term *primary* refers to application of physical unit processes; *secondary* refers to chemical and biological unit processes; and *tertiary* refers to combinations of all three. It should be noted that these terms are arbitrary and in most cases of little value. A more rational approach is first to establish the degree of constituent removal (treatment) required before the wastewater can be reused or dispersed in the environment. The unit processes necessary to achieve the required degree of treatment can then be grouped together on the basis of fundamental considerations. The constituents of major

Table 1–4

Levels of wastewater treatment

Treatment level	Description
Preliminary	Removal of wastewater constituents such as rags, sticks, floatables, grit, and grease that may cause maintenance or operational problems with the treatment operations, processes, and ancillary systems.
Primary	Removal of a portion of the suspended solids and organic matter from the wastewater.
Advanced primary	Enhanced removal of suspended solids and organic matter from the wastewater. Typically accomplished by chemical addition or filtration.
Secondary	Removal of biodegradable organic matter (in solution or suspension) and suspended solids. Disinfection is also typically included in the definition of conventional secondary treatment.
Secondary with nutrient removal	Removal of biodegradable organics, suspended solids, and nutrients (nitrogen, phosphorus, or both nitrogen and phosphorus).
Tertiary	Removal of residual suspended solids (after secondary treatment), usually by granular medium filters, cloth filters, or microscreens. Disinfection is also typically a part of tertiary treatment. Nutrient removal is often included in this definition.
Advanced	Removal of dissolved and suspended materials remaining after normal biological treatment when required for various water reuse applications.

interest in wastewater and the unit processes or methods applicable to the removal of these constituents are shown in Table 1–5.

Secondary treatment, as defined by the U.S. EPA, is directed principally toward the removal of readily biodegradable organics and suspended solids. To further protect the environment in some critical areas, more stringent standards have been directed toward the removal of nutrients and pathogens and achieving lower levels of oxygen demand than are now possible with secondary treatment techniques. When wastewaters are to be reused, standards may include removal requirements for refractory organics, heavy metals, and dissolved inorganic solids. In general, the complexity of the treatment-process flow diagram will depend on which constituents need to be removed and the required levels of removal.

Residuals Processing

For the most part, the methods and systems reported in Table 1–5 are used to treat the liquid portion of the wastewater. Of equal if not more importance in the overall design of treatment facilities are the corresponding processes or systems used to treat the sludge removed from the liquid portion of the wastewater. The principal methods now in use are reported in Table 1–6.

Typical Treatment Process Flow Diagrams

When treatment processes are grouped together to achieve a specific treatment objective, the grouping is identified as a *treatment process flow diagram* or as a *treatment train*. Representative treatment process flow diagrams are presented on Fig. 1–2.

Conventional Secondary Treatment. A typical flow diagram for secondary treatment is shown on Fig. 1–2(a). As noted above, conventional secondary treatment is used primarily for the removal of BOD_5 and TSS. The primary treatment portion of the

	Lagooning	14

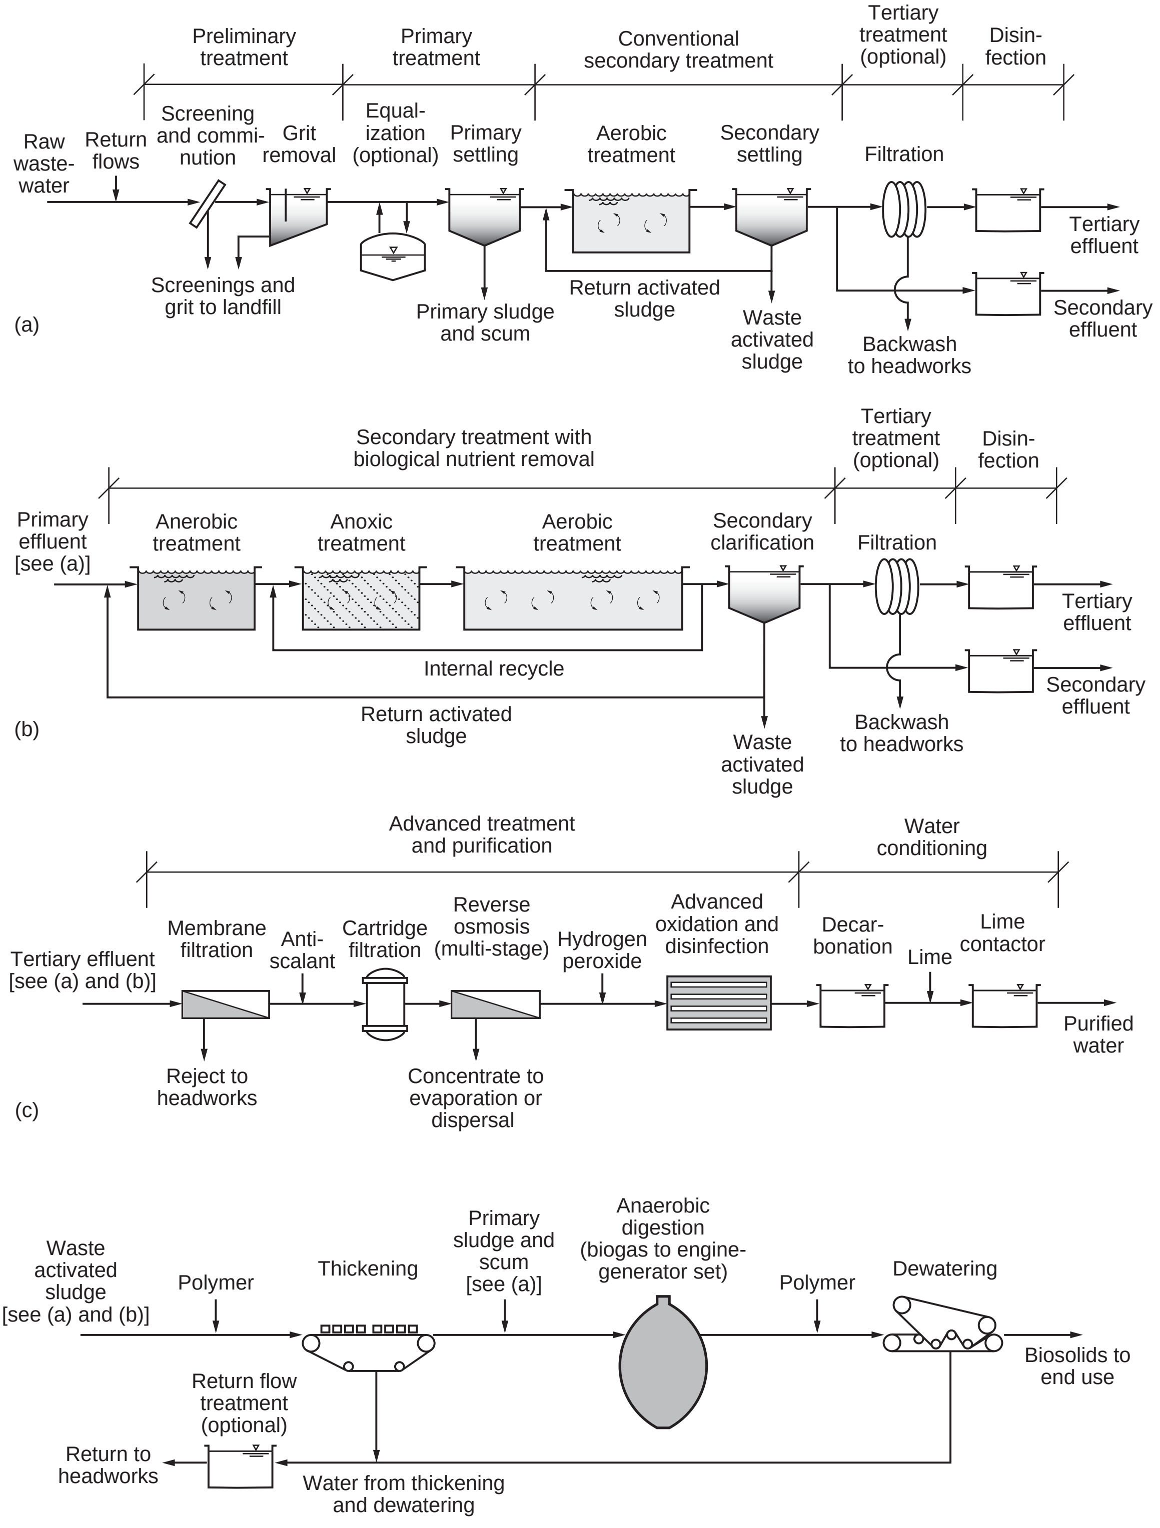

Figure 1–2

Typical flow diagrams for the treatment of wastewater and biosolids: (a) conventional biological treatment, (b) biological nutrient removal, (c) advance treatment following conventional or nutrient removal treatment, and (d) anaerobic treatment of sludge from primary sedimentation and excess biological sludge.

flow diagram is used for the removal of large, coarse solids by screening and those particles of sufficient density to be removed by gravity settling. Biological treatment is used to remove BOD_5, and TSS disinfection is used for the control of microorganisms. Tertiary treatment typically involves the filtration of settled secondary effluent to remove any residual suspended solids and thus enhance the disinfection process. Tertiary treatment is required for a number of reuse applications.

Conventional Treatment Plus Nutrient Removal. In many locations, especially around the Great Lakes in the United States and in communities surrounding inland lakes, the removal of nutrients is needed to limit eutrophication. A typical nutrient removal treatment process flow diagram is shown on Fig. 1–2(b). The flow diagram shown on Fig. 1–2(b) is similar to that shown on Fig. 1–2(a) with the exception that the biological treatment process is more complex.

Conventional Treatment with Advanced Treatment for the Production of Potable Water. Where potable water is to be produced from wastewater, advanced treatment processes beyond those used for secondary treatment or nutrient removal will be needed to remove residual suspended and colloidal and dissolved constituents. A typical advanced wastewater treatment process flow diagram is shown on Fig. 1–2(c). The process flow diagram shown on Fig. 1–2(c) is similar to that used at the Orange County Water District in California to produce potable water, which is injected into a groundwater aquifer from which it is withdrawn for use as a public water supply after a suitable residence time (Asano et al., 2007).

Processing the Coarse Solids, Primary Sludge, and Secondary Sludge from Wastewater Treatment. *Coarse solids* are produced from raw wastewater by screening and grit removal, *primary sludge* is produced from the primary sedimentation of raw wastewater, and *secondary sludge* is produced from the biological treatment of wastewater. Each of these solid fractions requires further processing. Coarse solids and grit are typically landfilled. Sludge obtained from primary sedimentation are combined with secondary solids from biological treatment and treated further by a number of different processes, with anaerobic digestion being the most common. Stabilized sludges are termed *biosolids*. A typical solids processing flow diagram is shown on Fig. 1–2(d). It should be noted that the processes shown on Fig. 1–2(d) are representative of the many different processes used for the treatment of sludge as reported in Table 1–5. Also shown on Fig. 1–2(d) is the option of treating the return flows from various solids processing equipment. Treatment of return flows is of importance where restrictive nutrient standards must be met to avoid returning excess nutrients that must be treated again (see Chap. 15).

1–6 STATUS OF WASTEWATER TREATMENT IN THE UNITED STATES

Up until the late 1980s, conventional secondary treatment was the most common method of treatment in the United States for the removal of BOD and TSS. Nutrient removal was used in special circumstances, such as in the Great Lakes area, Florida, and the Chesapeake Bay, where sensitive nutrient-related water quality conditions were identified. Because of nutrient enrichment that has led to eutrophication and water quality degradation (due in part to point source discharges), nutrient removal processes have evolved and now are used extensively in other areas as well. As a result of implementation

Table 1–7

Number of wastewater treatment facilities in the United States by flow range in 1996[a] and 2008[b]

Flow ranges		Number of facilities		Flowrate, Mgal/d		Flowrate, m^3/s

[c] Flow data unknown.

of the Federal Water Pollution Control Act Amendments, significant data have been obtained on the numbers and types of wastewater facilities used and needed in accomplishing the goals of the act.

Recent Survey Results

The most recent survey results on the number of facilities, published in 2008 (U.S. EPA, 2008), are reported in Tables 1–7 and 1–8 along with the data from the 1996 survey (U.S. EPA, 1998). The comparative data have been aggregated by treatment plant capacity in Table 1–7 and by the level of treatment in Table 1–8. These data are useful in forming an overall view of the current status of wastewater treatment in the United States. In 2008, the municipal wastewater treatment enterprise comprised more than 15,000 plants (including those not included in the survey) that are used to treat a total flow of 1417 cubic meters per second (m^3/s) [32,345 Mgal/d (million gallons per day)]. Approximately 93 percent of the total existing flow is handled by plants having a capacity of 0.044 m^3/s [1 million gallons per day (Mgal/d)] and larger. More than one-half of the present design capacity is situated in plants providing greater than secondary treatment.

Trends

Comparing the total flowrate between 1996 and 2008, the per capita flowrate has gone down because in the same period the population increased from about 266.5 million to 305 million persons. It is also interesting to note the shifts that have occurred in the level of treatment. The number of treatment plants providing less than secondary treatment has decreased from 176 to 30. Also, the number of treatment plants providing greater than secondary treatment has increased from 4428 to 5071. It is anticipated that the trends observed in these tables will continue, especially the decreasing flowrate per capita (discussed further in Chap. 3) and the shift in the level of treatment toward greater than secondary.

Table 1–8

Number of wastewater treatment facilities in the United States by level of treatment in 1996[a] and 2008[b]

1–7 INTRODUCTION TO PROCESS ANALYSIS

Most of the physical, chemical, and biological unit processes, identified in Tables 1–5 and 1–6, are carried out in vessels or tanks commonly known as "reactors." The fundamental approach used to describe the changes that take place when a reaction is occurring in a reactor or in some definable portion of a body of liquid is the mass-balance analysis. The basic aspects involved in such an analysis along with the types of reactors that are available and their applications are described in this section. Although, the material presented in this and in the subsequent sections that follow may be known to some, it is included here as background reference material that can be referred to as needed. Similarly, the material presented in Appendixes H and I on dispersion and tracer analysis serves the same purpose.

Mass-Balance Analysis

The fundamental basis for the analysis of the physical, chemical, and biological unit processes used for wastewater treatment is the *materials mass balance principle*, based on the principle that mass is neither created nor destroyed, but the form of the mass can be altered (e.g., liquid to a gas). The mass balance analysis affords a convenient way of defining what occurs within treatment reactors as a function of time. To illustrate the basic concepts involved in the preparation of a mass-balance analysis, consider the reactor shown on Fig. 1–3. For a given reactant, the general mass balance analysis is given by:

1. General word statement:

$$\begin{array}{ccccccc} \begin{array}{c}\text{Rate of accumulation}\\ \text{of reactant within the}\\ \text{system boundary}\end{array} & = & \begin{array}{c}\text{rate of flow of}\\ \text{reactant into the}\\ \text{system boundary}\end{array} & - & \begin{array}{c}\text{rate of flow of}\\ \text{reactant out of the}\\ \text{system boundary}\end{array} & + & \begin{array}{c}\text{rate of generation}\\ \text{of reactant within the}\\ \text{system boundary}\end{array} \\ (1) & & (2) & & (3) & & (4) \end{array} \tag{1–1}$$

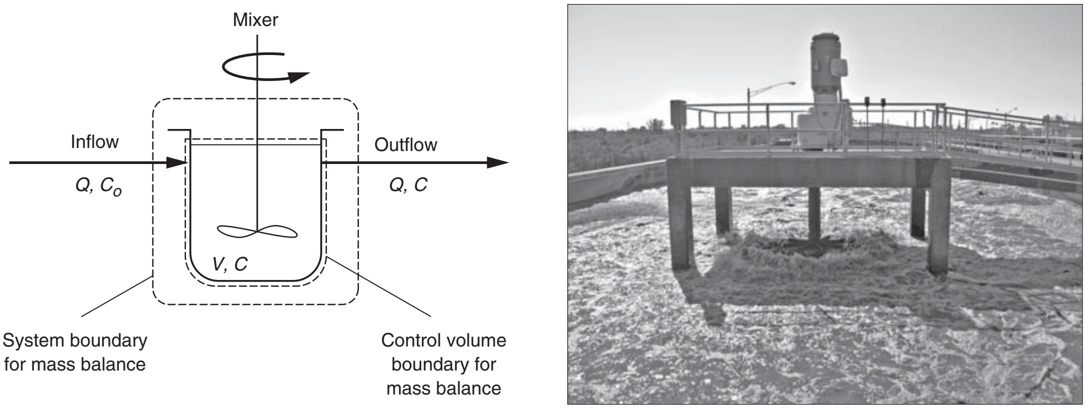

Figure 1–3

Definition sketch for the application of materials mass-balance analysis for a complete-mix reactor with inflow and outflow. The presence of a mixer is used to represent symbolically the fact that the contents of the reactor are mixed completely.

2. The corresponding simplified word statement is

$$\underset{(1)}{\text{Accumulation}} = \underset{(2)}{\text{inflow}} - \underset{(3)}{\text{outflow}} + \underset{(4)}{\text{generation}} \tag{1–2}$$

The material's mass balance is made up of the four terms cited above. Depending on the flow regime or treatment process, one or more of the terms can be equal to zero. For example, in a sealed batch reactor (i.e., no inflow or outflow) the second and third terms will be equal to zero. In the analysis of the hydraulic characteristics of reactors as well as in the analysis of separation processes discussed in Sec. 1–4, the fourth term, the rate of generation, r_c, will be equal to zero. In Eq. (1–2), a positive sign is used for the rate of generation term because the necessary sign for the operative process is part of the rate expression (e.g., $r_c = -kC$ for a decrease in the reactant or $r_c = +kC$ for an increase in the reactant).

Preparation of Mass Balances. In preparing mass balances it is helpful if the following steps are followed, especially as the techniques involved are being mastered:

1. Prepare a simplified schematic or flow diagram of the system or process for which the mass balance is to be prepared.
2. Draw a system boundary to define the limits over which the mass balance is to be applied. Proper selection of the system boundary is extremely important because, in many situations, it may be possible to simplify the mass balance computations.
3. List all of the pertinent data and assumptions that will be used in the preparation of the materials balance on the schematic or flow diagram.
4. List all of the rate expressions for the biological or chemical reactions that occur in the process.
5. Select a convenient basis on which the numerical calculations will be based.

It is recommended that these steps be followed routinely to avoid the errors that are often made in the preparation of mass balance analyses.

Application of the Mass-Balance Analysis

To illustrate the application of the mass balance analysis, consider the complete-mix reactor shown on Fig. 1–3. First, the system boundary must be established so that all the flows of mass into and out of the system can be identified. On Fig. 1–3, the boundary is shown by the outer dashed line.

To apply a mass balance analysis to the liquid contents of the reactor shown on Fig. 1–3, it will be assumed that

1. the volumetric flowrate in to and out of the control volume is constant;
2. the liquid within the control volume is not subject to evaporation (constant volume);
3. the liquid within the control volume is mixed completely;
4. a chemical reaction involving a reactant A is occurring within the reactor; and
5. the rate of change in the concentration of the reactant A that is occurring within the control volume is governed by a first order reaction ($r_c = -kC$).

Using the above assumptions, the mass balance can be formulated as follows:

1. Simplified word statement:

   Accumulation = inflow − outflow + generation

2. Symbolic representation (refer to Fig. 1–3):

$$\frac{dC}{dt}V = QC_o - QC + r_cV \tag{1–3}$$

Substituting $-kC$ for r_c yields

$$\frac{dC}{dt}V = QC_o - QC + (-kC)V \tag{1–4}$$

where dC/dt = rate of change of reactant concentration within the control volume, $ML^{-3}T^{-1}$
V = volume contained within control volume, L^3
Q = volumetric flowrate into and out of control volume, L^3T^{-1}
C_o = concentration of reactant entering the control volume, ML^{-3}
C = concentration of reactant leaving the control volume, ML^{-3}
r_c = first order reaction, ($-kC$), $ML^{-3}T^{-1}$
k = first order reaction rate coefficient, T^{-1}

Before attempting to solve any mass-balance expression, a unit check should always be made to assure that units of the individual quantities are consistent. For example, if the following units are substituted into Eq. (1–4)

V = m^3, L
dC/dt = $g/m^3 \cdot s$, mg/L·s
Q = m^3/s, L/s
C_o, C = g/m^3, mg/L
k = 1/s

the resulting unit check yields

$$\frac{dC}{dt}V = QC_o - QC + (-kC)V$$

$$(g/m^3 \cdot s)\ m^3 = m^3/s\ (g/m^3) - m^3/s\ (g/m^3) + (-1/s)(g/m^3)\ m^3$$

$$g/s = g/s - g/s - g/s \text{ (units are consistent)}$$

The analytical procedures that are adopted for the solution of mass balance equations usually are governed by (1) the nature of the rate expression, (2) the type of reactor under consideration, (3) the mathematical form of the final materials balance expression (i.e., ordinary or partial differential equation), and (4) the corresponding boundary conditions. The mass balance for a plug-flow reactor, as will be illustrated in the following section, results in a partial differential equation. A variety of solution procedures for mass balances in both ordinary and partial differential equation formats are readily available in the literature.

Steady-State Simplification. Fortunately, in most applications in the field of wastewater treatment, the solution of mass balance equations, such as the one given by Eq. (1–4), can be simplified by noting that the steady-state (i.e., long-term) concentration is of principal concern. If it is assumed that only the steady-state effluent concentration is desired, then Eq. (1–4) can be simplified by noting that, under steady-state conditions, the rate accumulation is zero ($dC/dt = 0$). Thus, Eq. (1–4) can be written as:

$$0 = QC_o - QC - r_c V \tag{1–5}$$

When solved for r_c, Eq. (1–5) yields the following expression

$$r_c = \frac{Q}{V}(C - C_o) \tag{1–6}$$

The solution to the expression given by Eq. (1–5) will depend on the nature of the rate expression (e.g., zero, first, or second order).

1–8 REACTORS USED IN WASTEWATER TREATMENT

As noted previously, the physical, chemical, and biological unit processes are carried out in vessels or tanks commonly known as “reactors.” The types of reactors that are available and their applications are introduced in this section.

Types of Reactors

The principal types of reactors used for the treatment of wastewater, illustrated on Fig. 1–4, are (1) the batch reactor, (2) the complete-mix reactor [also known as the continuous flow stirred-tank reactor (CFSTR) in the chemical engineering literature], (3) the plug-flow reactor (also known as a tubular-flow reactor), (4) complete-mix reactors in series, (5) the packed-bed reactor, and (6) the fluidized-bed reactor.

Batch Reactor. In the batch reactor [see Fig. 1–4(a)], flow is neither entering nor leaving the reactor (i.e., flow enters, is treated, and then discharged and the cycle repeats). The liquid contents of the reactor are mixed completely. For example, the BOD test discussed in Chap. 2 is carried out in a batch reactor (i.e., BOD bottle as shown on Fig. 2–21 in Chap. 2), although it should be noted that the contents are not mixed completely during the incubation period. Batch reactors are often used to blend chemicals or to dilute concentrated chemicals.

Complete-Mix Reactor (CMR). In the complete-mix reactor [see Fig. 1–4(b)], it is assumed that complete mixing occurs instantaneously and uniformly throughout the reactor as fluid particles enter the reactor. Fluid particles leave the reactor in proportion to their statistical population. Complete mixing can be accomplished in round or square reactors if the contents of the reactor are uniformly and continuously redistributed. The actual time required to achieve completely mixed conditions will depend on the reactor geometry and the power input.

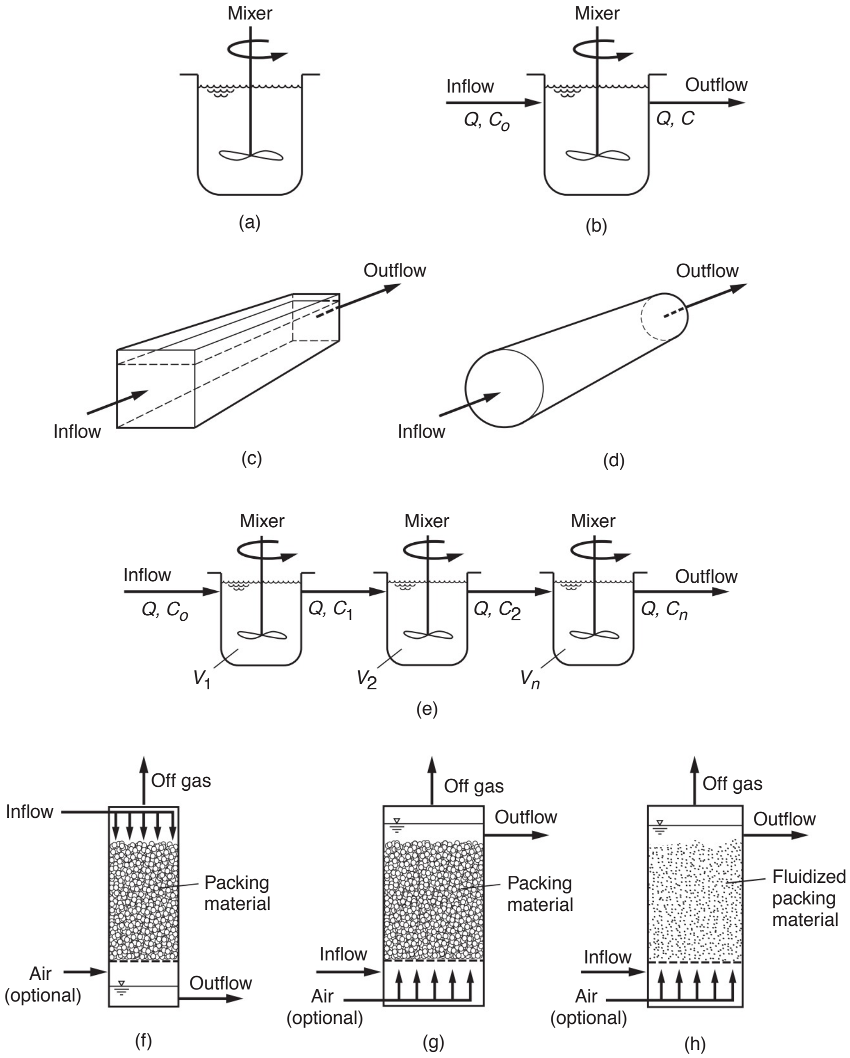

Figure 1–4

Definition sketch for the different types of reactors used for wastewater treatment: (a) batch reactor; (b) complete-mix reactor; (c) plug-flow open reactor; (d) plug-flow closed reactor, also known as a tubular reactor; (e) complete-mix reactors in series; (f) packed bed downflow reactor; (g) packed bed upflow reactor; and (h) expanded bed upflow reactor.

Plug-Flow Reactor (PFR). Fluid particles pass through the reactor with little or no longitudinal mixing and exist from the reactor in the same sequence in which they entered. The particles retain their identity and remain in the reactor for a time equal to the theoretical detention time. This type of flow is approximated in long open tanks with a high length-to-width ratio in which longitudinal dispersion is minimal or absent [see Fig. 1–4(c)] or closed tubular reactors [e.g., pipelines, see Fig. 1–4(d)].

Complete-Mix Reactors in Series. The series of complete-mix reactors [see Fig. 1–4(e)] is used to model the flow regime that exists between the ideal hydraulic flow patterns corresponding to the complete-mix and plug-flow reactors. If the series is composed of one reactor, the complete-mix regime prevails. If the series consists of an infinite number of reactors in series, the plug-flow regime prevails.

Packed-Bed Reactor. The packed-bed reactor is filled with a type of packing medium, such as rock, slag, ceramic, or, now more commonly, plastic. With respect to flow, the packed-bed reactor can be operated in either the downflow or upflow mode.

Dosing can be continuous or intermittent (e.g., trickling filter). The packing medium in packed bed reactors can be continuous [see Fig. 1–4(f)] or arranged in multiple stages, with flow from one stage to another. A packed-bed upflow anaerobic (without oxygen) reactor is shown on Fig. 1–4(g).

Fluidized-Bed Reactor. The fluidized-bed reactor is similar to the packed-bed reactor in many respects, but the packing medium is expanded by the upward movement of fluid (air or water) through the bed [see Fig. 1–4(h)]. The expanded porosity of the fluidized-bed packing medium can be varied by controlling the flowrate of the fluid.

Hydraulic Characteristics of Reactors

Complete-mix and plug-flow reactors are the two reactor types used most commonly in the field of wastewater treatment. The hydraulic flow characteristics of complete-mix and plug-flow reactors can be described as varying from ideal and nonideal, depending on the relationship of the incoming flow to outgoing flow. Ideal and nonideal flow, as well as application of reactors in wastewater treatment, are described in the following discussion.

Ideal Flow in Complete-Mix and Plug-Flow Reactors. The ideal hydraulic flow characteristics of complete-mix and plug-flow reactors are illustrated on Fig. 1–5 in which dye tracer response curves are presented for pulse (slug injection) and step inputs (continuous injection). On Fig. 1–5, t is the actual time and τ is equal to the theoretical hydraulic detention time defined as follows:

$$\tau = \frac{V}{Q} \tag{1–7}$$

where τ = the hydraulic detention time, T
V = volume of the reactor, L^3
Q = volumetric flowrate, L^3T^{-1}

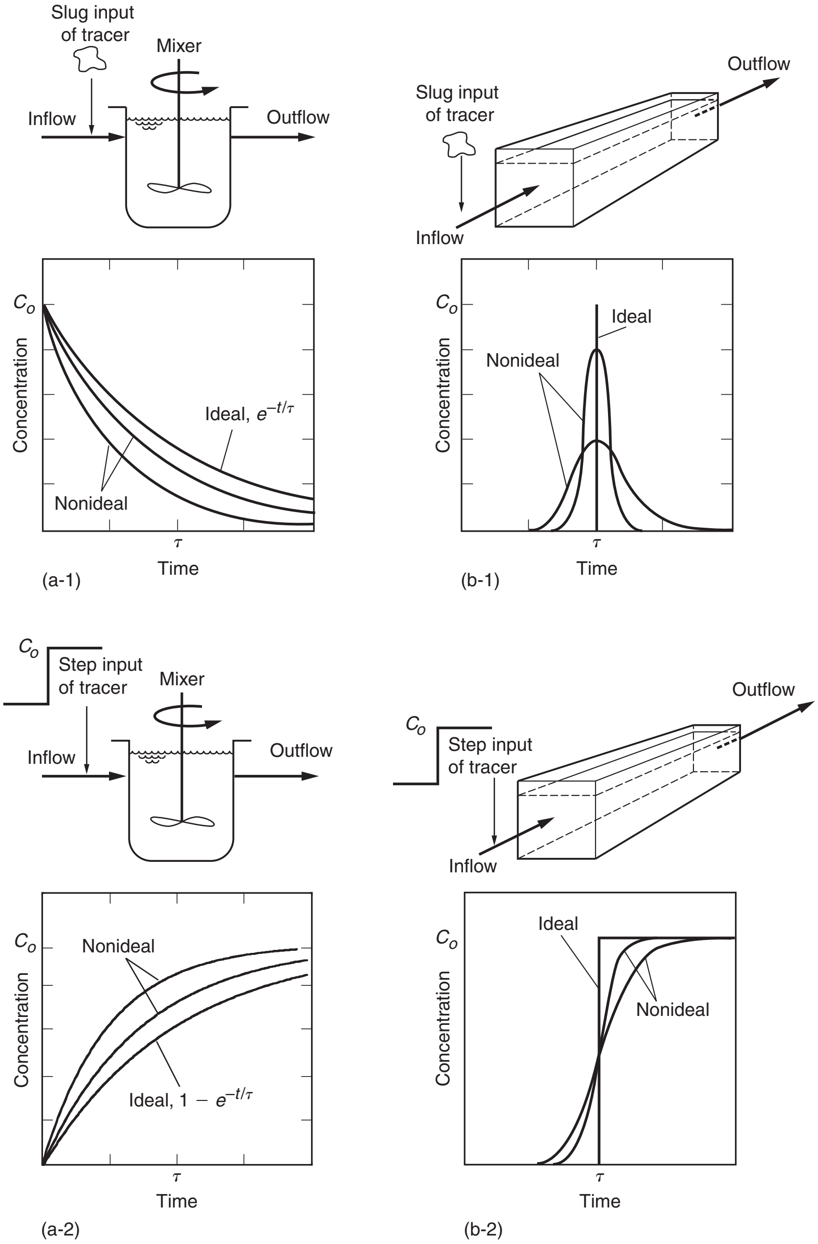
If a pulse input of a conservative (i.e., nonreactive) tracer is injected and dispersed instantaneously in an ideal flow complete-mix reactor, with a continuous inflow of clear water, the output tracer concentration would appear as shown on Fig. 1–5(a-1). If a continuous step input of a conservative tracer at concentration C_o is injected into the inlet of an ideal complete-mix reactor, initially filled with clear water, the appearance of the tracer at the outlet would occur as shown on Fig. 1–5(a-2).

In the case of an ideal plug-flow reactor, the reactor is initially filled with clear water before being subjected to a pulse or a step input of tracer. If an observer were positioned at the outlet of the reactor, the appearance of the tracer in the effluent for a pulse input, distributed uniformly across the reactor cross-section, would occur as shown on Fig. 1–5(b-1). If a continuous step input of a tracer were injected into such a reactor at an initial concentration C_o, the tracer would appear in the effluent as shown on Fig. 1–5(b-2).

Nonideal Flow in Complete-mix and Plug-Flow Reactors. In practice, the flow in complete-mix and plug-flow reactors is seldom ideal. For example, when a reactor is designed, how is the flow to be introduced to satisfy the theoretical requirement of instantaneous and complete dispersion? In practice, there is always some deviation from ideal conditions, and it is the precautions taken to minimize these effects that are important. Nonideal flow occurs when a portion of the flow that enters the reactor during a given time period arrives at the outlet before the bulk of the flow that entered the reactor during the same time period arrives. Nonideal flow is illustrated on Figs. 1–5(a-2) and 1–5(b-2).

Figure 1–5

Output tracer response curves from reactors subject to slug (pulse) and step inputs of a tracer: (a-1) and (a-2) complete-mix reactor and (b-1) and (b-2) plug-flow reactor.



The important issue with nonideal flow is that a portion of the flow will not remain in the reactor as long as may be required for a biological or chemical reaction to go to completion.

Application of Reactors

The principal applications of reactor types used for wastewater treatment are reported in Table 1–9. Operational factors that must be considered in the selection of the type of reactor or reactors to be used in the treatment process include (1) the nature of the wastewater to be treated, (2) the nature of the reaction (i.e., homogeneous or heterogeneous),

Table 1–9

Principal applications of reactor types used for wastewater treatment

Type of reactor	Applications in wastewater treatment
Batch	Conduct of BOD test, sequencing batch reactor activated sludge biological treatment, mixing of concentrated solutions into working solutions
Complete-mix without recycle	Aerated lagoons, aerobic sludge digestion, anaerobic digestion
Complete-mix with recycle	Activated sludge biological treatment
Plug-flow	Chlorine contact basin, reaeration basin, natural treatment systems
Plug-flow with recycle	Activated sludge biological treatment, aquatic treatment systems
Complete-mix reactors in series	Lagoon treatment systems, used to simulate nonideal flow in plug flow reactors
Packed bed	Nonsubmerged and submerged trickling filter biological treatment units, depth filtration, membrane filtration, adsorption, ion exchange, air stripping, natural treatment systems
Fluidized bed	Fluidized bed reactors for aerobic and anaerobic biological treatment, upflow sludge blanket reactors, air stripping, thermal oxidation of sludge

(3) the reaction kinetics governing the treatment process, (4) the process performance requirements, and (5) local environmental conditions. Homogeneous and heterogeneous reactions and reaction kinetics are discussed in Sec. 1–9. In practice, the construction costs and operation and maintenance costs also affect reactor selection. Because the relative importance of these factors varies with each application, each factor should be considered separately when the type of reactor is to be selected.

1–9 MODELING IDEAL FLOW IN REACTORS

Modeling of the hydraulic characteristics of reactors is important because the results can be used to determine the actual amount of time a given volume of water will remain in the reactor and its average age. In turn, the average ages can be related to the degree of treatment achieved, based on the applicable kinetics. The coupling of reactor hydraulic characteristics and reaction rates to determine treatment process performance is considered in Sec. 1–9.

Comparison of actual hydraulic characteristics of a reactor, measured using tracers, to the expected theoretical response can be used to assess the degree to which the design ideal has been achieved. The complete-mix and plug-flow reactors, as noted previously, are the reactor types used most commonly in the field of wastewater treatment. The mathematical analysis of ideal flow in complete-mix and plug-flow reactors is considered below. The modeling of nonideal flow is considered in Appendix I.

Ideal Flow in Complete-Mix Reactor

Analytically, using the mass-balance approach introduced above, the effluent tracer concentration from an ideal flow complete-mix reactor as a function of time for a pulse input of tracer, which is mixed instantaneously and is purged with clear water [see Fig. 1–5(a–1)] can be determined by writing a mass balance around the reactor.

1. **General word statement:**

$$\begin{matrix}\text{Rate of accumulation} & & \text{rate of flow of} & & \text{rate of flow of} \\ \text{of tracer within} & = & \text{tracer into} & - & \text{tracer out of} \\ \text{the reactor} & & \text{the reactor} & & \text{the reactor}\end{matrix} \qquad (1\text{–}8)$$

2. **Simplified word statement:**

   Accumulation = inflow − outflow (1–9)

3. **Symbolic representation [refer to Fig. 1–5(a-1)]:**

$$\frac{dC}{dt}V = QC_o - QC \qquad (1\text{–}10)$$

Rewriting Eq. (4–11) and simplifying by noting that $C_o = 0$ yields:

$$\frac{dC}{dt} = -\frac{Q}{V}C \qquad (1\text{–}11)$$

Integrating between the limits of $C = C_o$ to $C = C$, and $t = 0$ to $t = t$ yields

$$\int_{C_o}^{C}\frac{dC}{C} = -\frac{Q}{V}\int_0^t dt \qquad (1\text{–}12)$$

The resulting expression after integration is

$$C = C_o e^{-t(Q/V)} = C_o e^{-t/\tau} = C_o e^{-\theta} \qquad (1\text{–}13)$$

where C = concentration of the tracer in the reactor at time t, ML^{-3}
C_o = initial concentration of the tracer in the reactor, ML^{-3}
t = time, T
Q = volumetric flowrate, $\mathrm{L}^3\mathrm{T}^{-1}$
V = reactor volume, L^3
τ = the theoretical detention time, V/Q, T
θ = the normalized detention time, t/τ, unitless

The corresponding response for a continuous step input of tracer [see Fig. 1–5(a-2)] which is mixed instantaneously is given by

$$C = C_o(1 - e^{-t(Q/V)}) = C_o(1 - e^{-t/\tau}) = C_o(1 - e^{-\theta}) \qquad (1\text{–}14)$$

It will be noted that Eq. (1–14) has the same form as the BOD equation [see Chap. 2, Eq. (2–60)].

Ideal Plug-Flow Reactor

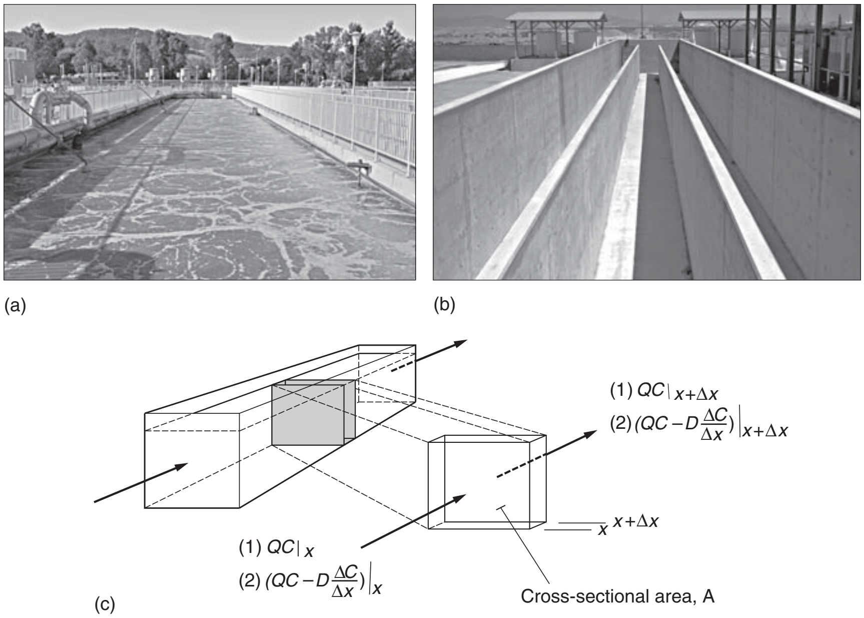
Under ideal plug-flow conditions, t, the measured detention time, should be the same as τ, the theoretical detention time (V/Q). To verify the form of the plot given previously on Fig. 1–5(b-2), it will be instructive to prepare a materials balance for an ideal plug-flow reactor (no axial dispersion) in which the concentration, C, of a nonreactive tracer is distributed uniformly across the cross-sectional area of the control volume. The materials balance for a nonreactive tracer for the differential volume element shown on Fig. 1–6 can be written as follows:

1. **General word statement:**

$$\begin{matrix}\text{Rate of accumulation of} & & \text{rate of flow of tracer} & & \text{rate of flow of tracer} \\ \text{tracer within differential} & = & \text{into differential} & - & \text{out of differential} \\ \text{volume element} & & \text{volume element} & & \text{volume element}\end{matrix} \qquad (1\text{–}15)$$

Figure 1–6

Views of plug-flow reactors and definition sketch: (a) view of plug-flow activated sludge process reactor, (b) view of empty plug-flow chlorine contact basin with long narrow channels, and (c) definition sketch for the hydraulic analysis of a plug-flow reactor with (1) advection only and (2) with advection and axial dispersion.



2. Simplified word statement:

Accumulation = inflow − outflow (1–16)

3. Symbolic representation (refer to Fig. 1–6)

$$\frac{\partial C}{\partial t}\Delta V = QC|_x - QC|_{x+\Delta x} \tag{1–17}$$

where $\partial C/\partial t$ = change in constituent concentration with time, $ML^{-3}T^{-1}$, (g/m^3·s)
ΔV = differential volume element, L^3, (m^3)
t = time, T, (s)
Q = volumetric flowrate, L^3T^{-1}, (m^3/s)
x = some point along the reactor length, L, (m)

The change in concentration with time term ($\partial C/\partial t$) is written as partial differential because the concentration is also changing with distance (i.e., the change in concentration is a function of both time and distance). Substituting the differential form for the term $QC|_{x+\Delta x}$ in Eq. (1–17) results in

$$\frac{\partial C}{\partial t}\Delta V = QC - Q\left(C + \frac{\Delta C}{\Delta x}\Delta x\right) \tag{1–18}$$

Substituting $A\Delta x$ for ΔV, where A is the cross-sectional area in the x direction, and simplifying yields

$$\frac{\partial C}{\partial t}A\Delta x = -Q\frac{\Delta C}{\Delta x}\Delta x \tag{1–19}$$

Dividing by A and Δx yields

$$\frac{\partial C}{\partial t} = -\frac{Q}{A}\frac{\Delta C}{\Delta x} \tag{1–20}$$

Taking the limit as Δx approaches zero yields

$$\frac{\partial C}{\partial t} = -\frac{Q}{A}\frac{\partial C}{\partial x} = -\upsilon\frac{\partial C}{\partial x} \tag{1–21}$$

where υ = the velocity of flow, LT^{-1}, (m/s)

Because both sides of the equation are the same (note $\partial t = \partial x/\upsilon$), except for the minus sign, the only way that the equation can be satisfied is if the change in concentration with distance is equal to zero. Thus, the effluent concentration must be equal to the influent concentration, which is consistent with the depiction on Fig. 1–5(b-2).

1–10 INTRODUCTION TO PROCESS KINETICS

From the standpoint of process selection and design, the controlling stoichiometry and the rates of the reaction for chemical and biological unit processes are of principal concern. The number of moles of a substance entering into a reaction and the number of moles of the substances produced are defined by the stoichiometry of a reaction. The stoichiometry of reaction refers to the definition of the quantities of chemical compounds involved in a reaction. The rate at which a substance disappears or is formed in any given stoichiometric reaction is defined as the rate of reaction. These and other related topics are discussed in this section. The rate expressions discussed in this section will be integrated with the hydraulic characteristics of the reactors, discussed previously, to define treatment kinetics.

Types of Reactions

The two principal types of reactions that occur in wastewater treatment are classified as homogeneous and heterogeneous (nonhomogeneous).

Homogeneous Reactions. In homogeneous reactions, the reactants are distributed uniformly throughout the fluid so that the potential for reaction at any point within the fluid is the same. Homogeneous reactions are usually carried out in the batch, complete-mix, and plug-flow reactors [see Figs. 1–4 (a), (b), (c), and (d)]. Homogeneous reactions may be either irreversible or reversible.

Examples of irreversible reactions are

1. Simple reactions

$$\mathrm{A \rightarrow B} \tag{1–22}$$

$$\mathrm{A + A \rightarrow C} \tag{1–23}$$

$$\mathrm{aA + bB \rightarrow C} \tag{1–24}$$

2. Parallel reactions

$$\mathrm{A + B \rightarrow C} \tag{1–25}$$

$$\mathrm{A + B \rightarrow D} \tag{1–26}$$

3. Consecutive reactions

$$\mathrm{A + B \rightarrow C} \tag{1–27}$$

$$\mathrm{A + C \rightarrow D} \tag{1–28}$$

Examples of reversible reactions are

$$\mathrm{A} \rightleftarrows \mathrm{B} \tag{1–29}$$

$$\mathrm{A} + \mathrm{B} \rightleftarrows \mathrm{C} + \mathrm{D} \tag{1–30}$$

As will be discussed subsequently, for both irreversible and reversible reactions, the rate of reaction will be an important consideration in the design of the treatment facilities in which these reactions will be carried out. Special attention must be given to the design of mixing facilities, especially for reactions that are rapid.

Heterogeneous Reactions. Heterogeneous reactions occur between one or more constituents that can be identified with specific sites, such as those on an ion-exchange resin in which one or more ions is replaced by another ion. Reactions that require the presence of a solid-phase catalyst are also classified as heterogeneous. Heterogeneous reactions are usually carried out in packed and fluidized bed reactors [see Fig. 1–4(f), (g), and (h)]. These reactions are more difficult to study because a number of interrelated steps may be involved. The typical sequence of these steps, as quoted from Smith (1981) is as follows:

1. Transport of reactants from the bulk fluid to the fluid-solid interface (external surface of catalyst particle)
2. Intraparticle transport of reactants into the catalyst particle (if it is porous)
3. Adsorption of reactants at interior sites of the catalyst particle
4. Chemical reaction of adsorbed reactants to adsorbed products (surface reaction)
5. Desorption of adsorbed products
6. Transport of products from the interior sites to the outer surface of the catalyst particle

Rate of Reaction

The rate of reaction is the term used to describe the change (decrease or increase) in the number of moles of a reactive substance per unit volume per unit time (for homogeneous reactions), or per unit surface area or mass per unit time (for heterogeneous reactions) (Denbigh and Turner, 1984).

For homogeneous reactions, the rate of reaction r is given by

$$r = \frac{1}{V}\frac{d[N]}{dt} = \frac{\text{moles}}{(\text{volume})(\text{time})} \tag{1–31}$$

If N is replaced by the term VC, where V is the volume and C is the concentration, Eq. (1–31) becomes

$$r = \frac{1}{V}\frac{d(VC)}{dt} = \frac{1}{V}\frac{VdC + CdV}{dt} \tag{1–32}$$

If the volume remains constant (i.e., isothermal conditions, no evaporation), Eq. (1–32) reduces to

$$r = \pm\frac{dC}{dt} \tag{1–33}$$

where the plus sign indicates an increase or accumulation of the substance, and the minus sign indicates a decrease of the substance.

For heterogeneous reactions where S is the surface area, the corresponding expression is

$$r = \frac{1}{S}\frac{d[N]}{dt} = \frac{\text{moles}}{(\text{area})(\text{time})} \tag{1–34}$$

For reactions involving two or more reactants with unequal stoichiometric coefficients, the rate expressed in terms of one reactant will not be the same as the rate for the other reactants. For example, for the reaction

$$aA + bB \rightarrow cC + dD \tag{1–35}$$

the concentration changes for the various reactants are given by

$$-\frac{1}{a}\frac{d[A]}{dt} = -\frac{1}{b}\frac{d[B]}{dt} = \frac{1}{c}\frac{d[C]}{dt} = \frac{1}{d}\frac{d[D]}{dt} \tag{1–36}$$

Thus, for reactions in which the stoichiometric coefficients are not equal, the rate of reaction is given by

$$r = \frac{1}{c_i}\frac{d[C_i]}{dt} \tag{1–37}$$

where the coefficient term $(1/c_i)$ is negative for reactants and positive for products.

The rate at which a reaction proceeds is an important consideration in wastewater treatment. For example, in some cases the operative reaction may take too long to go to completion. In such cases, treatment processes are designed on the basis of the rate at which the reaction proceeds rather than the equilibrium position of the reaction. Often, quantities of chemicals in excess of the stoichiometric, or exact reacting amount, may be used to accomplish the treatment step in a shorter period of time by driving the reaction to completion.

Specific Reaction Rate

From the law of mass action it can be shown that the rate of reaction for a given reaction is proportional to the remaining concentration of the reactants. Thus, for a reaction involving a single component *A*, the rate of reaction is given by

$$r = \pm k C_A \tag{1–38}$$

Where *k* is a constant of proportionality formally defined as the specific reaction rate (also known as the reaction-rate constant, velocity constant, and the rate coefficient). The specific reaction rate has the units of the specific reaction and concentration. For Eq. (1–38), the units of the specific reaction-rate constant are

$$k = \frac{r}{C} = \frac{1}{V}\frac{dN}{dt}\frac{1}{C} = \frac{\text{mole}}{\text{L}\cdot\text{s(mole/L)}} = \frac{1}{s} \tag{1–39}$$

In application, the rate of reaction, *r*, takes into account the effects of concentration, and the specific reaction-rate constant, *k*, takes into account the effects of all the other variables that may affect the reaction. Of the many variables in any given situation, temperature is usually the most important.

Effects of Temperature on Reaction Rate Coefficients

The temperature dependence of the specific reaction rate constants is important because of the need to adjust for other temperatures. The temperature dependence of the rate constant is given by the van't Hoff-Arrhenius relationship.

$$\frac{d(\ln k)}{dT} = \frac{E}{R^2} \tag{1–40}$$

where k = reaction rate constant at temperature T
T = temperature, K = 273.15 + °C
E = activation energy (a characteristic value for a reaction (e.g., J/mole)
R = ideal gas constant, 8.314 J/mole·K (1.99 cal/mole·K)

Integration of Eq. (1–40) between the limits T_1 and T_2 gives

$$\ln\frac{k_2}{k_1} = \frac{E(T_2 - T_1)}{RT_1T_2} = \frac{E}{RT_1T_2}(T_2 - T_1) \tag{1–41}$$

With k_1 known for a given temperature and with E known, k_2 can be calculated.

Activation Energy. The activation energy, E, can be calculated using Eq. (1–41) by determining the k at two different temperatures as illustrated in Example 1–1. Common values of E for wastewater treatment processes are in the range of 8400 to 84,000 J/mole (2000 to 20,000 cal/mole).

EXAMPLE 1–1 **Determination of Activation Energy** For a given chemical reaction it has been observed that the rate of reaction doubles for each 10°C increase in temperature. If the initial temperature was 10°C, estimate the activation energy for the reaction.

Solution

1. Solve Eq. (1–41) for the activation energy. The required equation is

$$E = \frac{R\ln(k_2/k_1)}{(1/T_1 - 1/T_2)}$$

2. Substitute known values and solve for E:

$T_1 = (273 + 10°\text{C}) = 283\text{ K}$

$T_2 = (273 + 20°\text{C}) = 293\text{ K}$

$k_2 = 2k_1$

$R = 8.314\text{ J/mole·K}$

$$E = \frac{(8.314\text{ J/mole·K})(\ln 2k_1/k_1)}{(1/283\text{K} - 1/293\text{K})} = 48{,}024\text{ J/mole}$$

Comment Although used as a constant, the value of the activation energy, E, will vary somewhat with temperature according to the above equation. However, the temperature range in which wastewater treatment process operate is relatively limited. There is much greater variability in the measured reaction rates.

Temperature Coefficient, θ. Because most wastewater treatment processes are carried out over a relatively narrow temperature range, the term, E/RT_1T_2, in Eq. (1–41) may be assumed to be constant for all practical purposes. If the term E/RT_1T_2 is designated by C, then Eq. (1–41) can be written as

$$\ln\frac{k_2}{k_1} = C(T_2 - T_1) \tag{1–42}$$

$$\frac{k_2}{k_1} = e^{C(T_2 - T_1)} \tag{1–43}$$

Replacing the term, e^C, in Eq. (1–43) with a temperature coefficient, θ, yields the following expression:

$$\frac{k_2}{k_1} = \theta^{(T_2 - T_1)} \tag{1–44}$$

Equation (1–44) is used commonly in the sanitary engineering field to adjust the value of the operative rate constant to reflect the effect of temperature. It should be noted, however, that although the value of θ is assumed to be constant, it can often vary considerably with temperature. Therefore, caution must be used in selecting appropriate values for θ for different temperature ranges. Typical values for various processes for different temperature ranges are given, where available, in the sections in which the individual topics are discussed. Values for θ for some biological treatment systems vary from about 1.020 to 1.10.

Reaction Order

The rate at which reactions occur is determined usually by measuring the concentration of either a reactant or product as the reaction proceeds to completion. The measured results are then compared to the corresponding results obtained from various standard rate equations by which the reaction under study is expected to proceed.

The order of a reaction with respect to a specified compound is equal to the stoichiometric coefficient for that compound. For example, in the following reaction, the reaction order for compound A is a, compound B is b, and so on.

$$\text{aA} + \text{bB} + \ldots \rightarrow \text{pP} + \text{qQ} + \ldots \tag{1–45}$$

If the rate is experimentally found to be proportional to the first power of the concentration of A (i.e., a = 1), then the reaction is said to be first order with respect to A.

When the mechanism of reaction is not known, the reaction rate for Eq. (1–45) may be approximated with the following expression:

$$r = kC_A^a C_B^b C_C^c \cdots C_P^p = kC_A^n \tag{1–46}$$

where a and b are the reaction orders with respect to reactants A and B, and n is the overall reaction order ($n = a + b + \ldots p$). The sum of the exponents to which the concentration(s) are raised is known as the order of the reaction. Several reaction rate expressions with different reaction orders are as follows.

$$r = \pm k \qquad \text{(Zero order)} \tag{1–47}$$

$$r = \pm kC \qquad \text{(First order)} \tag{1–48}$$

$$r = \pm k(C - C_s) \qquad \text{(First order)} \tag{1–49}$$

$$r = \pm kC^2 \qquad \text{(Second order)} \tag{1–50}$$

$$r = \pm kC_A C_B \qquad \text{(Second order)} \tag{1–51}$$

$$r = \pm \frac{kC}{K + C} \qquad \text{(Saturation or mixed order)} \tag{1–52}$$

$$r = \pm \frac{kC}{(1 + r_t t)^n} \qquad \text{(First order retarded)} \tag{1–53}$$

The application of various rate expressions in wastewater treatment are described in the following discussion.

Rate Expressions Used in Wastewater Treatment

The physical, chemical, and biological processes that are applied in wastewater treatment for the conversion or separation of constituents are numerous and varied. Important constituent treatment processes, along with the constituents affected, are reported in Table 1–10. The various processes listed in Table 1–10 will be referred to throughout this text.

Table 1–10

Common constituent conversion and separation processes (i.e., fate processes) in the environment and the constituents affected

Process	Comments	Constituents effected
Adsorption/ desorption	Many chemical constituents tend to attach or sorb onto solids. The implication for wastewater discharges is that a substantial fraction of some toxic chemicals are associated with the suspended solids in the effluent. Adsorption combined with solids settling results in the removal from the water column of constituents that might not otherwise decay.	Metals, trace organics, NH_4^+, PO_4^{3-}
Algal synthesis	The synthesis of algal cell tissue using the nutrients found in wastewater.	NH_4^+, NO_3^-, PO_4^{3-}, pH, etc.
Bacterial conversion	Bacterial conversion (both aerobic and anaerobic) is the most important process in the transformation of constituents released to the environment. The exertion of BOD and nitrogenous oxygen demand (NOD) are the most common examples of bacterial conversion encountered in water-quality management. The depletion of oxygen in the aerobic conversion of organic wastes is also known as deoxygenation. Solids discharged with treated wastewater are partly organic. Upon settling to the bottom, they decompose bacterially either anaerobically or aerobically, depending on local conditions. The bacterial transformation of toxic organic compounds is also of great significance.	BOD_5, nitrification, denitrification, sulfate reduction, anaerobic fermentation (in bottom sediments), conversion of priority organic pollutants, etc.
Chemical reactions	Important chemical reactions that occur in the environment include hydrolysis, photochemical, and oxidation-reduction reactions. Hydrolysis reactions occur between contaminants and water.	Chemical disinfection, decomposition of organic compounds, specific ion exchange, element substitution
Filtration	Removal of suspended and colloidal solids by straining (mechanical and chance contact), sedimentation, interception, impaction, and adsorption.	TSS, colloidal particles
Flocculation	Flocculation is the term used to describe the aggregation of smaller particles into larger particles that can be removed by sedimentation and filtration. Flocculation is brought about by Brownian motion, differential velocity gradients, and differential settling in which large particles overtake smaller particles and form larger particles.	Colloidal and small particles
Gas absorption/ desorption	The process whereby a gas is taken up by a liquid is known as absorption. For example, when the dissolved oxygen concentration in a body of water with a free surface is below the saturation concentration in the water, a net transfer of oxygen occurs from the atmosphere to the water. The rate of transfer (mass per unit time per unit surface area) is proportional to the amount by which the dissolved oxygen is below saturation. The addition of oxygen to water is also known as reaeration. Desorption occurs when the concentration of the gas in the liquid exceeds the saturation value, and there is a transfer from the liquid to the atmosphere.	O_2, CO_2, CH_4, NH_3, H_2S

(*continued*)

Table 1–10 (*Continued*)

Process	Comments	Constituents effected
Natural decay	In nature, contaminants will decay for a variety of reasons, including mortality in the case of bacteria and photooxidation for certain organic constituents. Natural and radioactive decay usually follow first-order kinetics.	Plants, animals, algae, fungi, protozoa, eubacteria (most bacteria), archaebacteria, viruses, radioactive substances, plant mass
Photochemical reactions	Solar radiation is known to trigger a number of chemical reactions. Radiation in the near-ultraviolet (UV) and visible range is known to cause the breakdown of a variety of organic compounds.	Oxidation of inorganic and organic compounds
Photosynthesis/ respiration	During the day, algal cells in water bodies will produce oxygen by means of photosynthesis. Dissolved oxygen concentrations as high as 30 to 40 mg/L have been measured. During the evening hours algal respiration will consume oxygen. Where heavy growths of algae are present, oxygen depletion has been observed during the evening hours.	Algae, duckweed, submerged macrophytes, NH_4^+, PO_4^{3-}, pH, etc.
Sedimentation	The suspended solids discharged with treated wastewater ultimately settle to the bottom of the receiving water body. This settling is enhanced by flocculation and hindered by ambient turbulence. In rivers and coastal areas, turbulence is often sufficient to distribute the suspended solids over the entire water depth.	TSS
Sediment oxygen demand	The residual solids discharged with treated wastewater will, in time, settle to the bottom of streams and rivers. Because the particles are partly organic, they can be decomposed anaerobically as well as aerobically, depending on conditions. Algae which settle to the bottom will also be decomposed, but much more slowly. The oxygen consumed in the aerobic decomposition of material in the sediment represents another dissolved oxygen demand in the water body.	O_2, particulate BOD
Volatilization	Volatilization is the process whereby liquids and solids vaporize and escape to the atmosphere. Organic compounds that readily volatilize are known as VOCs (volatile organic compounds). The physics of this phenomenon are very similar to gas absorption, except that the net flux is out of the water surface.	VOCs, NH_3, CH_4, H_2S, other gases

For example, bacterial conversion is considered in Chap. 2 in the analysis of the BOD reaction, and in greater detail in the chapters dealing with biological treatment. Because all of the processes summarized in Table 1–10 are rate dependent, representative rate expressions used to model these processes are presented in Table 1–11. The important thing to note about Table 1–11 is the variety of different rate expressions that have been used to model constituent conversion and separation processes.

Conversion Processes. Rate expressions have been used to describe the conversion of wastewater constituents in treatment processes and the fate of constituents released in the environment. For example, the first order reaction, Eq. (1–48), expressed as ($r_c = -kC$) is used to model the exertion of BOD and bacterial decay, as discussed subsequently in Chap. 2. Although Eq. (1–51) is second order overall, it is first order with respect to C_A and C_B, individually. Equation (1–52), known as a saturation type of equation (also known as a Monod type equation), is illustrated on Fig. 1–7. As shown on Fig. 1–7, when the concentration, C, is large the rate of reaction is zero order, and when the concentration is low, the rate of reaction is first order.

Table 1–11

Examples of rate expressions for selected conversion and separation processes given in Table 1–10[a]

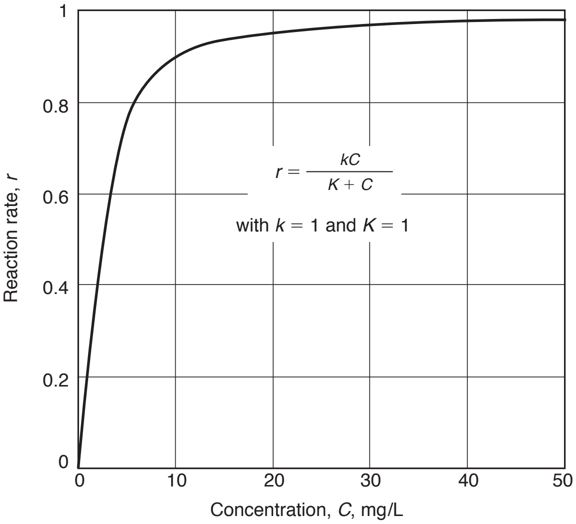
Process	Rate expression	Comments
Conversion processes		
Bacterial conversion	$r_c = -kC$	r_c = rate of conversion, M/L^3T k = first order reaction rate coefficient, $1/T$ C = concentration of organic material remaining, M/L^3
Chemical reactions	$r_c = \pm k_n C^n$	r_c = rate of conversion, M/L^3T k_n = reaction rate coefficient, $(M/L^3)^{n-1}/T$ C = concentration of constituent, $(M/L^3)^n$ n = reaction order (e.g. for second order $n = 2$)
Natural decay	$r_d = -k_d N$	r_d = rate of decay, no./T k_d = first order reaction rate coefficient, $1/T$ N = amount of organisms remaining, no.
Separation processes		
Gas absorption/ desorption	$r_{ab} = k_{ab}\frac{A}{V}(C_s - C)$ $r_{de} = -k_{de}\frac{A}{V}(C - C_s)$	r_{ab} = rate of absorption, M/L^3T r_{de} = rate of desorption, M/L^3T k_{ab} = coefficient of absorption, L/T k_{de} = coefficient of desorption, L/T A = area, L^2 V = volume, L^3 C_s = saturation concentration of constituent in liquid, M/L^3 (see Eq. 2–49) C = concentration of constituent in liquid, M/L^3
Sedimentation	$r_s = \frac{v_s}{H}(SS)$	r_s = rate of sedimentation, $1/T$ v_s = settling velocity, L/T H = depth, L SS = settleable solids, L^3/L^3
Volatilization	$r_v = -k_v(C - C_s)$	r_v = rate of volatilization per unit time per unit volume, M/L^3T k_v = volatilization constant, $1/T$ C = concentration of constituent in liquid, M/L^3 C_s = saturation concentration of constituent in liquid, M/L^3 (see Eq. 2–49)

[a] Adapted in part from Ambrose et al. (1988), Tchobanoglous et al. (2003).

The rate expression given by Eq. (1–53) is known as a retarded first order rate expression because the rate constant changes with distance or time, as illustrated on Fig. 1–8, or with the degree of treatment which, in turn, can be related to distance or time. The term, r_t, in the denominator is the retardation factor. In wastewater treatment applications, the exponent n in Eq. (1–53) is related to the particle size distribution (see Fig, 1–8). For example, if all of the particles are the same size and composition, the value of the exponent n is equal to one, and the retardation factor r_t is equal to zero. The retarded rate expression is also applied to the removal of organic matter from mixtures where the

Figure 1–7

Rate of reaction versus concentration for a saturation type expression. Beyond about 20 mg/L the rate of reaction is essentially zero order.



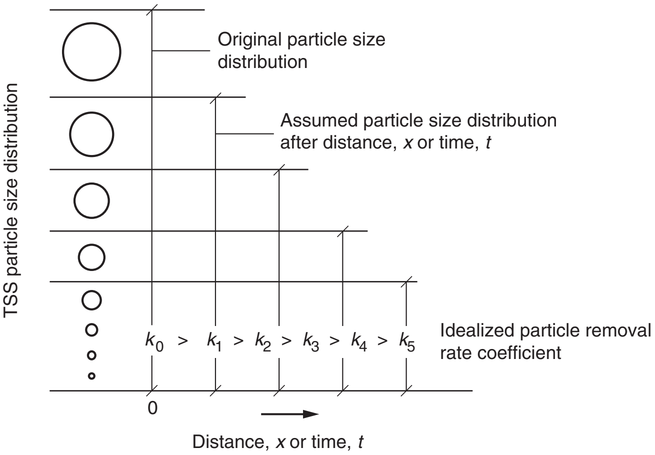
biodegradability of the individual constituents comprising the organic matter is different (Tchobanoglous et al., 2003).

Separation Processes. Unlike conversion processes where constituents are removed through transformation, separation processes bring about removal by the physical transfer of constituents from a diluted state to a concentrated state. Separation processes exploit particular characteristics of constituents to bring about removal. The removal methods for particulate and dissolved constituents are considered below.

Particulate Constituents. The removal of particulate constituents depends on the nature and size of the constituent but is brought about primarily through the application of gravity and pressure forces. For example, large coarse solids in wastewater, greater than about 6 mm (0.25 in.), are removed by screening (i.e., sieving). The force of gravity is used to bring about the separation (removal) of grit and other settleable material. Very light constituents such as oils and grease are also removed by the force of gravity and by flotation because their density is less that that of water. Smaller particulate constituents that cannot

Figure 1–8

Definition sketch to illustrate the change that can occur in the removal rate coefficient with distance or time when an influent wastewater with a particle size distribution such as shown is applied to a granular medium filter or a constructed wetland.



be removed by gravity can be removed by filtration, in which wastewater is passed through a filtering medium by the application of force in the form of pressure.

Dissolved Constituents. Dissolved constituents can also be removed from water by concentration on a solid surface (e.g., activated carbon adsorption and ion exchange). An important consideration in the modeling of adsorption-type separation processes is that because the reaction is assumed to be instantaneous after the constituent reaches the relevant surface, the reaction rate is controlled by the transport of the constituent to the point of reaction. The transfer of mass by molecular diffusion in stationary systems can be represented by the following expression, known as Fick's first law:

$$r = -D_m \frac{\partial C}{\partial x} \tag{1–54}$$

where r = rate of mass transfer per unit area per unit time, $\mathrm{ML^{-2}T^{-1}}$
D_m = coefficient of molecular diffusion in the x direction, $\mathrm{L^2T^{-1}}$
C = concentration of constituent being transferred, $\mathrm{ML^{-3}}$
x = distance, L

The negative sign in Eq. (1–54) is used to denote the fact that diffusion takes place in the direction of decreasing concentration. Also, it should be noted that the concentration gradient ($\partial C/\partial x$) is assumed to be constant. In the chemical engineering literature the symbol J is used to denote mass transfer in concentration units whereas the symbol N is used to denote the transfer of mass expressed as moles.

The coefficient of molecular diffusion is related to the frictional coefficient of a particle as given by the Stokes-Einstein law of diffusion. For spherical particles the coefficient of diffusion is given by the following expression (Shaw, 1966).

$$D = \frac{kT}{6\pi\mu r_p} = \frac{RT}{6\pi\mu r_p N} \tag{1–55}$$

where D = coefficient of diffusion, $\mathrm{m^2/s}$
k = Boltzmann constant 1.3805×10^{-23} J/K
T = temperature, K = 273.15 + °C
R = universal gas law constant, 8.3145 J/mole·K
μ = dynamic viscosity, $\mathrm{N{\cdot}s/m^2}$
r_p = radius of particle, m
N = Avogadro's number, 6.02×10^{23} molecules/g·mole

The terms in the denominator in Eq. (1–55) correspond to the coefficient of friction for a particle as defined by Stokes law. The coefficient of diffusion for a particle with a radius of 10^{-7} m (0.01 μm), which corresponds to the size of the smallest bacteria, for the following conditions is:

$T = 20°\mathrm{C}$

$\mu = 1.002 \times 10^{-3}\ \mathrm{N{\cdot}s/m^2}$

$$D = \frac{kT}{6\pi\mu r_p A} = \frac{(8.3145\ \mathrm{J/mole{\cdot}K})(293\ \mathrm{K})}{6(3.14)(1.002 \times 10^{-3}\ \mathrm{N{\cdot}s/m^2})(10^{-7}\mathrm{m})(6.02 \times 10^{23}/\mathrm{mole})}$$

$$= 21.43 \times 10^{-13}\ \mathrm{m^2/s} = 2.143 \times 10^{-8}\ \mathrm{cm^2/s}$$

From the above computation it is easy to see that as the particles get smaller the coefficient of molecular diffusion increases. Depending on the fluid regime, the coefficient of molecular diffusion in Eq. (1–55) will be replaced by the turbulent coefficient of dispersion, as described further in Appendix I.

Many important separation processes used in wastewater treatment involve mass transfer across the gas-liquid interface (e.g., aeration) or the removal of undesirable constituents (e.g., stripping). For example, the rate of flux of a slightly soluble gas from the gas to the liquid phase (liquid film controls transfer rate; see discussion in Sec. 5–10), based on Fick's first law, can be approximated as follows:

$$r = K_L(C_s - C_t) \tag{1–56}$$

where r = rate of mass transferred per unit area per unit time, $ML^{-2}T^{-1}$
K_L = overall liquid mass transfer coefficient, LT^{-1}
C_s = concentration in equilibrium with gas as given by Henry's Law, ML^{-3}
C_t = concentration in liquid bulk phase at time t, ML^{-3}

The mass transfer coefficient depends on the characteristics of the wastewater and the treatment process design and is, therefore, unique for each situation. The application of mass transfer for aeration is considered in Secs. 5–10 and 5–11. Other treatment processes that depend on mass transfer including carbon adsorption, gas stripping, and ion exchange are considered in Chap. 11.

Analysis of Reaction Rate Coefficients

Typically, reaction rate coefficients are determined using the results obtained from batch experiments (i.e., no inflow or outflow), from continuous flow experiments, and from pilot and field scale experiments. Using the data from batch experiments, the coefficients can be determined using a variety of methods including (1) the method of integration and (2) the differential method (see Table 1–12).

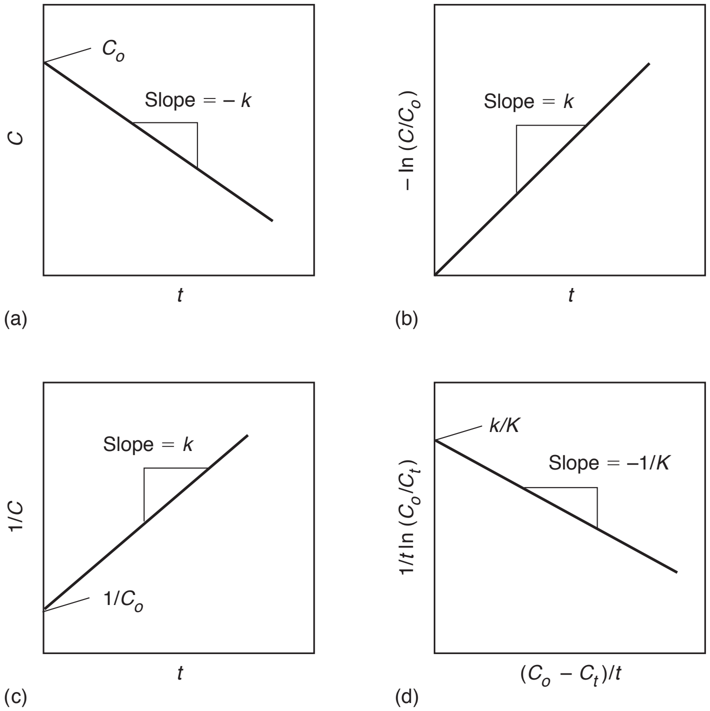
Table 1–12

Integration and differential methods used to determine reaction rate coefficients

Rate expression		Method used to determine the reaction rate coefficient
Integration method		
Zero order reaction	Integrated form	
$r_c = \frac{dC}{dt} = -k$	$C - C_o = -kt$	Graphically, by plotting C versus t [see Fig. 1–9(a)]
First order reaction		
$r_c = \frac{dC}{dt} = -kC$	$\ln\frac{C}{C_o} = -kt$	Graphically, by plotting $-\ln(C/C_o)$ versus t [see Fig. 1–9(b)]
Second order reaction		
$r_c = \frac{dC}{dt} = -kC^2$	$\frac{1}{C} - \frac{1}{C_o} = kt$	Graphically, by plotting $1/C$ versus t [see Fig. 1–9(c)]
Saturation reaction		
$r_c = \frac{dC}{dt} = -\frac{kC}{K + C}$	$kt = K\ln\frac{C_o}{C_t} + (C_o - C_t)$	Graphically, by plotting $1/t \ln(C_o/C_t)$ versus $(C_o - C_t)/t$ [see Fig. 1–9(d)]
Differential method		
$r_c = \frac{dC}{dt} = -kC^n$		Analytically, by solving for $n = \frac{\log[-d(C_1/dt)] - \log[-(dC_2/dt)]}{\log(C_1) - \log(C_2)}$ Once the order of the reaction is known, the reaction rate coefficient can be determined by substitution

Figure 1–9

Graphical analysis for the determination of reaction order and reaction-rate coefficients: (a) zero-order reaction, (b) first-order reaction, (c) second-order reaction, and (d) saturation type reaction.



As summarized in Table 1–12, the method of integration involves the substitution of the measured data on the amount of reactant remaining at various times into the integrated form of the rate expression. Plots of the integrated forms of the reaction rate expressions used to determine the reaction rate coefficients are shown on Fig. 1–9. In the differential method, where the order of the reaction is unknown, the concentrations remaining at two different times are used to solve the differential form of the rate expression for the order of the reaction. Once the reaction order is known, the reaction rate coefficient is determined by substitution using the test data. The application of these two methods is illustrated in Example 1–2.

EXAMPLE 1–2 **Determination of the Reaction Order and the Reaction Rate Coefficient** Given the following set of data obtained using a batch reactor [see Fig. 1–4(a)], determine the order of the reaction and the reaction rate coefficient using the integration and differential methods.

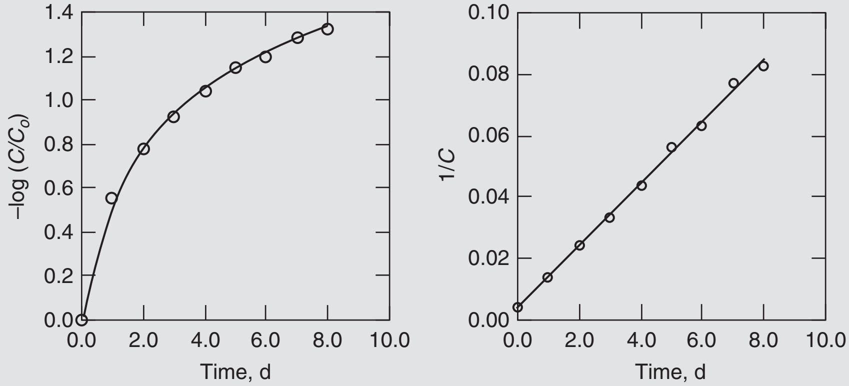
Time, d	Concentration, C, mole/L
0	250
1	70
2	42
3	30
4	23
5	18
6	16
7	13
8	12

Solution—Part 1 Integration Method

1. Determine the reaction order and the reaction rate constant using the integration method. Develop the data needed to plot the experimental data functionally, assuming the reaction is either first or second order.

Time, d	C, mole/L	$-\log(C/C_o)$	$1/C$
0	250	0	0.004
1	70	0.553	0.014
2	42	0.775	0.024
3	30	0.921	0.033
4	23	1.036	0.044
5	18	1.143	0.056
6	16	1.194	0.063
7	13	1.284	0.077
8	12	1.319	0.083

2. To determine whether the reaction is first or second order, plot $-\log(C/C_o)$ and $1/C$ versus t as shown below. Because the plot of $1/C$ versus t is a straight line, the reaction is second order with respect to the concentration C.



3. Determine the reaction rate coefficient.

Slope $= k$

The slope from the plot $= \dfrac{0.084 - 0.024}{8\text{d} - 2\text{d}} = 0.010/\text{d}$

$k = 0.010/\text{d}$

Solution—Part 2 Differential Method

1. Determine the reaction order and the reaction rate constant using the differential method.

$$n = \frac{\log[-(dC_1/dt)] - \log[-(dC_2/dt)]}{\log(C_1) - \log(C_2)}$$

a. Use the experimental data obtained at day 3 and 6.

Time, d	C, mole/L	$\frac{C_{t+1} - C_{t-1}}{2}$	$\approx \frac{dC_t}{dt}$
0	250		
1	70		
2	42		
3	30	(23 − 42)/2	−9.5
4	23		
5	18		
6	16	(13 − 18)/2	−2.5
7	13		
8	12		

b. Substitute and solve for n.

$$n = \frac{\log(9.5) - \log(2.5)}{\log(30.0) - \log(16.0)} = 2.07 \quad \text{use } n = 2$$

c. The reaction is second order.

d. The reaction rate constant is

$$\frac{1}{C} - \frac{1}{C_o} = kt$$

$$\frac{1}{42} - \frac{1}{250} = k(2)$$

$$k = 0.0103/\text{d}, \quad \text{use } k = 0.010/\text{d}$$

In the applications described above, the initial concentration of a constituent is generally known. However, in the conventional BOD test, described in Chap. 2, both UBOD (ultimate biological oxygen demand) and k_1 are unknown. To determine these values, the usual procedure is to run a series of BOD measurements with time. Using these measurements, the UBOD and k_1 values can be determined using a number of methods including the method of least-squares, the method of moments, the daily-difference method, the rapid-ratio method, the Thomas method, and the Fujimoto method, as discussed in Sec. 2–6 in Chap. 2.

1–11 INTRODUCTION TO TREATMENT PROCESS MODELING

In wastewater treatment, the chemical and biological reactions that are needed to bring about the treatment of wastewater are carried out in the reactors described previously in Sec. 1–7. Treatment process kinetics involves the coupling of reactors and reaction rates to determine treatment process performance. In this section, the focus is on modeling the reactions that occur in the reactors used for wastewater treatment. The reactors considered include (1) batch, (2) complete-mix, (3) complete-mix reactors in series, (4) ideal plug-flow, (5) ideal plug-flow with retarded reaction rate, and (6) plug-flow with axial dispersion.

Batch Reactor with Reaction

The derivation of the materials mass balance equation for a batch reactor [see Fig. 1–7 (a)] for a reactive constituent is written as follows:

Accumulation = inflow − outflow + generation

$$\frac{dC}{dt}V = QC_o - QC + r_C V \tag{1–57}$$

Because $Q = 0$ the resulting equation for a batch reactor is

$$\frac{dC}{dt} = r_C \tag{1–58}$$

Before proceeding further, it will be instructive to explore the difference between the rate of change term that appears as part of the accumulation term and the rate of generation or utilization or decay term. In general, these terms are not equal, except in the special case of a batch reactor in which there is no inflow or outflow from the control volume. The key point to remember is that when flow is not occurring, the concentration per unit volume is changing according to the applicable rate expression. On the other hand, when flow is occurring, the concentration in the reactor is also being modified by the inflow and outflow from the reactor.

If the rate of reaction is defined as first order (i.e., $r_c = -kC$), integrating between the limits $C = C_o$ and $C = C$ and $t = 0$ and $t = t$ yields

$$\int_{C=C_o}^{C=C} \frac{dC}{C} = -k\int_{t=0}^{t=t} dt = kt \tag{1–59}$$

The resulting expression is

$$\frac{C}{C_o} = e^{-kt} \tag{1–60}$$

Equation (1–60) is the same as the BOD equation Eq. (2–59) considered subsequently in Chap. 2.

Complete-Mix Reactor with Reaction

The general form of the mass-balance equation for a complete-mix reactor as shown on Figs. 1–4(b) and 1–5(a-1), in which the liquid in the reactor is mixed completely, follows:

Accumulation = inflow − outflow + generation

$$\frac{dC}{dt}V = QC_o - QC + r_c V \tag{1–61}$$

Assuming first order removal kinetics ($r_c = -kC$), Eq. (1–61) can be rearranged and written as follows

$$C' + \beta C = \frac{Q}{V}C_o \tag{1–62}$$

where $C' = dC/dt$

$\beta = k + Q/V$

To solve Eq. (1–62) both sides of the expression are multiplied by the integrating factor $e^{\beta t}$:

$$e^{\beta t}(C' + \beta C) = \frac{Q}{V}C_o e^{\beta t} \tag{1–63}$$

The left side of the above expression can be written as a differential as follows:

$$(Ce^{\beta t})' = \frac{Q}{V}C_o e^{\beta t} \tag{1–64}$$

The differential sign is removed by integrating the above expression

$$Ce^{\beta t} = \frac{Q}{V}C_o \int e^{\beta t} \tag{1–65}$$

Integration of Eq. (1–65) yields

$$Ce^{\beta t} = \frac{Q}{V}\frac{C_o}{\beta}e^{\beta t} + K \tag{1–66}$$

Dividing by $e^{\beta t}$ yields

$$C = \frac{Q}{V}\frac{C_o}{\beta} + Ke^{-\beta t} \tag{1–67}$$

But when $t = 0$, $C = C_o$ and K is equal to

$$K = C_o - \frac{Q}{V}\frac{C_o}{\beta} \tag{1–68}$$

Substituting for K in Eq. (1–68) and simplifying yields the following expression, which is the non-steady state solution of Eq. (1–61):

$$C = \frac{Q}{V}\frac{C_o}{\beta}(1 - e^{-\beta t}) + C_o e^{-\beta t} \tag{1–69}$$

The solution to Eq. (1–61) under steady-state conditions (i.e., the rate accumulation term is equal to zero [$dC/dt = 0$)] is given below.

$$C = \frac{C_o}{[1 + k(V/Q)]} = \frac{C_o}{(1 + k\tau)} \tag{1–70}$$

It should also be noted that when $t \rightarrow \infty$, Eq. (1–69) becomes the same as Eq. (1–67).

Complete-Mix Reactors in Series with Reaction

When complete-mix reactors are used in series, the steady-state solution is of concern as it is used for design. Two approaches are presented for the analysis of reactors in series: (1) analytical and (2) graphical. The graphical approach also applies to cascades of reactors, as discussed for mass transfer equilibria.

Analytical Solution. The steady-state form of the mass balance for the second reactor of the three reactor system (see Fig. 1–10), is given by

Accumulation = inflow − outflow + generation

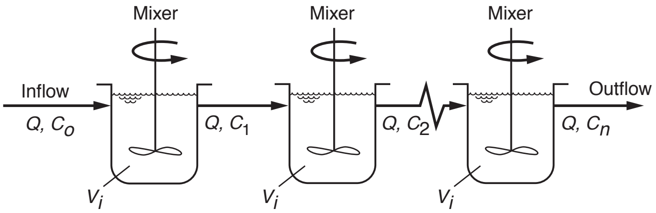
$$\frac{dC_2}{dt}\frac{V}{2} = 0 = QC_1 - QC_2 + r_c\frac{V}{2} \tag{1–71}$$

Assuming first order removal kinetics ($r_c = -kC_2$), Eq. (1–71) can be rearranged and solved for C_2 yielding

$$C_2 = \frac{C_1}{[1 + (kV/2Q)]} \tag{1–72}$$

Figure 1–10

Definition sketch for the analysis of complete-reactors in series.



But from Eq. (1–70), the value of C_1 is equal to

$$C_2 = \frac{C_o}{[1 + (kV/2Q)]} \tag{1–73}$$

Combining the above two expressions yields

$$C_2 = \frac{C_o}{[1 + (kV/2Q)]^2} \tag{1–74}$$

For n reactors in series the corresponding expression is

$$C_n = \frac{C_o}{[1 + (kV/nQ)]^n} = \frac{C_o}{[1 + (k/2\tau)]^n} \tag{1–75}$$

For example, consider three 1000 m^3 complete-mix reactors in series with a flowrate of 100 m^3/d and first order kinetics with a reaction rate coefficient value of $k = 0.1/d$. Using Eq. (1–75), the effluent concentration from the third reactor, assuming the starting concentration was 100 mg/L is

$$C_3 = \frac{C_o}{[1 + (kV/3Q)]^3} = \frac{100}{\left\{1 + \left[\frac{(0.1/\text{d})(3000\ \text{m}^3)}{(3 \times 100\ \text{m}^3/\text{d})}\right]\right\}^3} = 12.5\ \text{mg/L}$$

Solving Eq. (1–75) for the detention time yields

$$\tau = \frac{V}{Q} = \left[\frac{1}{(C_n/C_o)^{1/n}} - 1\right]\left(\frac{n}{k}\right) \quad \text{or} \quad \tau = \left[\left(\frac{C_o}{C_n}\right)^{\frac{1}{n}} - 1\right]\left(\frac{n}{k}\right) \tag{1–76}$$

Graphical Solution. The graphical solution for 3 (or for n) reactors in series is obtained as follows. For a single reactor, Eq (1–71) can be written as follows:

Accumulation = inflow − outflow + generation

$$0 = QC_o - QC_1 - r_cV \tag{1–77}$$

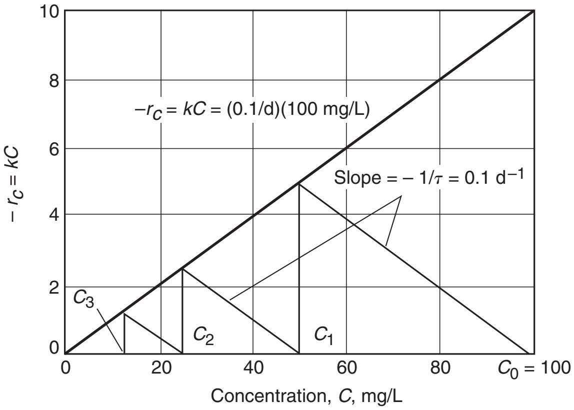
The first step in developing a graphical solution is to draw a graph of r_c versus C (see Fig. 1–10). To plot r_c versus C, Eq. (1–77) is now rewritten as follows:

$$r_c = -\frac{Q}{V}(C_1 - C_o) = -\frac{1}{\tau}(C_1 - C_o) \tag{1–78}$$

The above equation can be represented graphically by a straight line drawn from the point $r_c = 0$ and $C = 100$ mg/L with a slope of $-1/\tau$. The line drawn will intersect the graph of r_c versus C at $r_c = 5.0$ and $C_1 = 50$ mg/L as shown on Fig. 1–11. The value $C_1 = 50$ mg/L is the solution of Eq. (1–78) for a single rector for the stated conditions used to derive the

Figure 1–11

Graphical analysis used to determine the effluent concentration from a series of complete-mix reactors.



analytical solution, presented previously. If the procedure is repeated for a second and a third reactor, the final effluent concentration from the third reactor is found to be 12.5 mg/L, which is the same as the analytical solution determined above. The graphical approach is especially useful in solving phase separation processes as described previously in Sec. 1–9. To use the graphical procedure, the reaction rate coefficient must be a function of a single variable (e.g., *C*). Use of both the analytical and graphical methods of analysis are illustrated in Example 1–3. Additional details on the graphical solution of design equations may be found in Eldridge and Piret (1950) and Smith (1981).

EXAMPLE 1–3 **Analysis of Reactors in Series Using Both an Analytical and Graphical Approach** Two 1000 m^3 complete-mix reactors are to be used in series with a flowrate of 500 m^3/d and second order kinetics with a *k* value of 0.01/d. Determine the effluent concentration from the second reactor assuming the starting concentration is 100 mg/L.

Solution

1. Determine the effluent concentration from the series of two complete-mix reactors analytically.
   a. At steady-state, the mass balance for the first complete-mix reactor is:

$$0 = QC_o - QC_1 - k_c C_1^2 V$$

Substituting the given values and solving for C_1 yields

$$0 = \frac{(500\ m^3/d)}{1000\ m^3}(100\ mg/L) - \frac{(500\ m^3/d)}{1000\ m^3}C_1 - (0.01/d)C_1^2$$

$$C_1 = 50\ mg/L$$

   b. At steady-state, the mass balance for the second complete-mix reactor is

$$0 = QC_1 - QC_2 - kC_2^2 V$$

Substituting the given values and solving for C_2 yields

$$0 = \frac{(500\ m^3/d)}{1000\ m^3}(50\ mg/L) - \frac{(500\ m^3/d)}{1000\ m^3}C_2 - (0.01/d)C_2^2$$

$$C_2 = 30\ mg/L$$

2. Determine the effluent concentration from the series of two complete-mix reactors graphically.
   a. Prepare a plot of r_c versus C as shown below:

   b. Linearize the mass balance equation from Step 1a

$$r_c = -\frac{Q}{V}(C_1 - C_o)$$

   c. On the plot prepared above draw a straight line from the point $r_c = 0$ and $C =$ 100 mg/L with a slope of $-Q/V$ equal to -0.5/d [$-(500\ \text{m}^3/\text{d})/1000\ \text{m}^3$]. The line drawn intersects the graph of r_c versus C at $r_c = 0.25$ and $C_1 = 50$ mg/L. Repeating the above procedure the final effluent concentration from the second reactor is found to be 30 mg/L, which is the same as the analytical solution determined in Step 1.

Ideal Plug-Flow Reactor with Reaction

The derivation of the materials balance equation for an ideal plug-flow reactor, in which the concentration, C, of the constituent is uniformly distributed across the cross-sectional area of the control volume, and there is no longitudinal dispersion, can be illustrated by considering the differential volume element shown on Fig. 1–6. For the differential volume element ΔV shown on Fig. 1–6, the materials balance on a reactive constituent C is written as follows:

Accumulation = inflow − outflow + generation

$$\frac{\partial C}{\partial t}\Delta V = QC|_x - QC|_{x+\Delta x} + r_c\Delta V \tag{1–79}$$

Accumulation = inflow − outflow + generation

where $\partial C/\partial t$ = change in constituent concentration with time, $\text{ML}^{-3}\text{T}^{-1}$ ($\text{g/m}^3\cdot\text{s}$)
C = constituent concentration, ML^{-3} (g/m^3)
ΔV = differential volume element, L^3 (m^3)
Q = volumetric flowrate, L^3T^{-1} (m^3/s)
r_c = reaction rate for constituent C, $\text{ML}^{-3}\text{T}^{-1}$, ($\text{g/m}^3\cdot\text{s}$)

Substituting the differential form for the term $QC|_{x+\Delta x}$ in Eq. (1–79) results in

$$\frac{\partial C}{\partial t}\Delta V = QC - Q\left(C + \frac{\Delta C}{\Delta x}\Delta x\right) + r_c\Delta V \tag{1–80}$$

Substituting $A\Delta x$ for ΔV and dividing by A and Δx yields

$$\frac{\partial C}{\partial t} = -\frac{Q}{A}\frac{\Delta C}{\Delta x} + r_c \tag{1–81}$$

Taking the limit as Δx approaches zero yields

$$\frac{\partial C}{\partial t} = -\frac{Q}{A}\frac{\partial C}{\partial x} + r_c \tag{1–82}$$

If steady-state conditions are assumed ($\partial C/\partial t = 0$) and the rate of reaction is defined as $r_c = -kC^n$, integrating between the limits $C = C_o$ and $C = C$ and $x = 0$ and $x = L$ yields

$$\int_{C_o}^{C}\frac{dC}{C^n} = -k\frac{A}{Q}\int_0^L dx = -k\frac{AL}{Q} = -k\frac{V}{Q} = -k\tau \tag{1–83}$$

Equation (1–83) is the steady-state solution to the materials balance equation for a plug-flow reactor without dispersion. If it is assumed that n is equal to one, Eq. (1–83) becomes

$$\frac{C}{C_o} = e^{-k\tau} \tag{1–84}$$

which is equivalent to Eq. 1–60, derived previously for the batch reactor.

Comparison of Complete-Mix and Plug-Flow Reactors with Reaction

The combined effect of reactor type (e.g., complete-mix versus plug-flow) and kinetics is also of interest. The total volume required for various removal efficiencies for first order kinetics, using 1, 2, 4, 6, 8, or 10 reactors in series is reported in Table 1–13 and shown graphically on Fig. 1–12. The corresponding volume required for a plug-flow reactor is also reported in Table 1–13 As shown in Table 1–13, as the number of reactors in series is increased, the total reactor volume required approaches that of a plug-flow reactor. A comparison of reactor types for second-order kinetics is examined in Example 1–4.

It should be noted, however, that for zero order kinetics the volume of the two reactors will be the same. It is also important to note that biological processes do not obey the results presented in Table 1–13 (i.e., plug-flow is more efficient than complete-mix) because biological process are modeled using BOD and COD which includes microbial products in addition to any residual substrate. As a result, the volumes required for the two reactors will be the same. The use of a plug-flow reactor, or mixed cells in series, is often favored to help control the growth of filamentous organisms (see discussion in Chap. 7).

Table 1–13

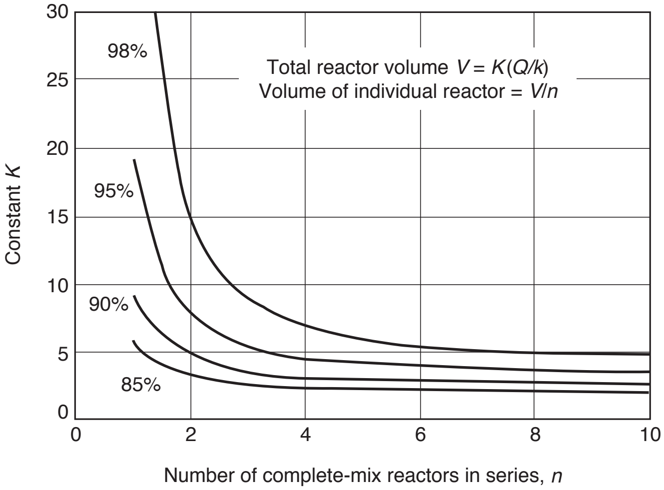
Required reactor volumes expressed in terms of Q/k for a series of complete-mix reactors and for a plug-flow reactor for various removal efficiencies for first-order kinetics[a]

	Reactor volume $V = K(Q/k)$			
	Removal efficiency, %			
No of reactors in series	85	90	95	98
1	5.67	9.00	19.00	49.00
2	3.16	4.32	6.94	12.14
4	2.43	3.11	4.46	6.64
6	2.23	2.81	3.89	5.52
8	2.14	2.67	3.63	5.05
10	2.09	2.59	3.49	4.79
Plug flow	1.90	2.30	3.00	3.91

[a] Volume of individual reactors equals value in table divided by the number of reactors in series.

Figure 1–12

Definition sketch for the total volume required versus the number of complete-mix reactors in series for various removal efficiencies. The K value on the vertical axis is multiplied by the flowrate and divided by the reaction coefficient to obtain the total volume required. The volume of an individual reactor is equal to the total volume divided by the number of reactors in series.



EXAMPLE 1–4 **Comparison of Required Reactor Volumes for Second-order Kinetics**

Assuming that second-order kinetics apply ($r_c = -kC^2$), compare the required volume of a complete-mix reactor to the volume of a plug-flow reactor to achieve a 90 percent reduction in the concentration ($C_o = 1$ and $C_e = 0.1$).

Solution

1. Compute the required volume for a complete-mix reactor in terms of Q/k.
   a. At steady state, a mass balance for a complete-mix reactor yields

$$0 = QC_o - QC_e - kC_e^2V$$

   b. Simplify and substitute the given data.

$$V = \frac{Q}{k}\left(\frac{C_o - C_e}{C_e^2}\right) = \frac{Q}{k}\frac{1 - 0.1}{(0.1)^2} = 90\frac{Q}{k}$$

2. Compute the required volume for a plug-flow reactor in terms of Q/k.
   a. At steady state, a mass balance for a plug-flow reactor yields

$$0 = -Q\frac{dC}{dx}dx + Adx(-kC^2)$$

   b. The integrated form of the steady-state equation is

$$V = \frac{Q}{k}\int_{C_o}^{C_e}\frac{dC}{C^2} = \frac{Q}{k}\frac{1}{C}\bigg|_{C_o}^{C_e} = \frac{Q}{k}\left(\frac{1}{C_e} - \frac{1}{C_o}\right)$$

   c. Substituting the given concentration values yields

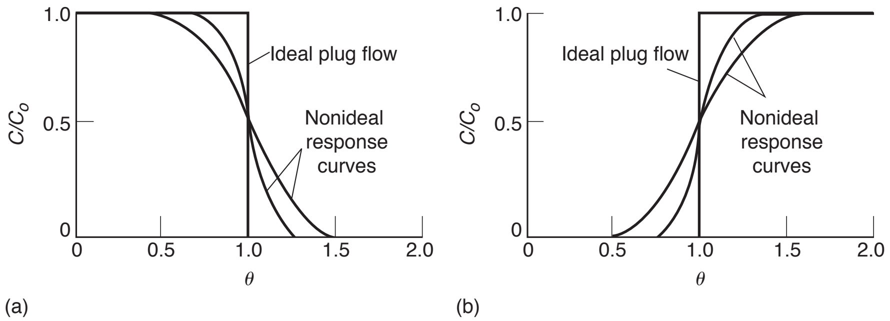
$$V = \frac{Q}{k}\left(\frac{1}{0.1} - \frac{1}{1}\right) = \frac{9Q}{k}$$

3. Determine the volume ratio.

$$\frac{V_{\text{CMR}}}{V_{\text{PFR}}} = \frac{(90\,Q/k)}{(9\,Q/k)} = 10$$

Figure 1–13

Theoretical and generalized nonideal response curves for a plug-flow reactor with axial dispersion.



Plug-Flow Reactor with Axial Dispersion and Reaction

In most full-scale plug-flow reactors, the flow usually is non-ideal because of entrance and exit flow disturbances, axial dispersion, and dispersion caused by advection (see Appendix I for an expanded discussion of dispersion and advection). Depending on the magnitude of these effects, the ideal effluent-tracer curves may look like the curves shown on Fig. 1–13. Using first order removal kinetics, Wehner and Wilhelm (1958) have developed a solution for a plug-flow reactor with dispersion numbers varying from complete-mix ($d = \infty$) to ideal plug-flow ($d = 0$). The equation developed by Wehner and Wilhelm is as follows:

$$\frac{C}{C_o} = \frac{4a\exp(1/2\mathrm{d})}{(1 + a)^2\exp(a/2\mathrm{d}) - (1 - a)^2\exp(-a/2\mathrm{d})} \qquad (1\text{–}85)$$

where C = effluent concentration, ML^{-3}

C_o = influent concentration, ML^{-3}

$a = \sqrt{1 + 4k\tau\mathrm{d}}$

d = dispersion factor = D/vL [see Eq. (I–9), Appendix I]

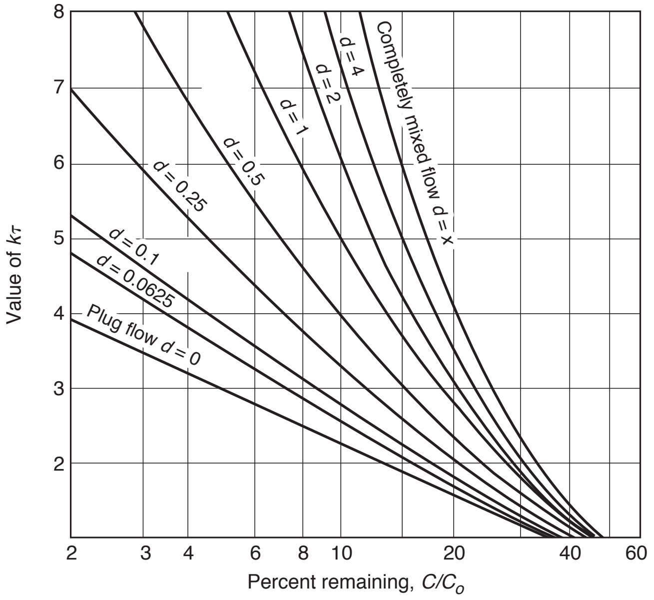
k = first order reaction constant, T^{-1}, (1/h)

τ = hydraulic detention time, V/Q, T, (h)

To facilitate the use of Eq. (1–85) for the design of treatment processes such as stabilization ponds and natural systems, Thirumurthi (1969) developed Fig. 1–14, in which the

Figure 1–14

Values of kt in the Wehner and Wilhelm equation (Eq. 1–85) versus percent remaining for various dispersion factors and first order kinetics for a plug flow reactor. (Adapted from Thirumurthi, 1969.)



term $k\tau$ is plotted against C/C_o for dispersion factors varying from zero for an ideal plug-flow reactor to infinity for a complete-mix reactor. The application of Fig. 1–14 is illustrated in the following example.

EXAMPLE 1–5 **Comparison of the Performance of a Treatment Process Occurring in a Plug-flow Reactor Without and with Axial Dispersion** A treatment process reactor was designed assuming ideal plug-flow with a first order BOD removal rate constant of 0.5/d at 20°C and a detention time of 5 d. Once in operation, a considerable amount of axial dispersion was observed in the reactor. What effect will the observed axial dispersion have on the performance of the treatment process? The dispersion factor for the reactor, *d*, has been estimated to be about 0.5. Determine how much longer the detention time must be for a reactor with a dispersion factor of 0.5 to achieve the same degree of treatment as expected initially with the ideal plug-flow reactor.

Solution

1. Estimate the percentage removal for an ideal plug-flow reactor using Eq. (1–84).
    a. The BOD remaining is:

$$\frac{C}{C_o} = e^{-k\tau}$$

$$\frac{C}{C_o} = e^{-0.5\times 5} = 0.082 = 8.2\%$$

    b. The percentage removal is

Percentage removal $100 - 8.2 = 91.8\%$

2. Determine the percentage removal for the reactor using Fig. 1–14.
    a. The value of $k\tau$ equals

$$k\tau = (0.5/\text{d} \times 5\ \text{d}) = 2.5$$

    b. The percent remaining from Fig 1–14 is equal to

$$C/C_o = 0.20 = 20\%$$

Percentage removal $100 - 20 = 80.0\%$

3. Determine the required detention time to achieve 91.8 percent removal
    a. The value of $k\tau$ from Fig. 1–14 for a C/C_o value of 8.2% is 4.6.
    b. The required detention time is

$$k\tau = 4.6$$

$$\tau = 4.6/0.5 = 9.2\ \text{d}$$

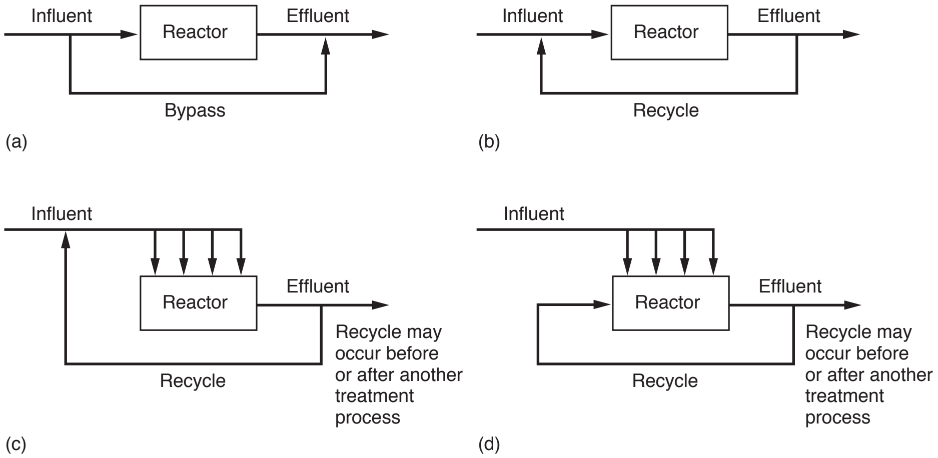
Comment Clearly, axial dispersion can affect the predicted performance of a treatment process designed to function as an ideal plug-flow reactor. Because of axial dispersion and temperature effects, the actual performance of the treatment process will generally be less than expected.

Other Reactor Flow Regimes and Reactor Combinations

In the previous discussions of complete-mix and plug-flow reactors, a single-pass straight-through flow pattern has been used for the purpose of analyses. In practice, other flow regimes and reactor combinations are also used. Some of the more common alternative

Figure 1–15

Flow regimes commonly used in the treatment of wastewater: (a) direct input with bypass flow (plug-flow or complete-mix reactor), (b) direct input with recycle flow (plug-flow or complete-mix reactor), (c) stepped input with recycle (recycle flow mixed with influent, recycle type 1), and (d) stepped input with recycle (recycle flow introduced at influent end of reactor, recycle type 2).

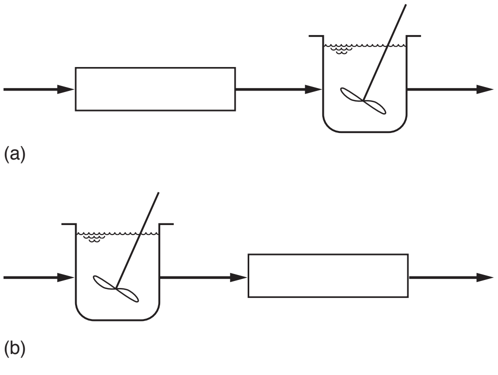


flow regimes are shown schematically on Fig. 1–15. The flow regime shown on Fig. 1–15(a) is used to achieve intermediate levels of treatment by blending various amounts of treated and untreated wastewater. The flow regime used on Fig. 1–15(b) is often adopted to achieve greater process control and will be considered specifically in Chaps. 9 and 10 which deal with biological wastewater treatment. The flow regime shown on Fig. 1–15(c) is used to reduce the loading rate applied to the process. On Fig. 1–15(d), the return flow is not mixed with the influent, but is introduced at the entrance of the reactor to achieve greater initial dilution of the wastewater to be treated. Each of these hydraulic regimes is considered further in the following chapters.

Among the numerous types of reactor combinations that are possible and that have been used, two combinations using a plug-flow reactor and a complete-mix reactor are shown on Fig. 1–16. In the arrangement shown on Fig. 1–16(a), complete-mixing takes place second; in the arrangement shown on Fig. 1–16(b), it occurs first. If no reaction takes place and the reactors are used only to equalize temperature, for example, the result will be identical. If a reaction is occurring, however, the product yields of the two reactor systems can be different. The use of such hybrid reactor systems will depend on the specific product requirements. Additional details on the analysis of such processes may be found in Denbigh and Turner (1965), Kramer and Westererp (1963), and Levenspiel (1972).

Figure 1–16

Hybrid reactor systems: (a) plug-flow reactor followed by complete-mix reactor and (b) complete-mix reactor followed by plug-flow reactor.



PROBLEMS AND DISCUSSION TOPICS

1–1 A water storage tank receives a constant feed rate of 0.2 m^3/s and the demand varies according to the relationship $0.2[1 - \cos \pi t/(43{,}200)\ m^3/s]$. The tank is cylindrical with a cross-sectional area of 1000 m^2. If the depth at $t = 0$ is 5 m, plot the water depth as a function of time.

1–2 Solve Problem 1–1 assuming the feed rate is 0.33 m^3/s and that the storage tank is a square with a cross-sectional area of 1600 m^2.

1–3 A large tank having a floor area of 1000 m^2 and a sidewall depth of 10 m is used as an equalization reservoir. Flow out of the basin is 0.3 m^3/s, while flow into the basin is $0.3[1 + \cos \pi t/(43{,}200)\ m^3/s)]$. Plot the hourly values of water depth versus time, assuming $h = h_o = 5$ m at $t = 0$.

1–4 Solve Problem 1–3 assuming the feed rate is $0.35[1 + \cos \pi t/(43{,}200)\ m^3/s]$, the flow out of the basin is 0.35 m^3/s, and the floor area for the storage tank is 2000 m^2. Plot the hourly values of water depth versus time, assuming $h = h_o = 2$ m at $t = 0$.

1–5 Wastewater is being pumped into a 4.2 m diameter tank at the rate of 0.5 m^3/min. At the same time, water leaves the tank at a rate that is dependent on the height of the liquid in the tank. The relationship governing the flow from the tank is $q = [2.1\ (m^2/min) \times h(m)]$. If the tank was initially empty, develop a relationship that can be used to define the height of the liquid in the tank as a function of time. What is the steady state height of the liquid in the tank?

1–6 Solve Problem 1–5 assuming the feed rate is 0.75 m^3/min and the tank outflow is $q = [2.7\ (m^2/min) \times h(m)]$.

1–7 The following data were obtained for four different reactants for the reaction $A \rightarrow B + C$. Determine the order of the reaction for one reactants (to be selected by instructor) and the value of the reaction rate constant *k*.

Time, *t*, min	Concentration, mg/L			
	Reactant number			
	1	2	3	4
0	90	1.9	240	113
10	72	1.55	150	80
20	57	1.31	110	56
40	36	0.99	70	28
60	23	0.8	51	14

1–8 A bimolecular reaction $A + B \rightarrow P$ is 10 percent complete in 10 min. If the initial concentration of A and B is equal to 1 mole/L, determine the reaction rate constant and how long it will take for the reaction to be 90 percent complete.

1–9 A bimolecular reaction $A + B \rightarrow P$ is 8 percent complete in 12 min. If the initial concentration of A and B is equal to 1.33 mole/L, determine the reaction rate constant and how long it will take for the reaction to be 96 percent complete.

1–10 The reaction rates at 10 and 25°C for a given reaction were found to differ by a factor of 2.75. Estimate the activation energy, *E*, for this reaction.

1–11 If two reaction rates differ by a factor on 2.4 and the activation energy, *E*, is 58,000 J/mole what is the temperature difference if the temperature at which the lowest reaction rate is observed is 15°C?

1–12 What is the difference in the reaction rates when the activation energy, *E*, is equal to 52,000 J/mole, the temperature difference is 15°C, and the temperature at the higher reaction rate is 27°C?

1–13 The following values have been obtained for the rate constant for the reaction A + B → P. Using these data, determine the activation energy E and the value of the rate constant at 15°C.

$k_{25°\text{C}} = 1.5 \times 10^{-2}$ L/mole·min

$k_{45°\text{C}} = 4.5 \times 10^{-2}$ L/mole·min

1–14 Solve Problem 1–13 for the following rate constant values.

$k_{20°\text{C}} = 1.25 \times 10^{-2}$ L/mole·min

$k_{35°\text{C}} = 3.55 \times 10^{-2}$ L/mole·min

1–15 An aqueous reaction is being studied in a laboratory-sized complete-mix reactor with a volume of 5 L. The stoichiometry of the reaction is A → 2R, and reactant A is introduced into the reactor at a concentration of 1 mole/L. From the results given in the following table, find the rate expression for this reaction. Assume steady-state flow.

Run	Feed rate, cm^3/s	Temperature, °C	Concentration of R in effluent, mole/L
1	2	13	1.8
2	15	13	1.5
3	15	84	1.8

1–16 The rate of reaction for an enzyme-catalyzed substrate in a batch reactor can be described by the following relationship.

$$r_c = \frac{kC}{K + C}$$

where k = maximum reaction rate, mg/L min
C = substrate concentration, mg/L
K = constant, mg/L

Using this rate expression, derive an equation that can be used to predict the reduction of substrate concentration with time in a batch reactor. If k equals 40 mg/L·min and K = 100 mg/L, determine the time required to decrease the substrate concentration from 1000 to 100 mg/L.

1–17 Solve Problem 1–16 for the following values: k equals 28 mg/L·min and K = 116 mg/L.

1–18 A wastewater is to be treated in a complete-mix reactor. Assuming that the reaction is irreversible and first-order ($r = -kC$) with a reaction rate coefficient equal to 0.15 d, determine the flowrate that can be treated if the reactor has a volume of 20 m^3 and 98 percent treatment efficiency is required. What volume would be required to treat the flowrate determined above if the required treatment efficiency is 92 percent?

1–19 For first-order removal kinetics, demonstrate that the maximum treatment efficiency in a series of complete-mix reactors occurs when all the reactors are the same size.

1–20 Determine the number of completely mixed chlorine contact chambers each having a detention time of 30 min that would be required in a series arrangement to reduce the bacterial count of a treated effluent from 10^6 to 14.5 organisms/mL if the first-order removal rate constant is equal to 6.1 h^{-1}. If a plug-flow chlorine contact chamber were used with the same detention time as the series of completely mixed chambers, what would the bacterial count be after treatment?

1–21 Derive the integrated expression for a plug-flow reactor assuming the removal of the constituent in question can be described by retarded first order reaction [Eq. (1–53)] for the following conditions $n = 1$ and $n \neq 1$.

1–22 Plot the ratio of required tank volume for a plug-flow reactor to that of a complete-mix reactor (V_{PFR}/V_{CMR}) versus the fraction of the original substrate that is converted for the following reaction rates.

$r = -k$

$r = -kC^{0.5}$

$r = -kC$

$r = -kC^2$

What is the value of the required volume ratio for each of these rates when $C = 0.25$ mg/L and $C_o = 1.0$ mg/L?

1–23 Solve Problem 1–22 for the following values: $C = 0.17$ mg/L and $C_o = 1.25$ mg/L.

1–24 If second-order reaction kinetics are applicable ($r = -kC^2$), determine the effluent concentration for each of the reactor systems shown on Fig. 1–16. To simplify the computations, assume that the following data apply.

$k = 1.0\ \text{m}^3/\text{kg}\cdot\text{d}$

$Q = 1.0\ \text{m}^3/\text{d}$

$V_{\text{PFR}} = 1.0\ \text{m}^3$

$V_{\text{CMR}} = 1.0\ \text{m}^3$

$C_o = 1.0\ \text{kg/m}^3$

Explain your results. What would happen if first- or zero-order kinetics are applicable?

1–25 A portion of the outflow, αQ, from an ideal plug-flow reactor is recycled around the reactor where $\alpha \geq 0$. Assume that the rate of conversion can be defined as $r_c = -kC$.

a. Sketch the generalized curve of conversion versus the recycle ratio.

b. Sketch a family of curves showing the effect of the recycle ratio α on the longitudinal concentration gradient.

c. If a complete-mix reactor were substituted for the plug-flow reactor, what effect would the recycle have on conversion?

1–26 Determine the effect of recycle on the performance of a complete-mix reactor for first and second order reactions.

1–27 Derive an expression that can be used to compute the effluent concentration from a free-surface constructed wetland treatment system, designed as an ideal plug-flow reactor, assuming the removal of the constituent in question can be described by a retarded second order equation. Assume the exponent n in the retardation term is equal to one. If the value of the retardation coefficient r_t is equal to 0.2, compare the effluent concentration with and without retardation. Assume the following values also apply: $C_o = 1$, $k = 0.1$, and $t = 1$.

Wastewater Characteristics

WORKING TERMINOLOGY

Term	Definition
Absorbance	A measure of the amount of light, of a specified wavelength, that is absorbed by the constituents in solution.
Antibodies	Proteins used by the immune system to neutralize specific foreign material such as bacteria and viruses.

Term	Definition
Antigen	Any substance that stimulates the immune system to produce antibodies to protect against it.
Anthropogenic compounds	Chemical compounds created by humans, often resistant to biodegradation.
Bacteria	Microscopic organisms typically ranging from approximately 0.5 to 5 μm in length. Municipal wastewater can contain a wide variety and concentration of bacteria, including those pathogenic to humans.
Coliform group of bacteria	Coliforms include several genera of bacteria belonging to the family *Enterobacteriaceae*. Coliform organisms are common in the environment and in the feces of humans and warm blooded animals. Members of the coliform group include *Escherichia, Enterobacter, Klebsiella, and Citrobacter* among others.
Disinfection byproducts (DBPs)	A variety of organic compounds that are formed in treated wastewater when a strong oxidant for the purpose of disinfection such as chlorine or ozone is combined with residual organic matter.
Emerging contaminants	Constituents, which have been identified in water, that are considered for regulatory action pending the development of additional information on health and environmental impacts.
Endocrine disrupting compounds (EDCs)	Synthetic and natural compounds that mimic, block, stimulate, or inhibit natural hormones in the endocrine systems of animals, including humans. The origins of EDCs include pesticides, pharmaceutically active chemicals (PhACs), personal care products (PCPs), herbicides, industrial chemicals, and disinfection byproducts.
Enteric virus	An intracellular parasite that is an obligate human pathogen, which means it can only replicate in the human host.
Escherichia coli (E coli)	A species of the total coliform group that is specific to the intestinal tract of humans and warm blooded animals, commonly associated with fecal contamination. Although most *E. coli* are non-pathogenic, some strains (serotypes) such as *E. coli* O157:H7 can cause serious disease.
Fecal coliforms	A thermo-tolerant sub-group of total coliform group found in the intestinal tract of humans and warm blooded animals.
Helminths	A group of parasitic worms; worldwide, helminths are one of the principal causative agents of human disease. Helminths and helminth ova (eggs) are found increasingly in untreated municipal wastewater in the United States.
Higher heating value (HHV)	The amount of heat produced by complete combustion of a unit quantity of fuel.
Lower heating value (LHV)	The lower heating value is obtained by deducting the latent heat of vaporization of water vapor formed by combustion from the HHV.
Nanoparticles	Small objects or particles, ranging in size from 1 to 100 nm, which behave as an entire unit with respect to their properties and transport.
Pathogens	Microorganisms capable of causing diseases of varying severity.
Personal care products	Products such as shampoo, hair conditioner, deodorants, and body lotion.
Pharmaceutically active compounds (PhACs)	Chemicals synthesized for medical purposes (e.g., antibiotics).
Priority pollutants	Constituents, both inorganic and organic, that have been identified by the Environmental Protection Agency as known or suspected carcinogens, mutagens, teratogens, or highly toxic are to be regulated by categorical discharge standards.
Protozoa	Protozoa are single-celled organisms that lack a cell wall. They are common in fresh and marine water and some can grow in soil and other locations.
Trace constituent	A diverse classification of constituents found in low concentrations in untreated wastewater and not readily removed by conventional secondary treatment.
Trace organics	Organic compounds detected at at nanogram or microgram per liter concentrations in untreated and treated wastewater by the means of sophisticated laboratory instrumentation.
Viruses	Viruses are infectious agents able to multiply only within a host cell.

An understanding of the nature of wastewater is essential in the design and operation of collection, treatment, and reuse facilities, and in the engineering management of environmental quality. To promote this understanding, the information in this chapter is presented in ten sections dealing with (1) an introduction to the characterization of wastewater, (2) sampling and analytical procedures, (3) physical properties, (4) inorganic nonmetallic constituents, (5) metallic constituents, (6) aggregate organic constituents, (7) individual organic constituents and compounds, (8) microbial characteristics, (9) radionuclides, and (10) toxicity tests. The material in this chapter has been organized in a manner similar to that used in Standard Methods (2012), the standard reference work for the characterization of wastewater in the field of environmental engineering.

2–1 WASTEWATER CHARACTERIZATION

The principal constituents in wastewater, derived from domestic, municipal, and industrial sources, are: human excreta (i.e., feces and urine), shower/bath water, food waste, personal and household maintenance products, along with a wide variety of other inorganic and organic compounds in trace amounts. Given the wide variety of constituents that may be found in wastewater, it is common practice to characterize wastewater in terms of its physical properties and its chemical and biologic constituents. The physical properties and constituents found in wastewater and the constituents of concern in wastewater treatment are introduced briefly in the following discussion.

Wastewater Properties and Constituents

The principal physical properties and the chemical and biological constituents of wastewater and their sources are reported in Table 2–1. It should be noted that many of the physical properties and chemical and biological characteristics listed in Table 2–1 are interrelated. For example, temperature, a physical property, affects both the amounts of gases dissolved in the wastewater as well as the biological activity in the wastewater. Another distinction that can be made about the constituents reported in Table 2–1 is whether they are aggregate or individual constituents.

Constituents of Concern in Wastewater Treatment

The important constituents of concern in wastewater treatment are listed in Table 2–2. Secondary treatment standards, as reported in Table 1–2 in Chap. 1, are concerned with the removal of biodegradable organics, total suspended solids, and pathogens. Many of the more stringent standards that have been developed recently deal with the removal of nutrients, heavy metals, and priority pollutants. When wastewater is to be reused, standards normally include additional requirements for the removal of refractory organics, heavy metals, and in some cases, dissolved inorganic solids.

2–2 SAMPLING AND ANALYTICAL PROCEDURES

Proper sampling and analytical techniques are of fundamental importance in the characterization of wastewater. Sampling techniques, the methods of analysis, the units of measurement for chemical constituents, and some useful concepts from chemistry are considered in the next sections.

Table 2–1

Common analyses used to assess the constituents found in wastewater[a]

Test[a]	Abbreviation/ definition	Use or significance of test results
Physical characteristics		
Total solids	TS	To assess the reuse potential of a wastewater and to determine the most suitable type of operations and processes for its treatment
Total volatile solids	TVS	
Total fixed solids	TFS	
Total suspended solids	TSS	
Volatile suspended solids	VSS	
Fixed suspended solids	FSS	
Total dissolved solids	TDS (TS − TSS)	
Volatile dissolved solids	VDS	
Total fixed dissolved solids	FDS	
Settleable solids	SS	To determine those solids that will settle by gravity in a specified time period
Particle size	PS	To asses the performance of treatment processes, especially disinfection
Particle size distribution	PSD	To asses the performance of treatment processes
Turbidity	NTU[b]	Used to asses the quality of treated wastewater
Color	Light brown, grey, black	To assess the condition of wastewater (fresh or septic)
Transmittance	%T	To assess the suitability of treated effluent for UV disinfection
Odor	TON	To determine if odors will be a problem
Temperature	°C or °F	Important in the design and operation of biological processes in treatment facilities
Thermal energy content	J/g·°C	Important parameter in the recovery of heat from wastewater
Density	ρ	
Conductivity	EC	Used to assess the suitability of treated effluent for agricultural applications
Inorganic chemical characteristics		
Ammonia	NH_3	Used as a measure of the nutrients present and the degree of decomposition in the wastewater; the oxidized forms can be taken as a measure of the degree of oxidation.
Ammonium	NH_4^+	
Nitrite	NO_2^-	
Nitrate	NO_3^-	
Organic nitrogen	Org N	
Phosphorus, inorganic	Inorg P	Includes orthophosphates and polyphosphates
Orthophosphate	PO_4^{3-}	Simplest of the phosphoric acids salts
Organic phosphorus	Org P	
pH	$pH = -\log [H^+]$	A measure of the acidity or basicity of an aqueous solution

(*continued*)

Table 2–1 (*Continued*)

Test[a]	**Abbreviation/ definition**	**Use or significance of test results**
Inorganic chemical characteristics (continued)		
Alkalinity	$\Sigma(HCO_3^- + CO_3^{2-} + OH^- - H^+)$	A measure of the buffering capacity of the wastewater
Chloride	Cl^-	To assess the suitability of wastewater for agricultural reuse
Sulfate	SO_4^{2-}	To assess the potential for the formation of odors and may impact the treatability of the waste sludge
Metals	As, Cd, Ca, Cr, Co, Cu, Pb, Mg, Hg, Mo, Ni, Se, Na, Zn	To assess the suitability of the wastewater for reuse and for toxicity effects in treatment. Trace amounts of metals are important in biological treatment
Specific inorganic elements and compounds		To assess presence or absence of a specific constituent
Various gases	O_2, CO_2, NH_3, H_2S, CH_4	The presence or absence of specific gases
Organic chemical characteristics		
Five-day biochemical oxygen demand	BOD_5	A measure of the amount of oxygen required to stabilize a waste biologically over a 5-d period
Five-day carbonaceous biochemical oxygen demand	$CBOD_5$	A measure of the amount of oxygen required to stabilize a waste biologically, over a 5-d period, in which nitrogen oxidation is suppressed
Ultimate carbonaceous biochemical oxygen demand	UBOD (also BOD_u, BOD_L)	A measure of the amount of oxygen required to stabilize a waste biologically
Nitrogenous oxygen demand	NOD	A measure of the amount of oxygen required to oxidize biologically the nitrogen in the wastewater to nitrate
Chemical oxygen demand	COD	Often used as a substitute for the BOD test
Total organic carbon	TOC	Often used as a substitute for the BOD test
Specific organic compounds and classes of compounds	MBAS[c], CTAS[d]	To determine presence of specific organic compounds and to assess whether special design measures will be needed for removal
Chemical energy content	MJ/kg COD	To assess the chemical energy in wastewater
Biological characteristics		
Coliform organisms	MPN (most probable number)	To asses potential presence of pathogenic bacteria and effectiveness of disinfection process
Specific microorganisms	Bacteria, protozoa helminths, viruses	To asses presence of specific organisms in connection with plant operation and for reuse
Toxicity	TU_a[e] and TU_c[f]	To assess acute and chronic toxicity of various wastewater samples

[a] Details on the various tests may be found in Standard Methods (2012).

[b] NTU = Nephelometric turbidity unit.

[c] MBAS = Methylene blue active substances.

[d] CTAS = Cobalt thiocyanate active substances.

[e] TU_a = toxic unit acute.

[f] TU_c = toxic unit chronic.

Table 2–2

Principal constituents of concern in wastewater treatment

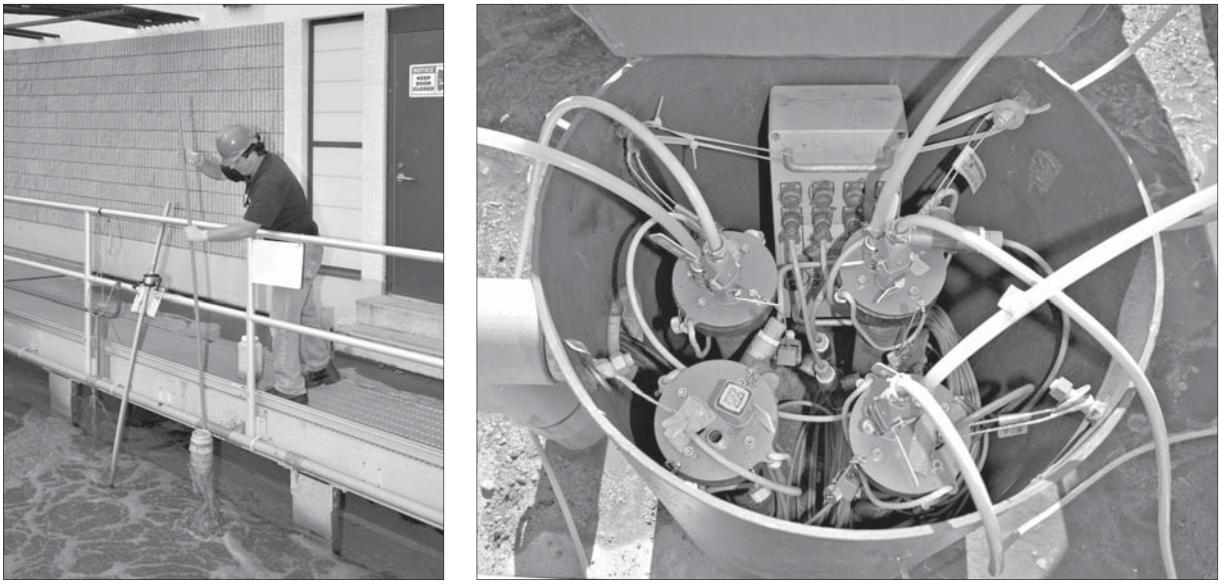
Constituent	Reason for importance
Suspended solids	Suspended solids can lead to the development of sludge deposits and anaerobic conditions when untreated wastewater is discharged in the aquatic environment.
Biodegradable organics	Composed principally of proteins, carbohydrates, and fats, biodegradable organics are measured most commonly in terms of BOD (biochemical oxygen demand) and COD (chemical oxygen demand). If discharged untreated to the environment, their biological stabilization can lead to the depletion of natural oxygen resources and to the development of septic conditions.
Pathogens	Communicable diseases can be transmitted by the pathogenic organisms that may be present in wastewater.
Nutrients	Both nitrogen and phosphorus, along with carbon, are essential nutrients for growth. When discharged to the aquatic environment, these nutrients can lead to the growth of undesirable aquatic life. When discharged in excessive amounts on land, they can also lead to the pollution of groundwater.
Priority pollutants	Organic and inorganic compounds selected on the basis of their known or suspected carcinogenicity, mutagenicity, teratogenicity, or high acute toxicity. Many of these compounds are found in wastewater.
Refractory organics	These organics tend to resist conventional methods of wastewater treatment. Typical examples include surfactants, phenols, and agricultural pesticides.
Heavy metals	Heavy metals are usually added to wastewater from commercial and industrial activities and may have to be removed if the wastewater is to be reused.
Dissolved inorganics	Inorganic constituents such as calcium, sodium, and sulfate are added to the original domestic water supply as a result of water use and may have to be removed if the wastewater is to be reused.

Sampling

Sampling programs are undertaken for a variety of reasons, such as to obtain (1) routine operating data on overall plant performance, (2) data that can be used to document the performance of a given treatment process, (3) data that can be used to implement proposed new programs, and (4) data needed for reporting regulatory compliance. To meet the goals of the sampling program, the data collected must be

1. *Representative:* The data must represent the wastewater or environment being sampled.
2. *Reproducible:* The data obtained must be reproducible by others following the same sampling and analytical protocols.
3. *Defensible:* Documentation must be available to validate the sampling procedures. The data must have a known degree of accuracy and precision.
4. *Useful:* The data can be used to meet the objectives of the monitoring plan (Pepper et al., 1996).

Because the data from the analysis of the samples will ultimately serve as a basis for implementing wastewater management facilities and programs, the techniques used in a



(a) (b)

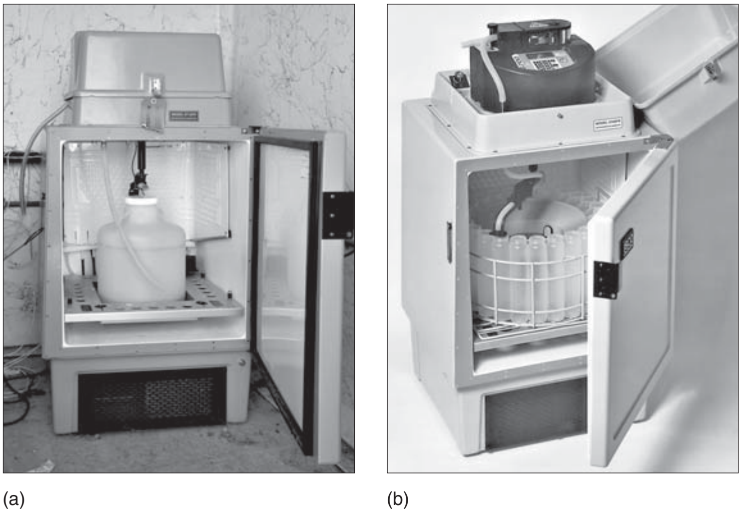
Figure 2–1

Collection of samples for analysis: (a) collection of a mixed liquor sample from end of plug flow activated sludge reactor and (b) view of an uncapped monitoring well equipped with sampling outlets for four different well depths. Samples are collected from each depth to monitor a groundwater injection system.

wastewater sampling program must be such that representative samples are obtained. There are no universal procedures for sampling; sampling programs must be tailored individually to fit each situation (see Fig. 2–1). Special procedures are necessary to handle sampling problems that arise when wastes vary considerably in composition.

Before a sampling program is undertaken, a detailed sampling protocol must be developed along with a quality assurance project plan (QAPP) (known previously as quality assurance/quality control, QA/QC). As a minimum, the following items must be specified in the QAPP (Pepper et al., 1996). Additional details on the subject of sampling may be found in Standard Methods (2012).

1. *Sampling plan:* Number of sampling locations, number and type of samples, time intervals (e.g., real time and/or time-delayed samples).
2. *Sample types and size:* Catch or grab samples, composite samples, or integrated samples, separate samples for different analyses (e.g., for metals). Sample size (i.e., volume) required.
3. *Sample labeling and chain of custody:* Sample labels, sample seals, field log book, chain of custody record, sample analysis request sheets, sample delivery to the laboratory, receipt and logging of sample, and assignment of sample for analysis.
4. *Sampling methods:* Specific techniques and equipment to be used (e.g., manual, automatic, or sorbent sampling).
5. *Sampling storage and preservation:* Type of containers (e.g., glass or plastic), preservation methods, maximum allowable holding times.
6. *Sample constituents:* A list of the parameters to be measured.
7. *Analytical methods:* A list of the field and laboratory test methods and procedures to be used and the detection limits for the individual methods.



(a) (b)

Figure 2–2

Typical refrigerated automatic composite samplers used to collect process and effluent samples over a 24-h period: (a) sampler with single sample bottle in place used to obtain a 24-h composite sample and (b) sampler used to collect individual hourly samples throughout the day. The individual samples can be composited in proportion to flow to obtain flow-weighted mass loading rates. (Courtesy of Teledyne Laboratory & Field Instruments.)

If the physical, chemical, or biological integrity of the samples is not maintained during interim periods between sample collection and sample analysis, a carefully performed sampling program will become worthless. Considerable research on the problem of sample preservation has failed to perfect a universal treatment or method or to formulate a set of fixed rules applicable to samples of all types. Prompt analysis is undoubtedly the most positive assurance against error due to sample deterioration. When analytical and testing conditions dictate a lag between collection and analysis, such as when a 24-h composite sample is collected, provisions must be made for preserving samples (see Fig. 2–2). Current methods of sample preservation for the analysis of properties subject to deterioration must be used (Standard Methods, 2012). Probable errors due to deterioration of the sample should be noted in reporting analytical data.

Methods of Analysis

The analyses used to characterize wastewater vary from precise quantitative chemical determinations to the more qualitative biological and physical determinations. The quantitative methods of analysis are gravimetric, volumetric, or physicochemical. In the physicochemical methods, properties other than mass or volume are measured. Instrumental methods of analysis such as turbidimetry, colorimetry, potentiometry, polarography, adsorption spectrometry, fluorometry, spectroscopy, and nuclear radiation are representative of the physicochemical analyses. Details concerning the various analyses may be found in Standard Methods (2012), the accepted reference that details the conduct of water and wastewater analyses.

Regardless of the method of analysis used, the detection level must be specified. Several detection limits are defined and are listed here in order of increasing levels (Standard Methods, 2012).

1. *Instrumental detection level (IDL).* Constituent concentration that produces a signal greater than five times the signal/noise ratio of the instrument.
2. *Lower level of detection (LLD).* Constituent concentration in reagent water that produces a signal ($2 \times 1.645s$) above the mean of blank analyses where s is the standard deviation.
3. *Method detection level (MDL).* Constituent concentration that, when processed through the complete method, produces a signal with a 99 percent probability that it is different from the blank.

4. *Level of quantification (LOQ).* Constituent concentration that produces a signal sufficiently greater than the blank that can be detected within specified levels by good laboratories during routine operating conditions. Typically it is the concentration that produces a signal 10*s* above the reagent blank signal.
5. *Minimum reporting level (MRL).* Minimum constituent concentration that can be reported as a quantitative value.

Units of Expression for Physical and Chemical Parameters

The results of the analysis of wastewater samples are expressed in terms of physical and chemical units of measurement. The most common units for these measurements are reported in Table 2–3. Measurements of chemical parameters are usually expressed in the physical unit of milligrams per liter (mg/L) or grams per cubic meter (g/m^3). The concentration of trace constituents is usually expressed as micrograms per liter (μg/L) or nanograms per liter (ng/L). As noted in Table 2–3, the concentration can also be expressed as parts per million (ppm), which is a mass-to-mass ratio. The relationship between mg/L and ppm is

$$\text{ppm} = \frac{\text{mg/L}}{\text{specific gravity of fluid}} \tag{2–1}$$

For dilute systems, such as those encountered in natural waters and wastewater in which one liter of sample weighs approximately one kilogram, the units of mg/L or g/m^3 are interchangeable with ppm. The terms *parts per billion* (ppb) and *parts per trillion* (ppt) are used interchangeably with μg/L and ng/L, respectively. Dissolved gases, considered to be chemical constituents, are expressed in parts per million by volume (ppm$_v$), μg/m^3, or mg/L. Conversion of gas concentrations between ppm$_v$ and μg/m^3 is given by Eq. (2–45), the universal law. Gases that evolve as by-products of wastewater treatment, such as carbon dioxide and methane (from anaerobic decomposition), are measured in terms of L or m^3 (ft^3). Parameters such as temperature, odor, hydrogen ion, and biological organisms are expressed in other units.

Useful Chemical Relationships

Other useful relationships from chemistry used in the analysis and evaluation of wastewater test results and in the design of treatment facilities include mole fraction, electroneutrality, chemical equilibrium, activity coefficient, ionic strength, and solubility product.

Mole Fraction. The ratio of the number of moles of a given solute to the total number of moles of all components in solution is defined as the *mole fraction.* Along with its importance in solution chemistry, the mole fraction is of importance in the mass transfer of gases into and out of liquids. In equation form,

$$x_B = \frac{n_B}{n_A + n_B + n_C \ldots n_N} \tag{2–2}$$

where x_B = mole fraction of solute B
n_B = number of moles of solute B
n_A = number of moles of solute A
n_C = number of moles of solute C
n_N = number of moles of solute N

Table 2–3

Units commonly used to express analytical results

Basis	Application	Unit
Physical analyses:		
Density	$\frac{\text{Mass of solution}}{\text{Unit of volume}}$	$\frac{\text{kg}}{\text{m}^3}$
Percent by volume	$\frac{\text{Volume of solute} \times 100}{\text{Total volume of solution}}$	% (by vol)
Percent by mass	$\frac{\text{Mass of solute} \times 100}{\text{Combined mass of solute} + \text{solvent}}$	% (by mass)
Volume ratio	$\frac{\text{Milliliters}}{\text{Liter}}$	$\frac{\text{mL}}{\text{L}}$
Mass per unit volume[a]	$\frac{\text{Picograms}}{\text{Liter of solution}}$	$\frac{\text{pg}}{\text{L}}$
	$\frac{\text{Nanograms}}{\text{Liter of solution}}$	$\frac{\text{ng}}{\text{L}}$
	$\frac{\text{Micrograms}}{\text{Liter of solution}}$	$\frac{\mu\text{g}}{\text{L}}$
	$\frac{\text{Milligrams}}{\text{Liter of solution}}$	$\frac{\text{mg}^a}{\text{L}}$
	$\frac{\text{Grams}}{\text{Cubic meter of solution}}$	$\frac{\text{g}}{\text{m}^3}$
Mass ratio	$\frac{\text{Milligrams}}{10^9 \text{ milligrams}}$	ppb[b]
	$\frac{\text{Milligrams}}{10^6 \text{ milligrams}}$	ppm
Chemical analyses:		
Molality	$\frac{\text{Moles of solute}}{\text{1000 grams solvent}}$	$\frac{\text{mole}}{\text{kg}}$
Molarity	$\frac{\text{Moles of solute}}{\text{Liter of solution}}$	$\frac{\text{mole}}{\text{L}}$
Normality	$\frac{\text{Equivalents of solute}}{\text{Liter of solution}}$	$\frac{\text{eq}}{\text{L}}$
	$\frac{\text{Milliequivalents of solute}}{\text{Liter of solution}}$	$\frac{\text{meq}}{\text{L}}$

[a] mg/L = g/m^3.

[b] ppb = parts per billion, ppm = parts per million, 10^3 ppb = ppm.

Note: 10^{12} pg = 10^9 ng = 10^6 μg = 10^3 mg = 1 gm.

The application of Eq. (2–2) is illustrated subsequently in Example 2–1.

EXAMPLE 2–1 **Determination of Mole Fraction** Determine the mole fraction of oxygen in water if the concentration of dissolved oxygen is 10.0 mg/L.

Solution

1. Determine the mole fraction of oxygen using Eq. (2–2) written as follows:

$$x_{O_2} = \frac{n_{O_2}}{n_{O_2} + n_w}$$

a. Determine the moles of oxygen.

$$n_{O_2} = \frac{(10 \text{ mg/L})}{(32 \times 10^3 \text{ mg/mole } O_2)} = 3.125 \times 10^{-4} \text{ mole/L}$$

b. Determine the moles of water.

$$n_w = \frac{(1000 \text{ g/L})}{(18 \text{ g/mole of water})} = 55.556 \text{ mole/L}$$

c. The mole fraction of oxygen is:

$$x_{O_2} = \frac{3.125 \times 10^{-4}}{3.125 \times 10^{-4} + 55.556} = 5.62 \times 10^{-6}$$

Electroneutrality. The principle of *electroneutrality* requires that the sum of the positive ions (cations) must equal the sum of negative ions (anions) in solution, thus

$$\Sigma \text{ cations} = \Sigma \text{ anions} \tag{2–3}$$

where cations = positively charged species in solution expressed in terms of equivalent weight per liter, eq/L or milliequvalent weight per liter, meq/L
anions = negatively charged species in solution, eq/L or meq/L

The equivalent weight of a compound is defined as:

$$\text{Equivalent weight, g/eq} = \frac{\text{molecular weight, g}}{Z} \tag{2–4}$$

where Z = (1) the absolute value of the ion charge, (2) the number of H^+ or OH^- ions a species can react with or yield in an acid-base reaction, or (3) the absolute value of the change in valence occurring in an oxidation reduction reaction (Sawyer et al., 2003).

Equation (2–3) can be used to check the accuracy of chemical analyses by taking into account the percent difference defined as follows (Standard Methods, 2012):

$$\text{Percent difference} = 100 \times \left(\frac{\Sigma \text{ cations} - \Sigma \text{ anions}}{\Sigma \text{ cations} + \Sigma \text{ anions}} \right) \tag{2–5}$$

The acceptance criteria are as given below.

Σ anions, meq/L	Acceptable difference
0–3.0	±0.2 meq/L
3.0–10.0	±2%
10–800	5%

From Standard Methods (2012).

The application of Eqs. (2–3) and (2–5) is illustrated in Example 2–2.

EXAMPLE 2–2 **Checking the Accuracy of Analytical Measurements** The following analysis has been completed on a filtered effluent, from an extended aeration wastewater treatment plant, that is to be used for landscape watering. Check the accuracy of the analysis to determine if the analysis is sufficiently accurate, based on the criteria given above.

Cation	Conc., mg/L	Anion	Conc., mg/L
Ca^{2+}	82.2	HCO_3^-	220.0
Mg^{2+}	17.9	SO_4^{2-}	98.3
Na^+	46.4	Cl^-	78.0
K^+	15.5	NO_3^-	25.6

Solution

1. Prepare a cation-anion balance.

Cation	Conc., mg/L	mg/meq[a]	meq/L	Anion	Conc., mg/L	mg/meq[a]	meq/L
Ca^{2+}	82.2	20.04[b]	4.10	HCO_3^-	220.0	61.02	3.61
Mg^{2+}	17.9	12.15	1.47	SO_4^{2-}	98.3	48.03	2.05
Na^+	46.4	23.00	2.02	Cl^-	78.0	35.45	2.20
K^+	15.5	39.10	0.40	NO_3^-	25.6	62.01	0.41
	Σ cations		7.99		Σ anions		8.27

[a] Molecular weight in grams/Z

[b] For calcium, eq wt = 40.08/2 = 20.04 g/eq or 20.04 mg/meq

2. Check the accuracy of the cation-anion balance using Eq. (2–5).

$$\text{Percent difference} = 100 \times \left(\frac{\Sigma \text{ cations} - \Sigma \text{ anions}}{\Sigma \text{ cations} + \Sigma \text{ anions}}\right)$$

$$\text{Percent difference} = 100 \times \left(\frac{7.99 - 8.27}{7.99 + 8.27}\right) = -1.72\%$$

For a total anion concentration between 3 and 10 meq/L, the acceptable difference must be equal to or less than 2 percent (see table given above), thus, the analysis is of sufficient accuracy.

Comment If the cation-anion balance is not of sufficient accuracy, the problem may be analytical or a constituent of significant concentration may be missing.

Chemical Equilibrium. A reversible chemical reaction in which reactants *A* and *B* combine to yield products *C* and *D* may be written as

$$aA + bB \rightleftarrows cC + dD \tag{2–6}$$

Where the *stoichiometry* coefficients *a*, *b*, *c*, and *d* correspond to the number of moles of constituents *A, B, C*, and *D*, respectively. The *stoichiometry* of a reaction refers to the definition of the quantities of chemical compounds involved in a reaction (e.g., *a* of *A, b* of *B*, etc.). When the chemical species come to a state of equilibrium, as governed by the law of mass action, the numerical value of the ratio of the products over the reactants is known as the *equilibrium constant K* and is written as

$$\frac{[C]^c[D]^d}{[A]^a[B]^b} = K \tag{2–7}$$

For a given reaction, the value of the equilibrium constant will change with temperature and the ionic strength of the solution. It should also be noted that in Eq. (2–7) it is assumed that that activity of the individual ions is equal to one.

Brackets are used in Eq. (2–7) to denote molar concentrations. The use of molal concentrations (see Table 2–3) is more correct theoretically, but for dilute solutions encountered in wastewater applications, molar concentrations are used. Molal concentrations must be used for brine solutions and sea water. To account for non-ideal conditions encountered due to ion-ion interactions, a new concentration term called *activity* is used. The activity of an ion is defined as follows:

$$a_i = \gamma[C_i] \tag{2–8}$$

where a_i = activity of *i*th ion, mole/L
γ = activity coefficient for the *i*th ion
C_i = concentration of *i*th ion in solution, mole/L

If Eq. (2–7) is written in terms of activity and activity coefficients rather than concentrations, the resulting expression is:

$$\frac{[a_C]^c[a_D]^d}{[a_A]^a[a_B]^b} = \frac{[\gamma_c C]^C[\gamma_D D]^d}{[\gamma_A A]^a[\gamma_B B]^b} = K \tag{2–9}$$

Ionic Strength. The *ionic strength* of a solution is a measure of the concentration of dissolved chemical constituents. The ionic strength of a solution can be estimated using the following expression:

$$I = \frac{1}{2}\Sigma\, C_i Z_i^2 \tag{2–10}$$

where I = ionic strength
C_i = concentration of the *i*th species, mole/L
Z_i = the valance (or oxidation) number of the *i*th species [see Eq. (2–4)]

The ionic strength can also be estimated based on the total dissolved solids concentration using the following expression:

$$I = 2.5 \times 10^{-5} \times \text{TDS} \tag{2–11}$$

where TDS = total dissolved solids, mg/L or g/m^3

Equation (2–11) is often used to estimate the ionic strength of treated wastewater in groundwater recharge applications.

Activity Coefficient. The activity coefficient can be estimated using the following expression, derived from the Debye-Huckel theory, as proposed by Davies (1962). Computation of the activity coefficient is illustrated in Example 2–3 following the discussion of ionic strength and solubility.

$$\log \gamma = -0.5\,(Z_i)^2\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I\right) \tag{2–12}$$

where Z_i = charge on ith ionic species
I = ionic strength

The above relationship, without the $-0.3I$, term is often used for solutions with an ionic strength that does not exceed 0.1 M. A number of other similar relationships will be found in the literature. Computation of the activity coefficient is illustrated in Example 2–3 following the discussion of ionic strength and solubility.

Solubility Product. The equilibrium constant for a reaction involving a precipitate and its constituent ions is known as the *solubility product.* For example, the reaction for calcium carbonate ($CaCO_3$) is

$$CaCO_3 \rightleftarrows Ca^{2+} + CO_3^{2-} \tag{2–13}$$

Because the activity of the solid phase is usually taken as 1, the solubility product is written as

$$[Ca^{2+}][CO_3^{2-}] = K_{sp} \tag{2–14}$$

where K_{sp} = solubility product constant.

It is important to note that the value of the equilibrium constant will change with the temperature of the solution. Written in terms of activity coefficients, Eq. (2–14) becomes

$$\gamma_{Ca^{2+}}[Ca^{2+}]\gamma_{CO_3^{2-}}[CO_3^{2-}] = K_{sp} \tag{2–15}$$

The application of Eq. (2–15) is illustrated in Example 2–3.

EXAMPLE 2–3 Determine the Activity Coefficients and Solubility of Calcium Carbonate

Determine the activity coefficients for the mono and divalent ions in the wastewater given in Example 2–2. Using the value of the activity coefficient for a divalent ion, estimate the equilibrium concentration of calcium in solution needed to satisfy the solubility product for calcium carbonate ($CaCO_3$) at 25°C. The value of the solubility product constant K_{sp} for $CaCO_3$ at 25°C is 5×10^{-9}.

Solution

1. Determine the ionic strength of the wastewater using Eq. (2–10).
   a. Prepare a computation table to determine the summation term in Eq. (2–10) using the data from Example 2–2.

Ion	Conc., C, mg/L	$C \times 10^3$, mole/L	z^2	$cz^2 \times 10^3$
Ca^{2+}	82.2	2.051	4	8.404
Mg^{2+}	17.9	0.736	4	2.944
Na^+	46.4	2.017	1	2.017
K^+	15.5	0.396	1	0.397
HCO_3^-	220	3.607	1	3.607
SO_4^{2-}	98.3	1.024	4	4.096
Cl^-	78.0	2.200	1	2.200
NO_3^-	25.6	0.413	1	0.413
Sum				23.876

b. Determine the ionic strength of the wastewater.

$$I = \frac{1}{2}\Sigma C_i Z_i^2 = \frac{1}{2}(23.876 \times 10^{-3}) = 11.938 \times 10^{-3}$$

2. Determine the activity coefficients for Ca^{2+} and CO_3^{2-}. Because both species have a valance (charge) of 2, the activity of each will be the same.

   a. For monovalent ions

$$\log \gamma = -0.5(Z_i)^2\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I\right)$$

$$\log \gamma = -0.5(1)^2\left[\frac{\sqrt{11.938 \times 10^{-3}}}{1+\sqrt{11.938 \times 10^{-3}}} - 0.3(11.938 \times 10^{-3})\right] = -0.0475$$

$$\gamma = 0.896$$

   b. For divalent ions

$$\log \gamma = -0.5(2)^2\left[\frac{\sqrt{11.938 \times 10^{-3}}}{1+\sqrt{11.938 \times 10^{-3}}} - 0.3(11.938 \times 10^{-3})\right] = -0.1898$$

$$\gamma = 0.646$$

3. Determine the minimum solubility of calcium using Eq. (2–15).

   a. Because the molar concentrations of calcium and carbonate ions are the same, Eq (2–15) can be written as follows:

$$\gamma^2 [C^2] = K_{sp}$$

   b. Solve for the concentration C.

$$C = \sqrt{\frac{K_{sp}}{\gamma^2}} = \sqrt{\frac{5 \times 10^{-9}}{(0.646)^2}} = 1.09 \times 10^{-4} \text{ mole/L}$$

   c. Convert the molar concentration of calcium carbonate to mg/L.

$$\text{Ca} = 1.09 \times 10^{-4} \text{ mole/L} \times 40{,}000 \text{ mg/mole} = 4.36 \text{ mg/L}$$

Comment The computed value represents the minimum concentration of calcium that would be required in solution to be in equilibrium with solid calcium carbonate.

2–3 PHYSICAL PROPERTIES

Important physical characteristics, as reported in Table 2–1, include total solids, particle size, particle size distribution, turbidity, color, transmittance, temperature, and conductivity. Total solids includes floating matter, settleable matter, colloidal matter, and matter in solution. Density, specific gravity, and specific weight, of general importance in water, are also important for wastewater.

Sources of Physical Properties

The sources of the physical properties used to characterize wastewater are of both natural and anthropogenic origin. Natural physical properties will depend on the source of the water and what treatment it has received prior to distribution as potable water. For example, the initial temperature of the water will vary depending on whether the source is surface water or groundwater as well as the part of the country. The specific gravity and weight are inherent properties of natural water. The other physical properties of wastewater are derived from the constituents added during usage, commercial and industrial discharges, and constituents found in inflow and infiltrating groundwater.

Solids

Wastewater contains a variety of solid materials varying from rags to colloidal material. In the characterization of wastewater, coarse materials are usually removed before the sample is analyzed for solids. The various solids classifications are identified in Table 2–4. The interrelationship between the various solids fractions found in wastewater is illustrated graphically on Fig. 2–3. The standard test for settleable solids consists of placing a wastewater sample

Table 2–4

Definitions for solids found in wastewater[a]

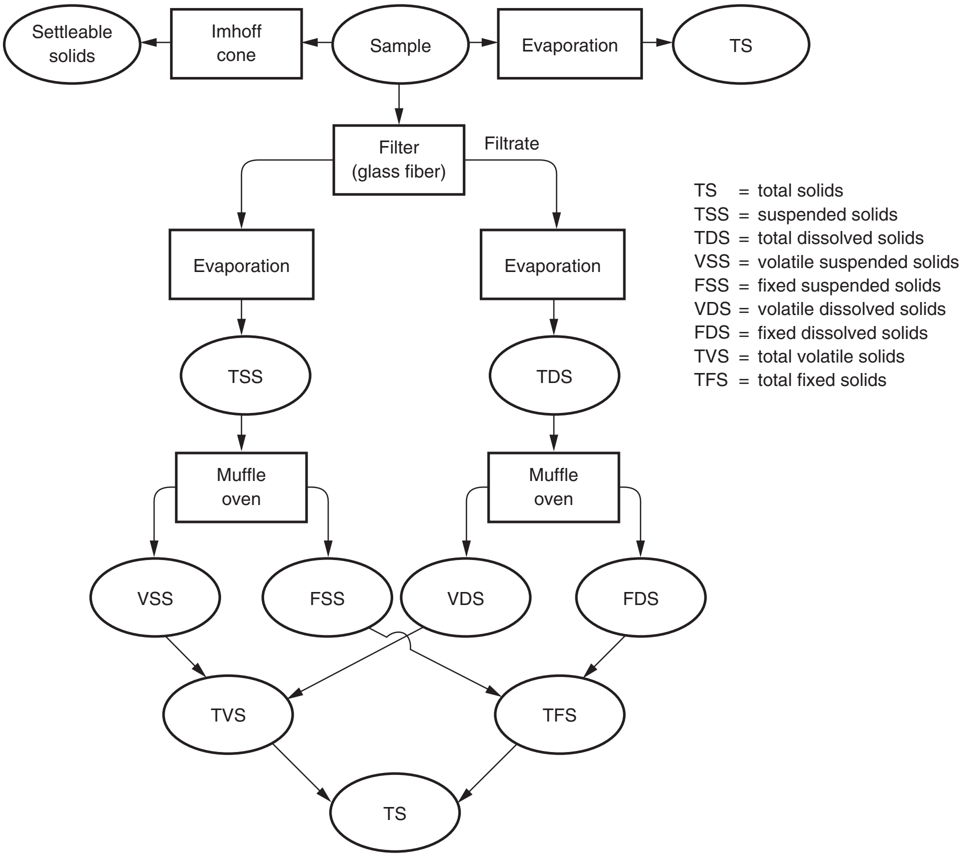
Test[b]	Description
Total solids (TS)	The residue remaining after a wastewater sample has been evaporated and dried at a specified temperature (103 to 105°C)
Total volatile solids (TVS)	Those solids that can be volatilized and burned off when the TS are ignited (500 ± 50°C)
Total fixed solids (TFS)	The residue that remains after TS are ignited (500 ± 50°C)
Total suspended solids (TSS)	Portion of the TS retained on a filter (see Fig. 2–3) with a specified pore size, measured after being dried at a specified temperature (105°C). The filter used most commonly for the determination of TSS is the Whatman glass fiber filter, which has a nominal pore size of about 1.58 μm
Volatile suspended solids (VSS)	Those solids that can be volatilized and burned off when the TSS are ignited (500 ± 50°C)
Fixed suspended solids (FSS)	The residue that remains after TSS are ignited (500 ± 50°C)
Total dissolved solids (TDS) (TS − TSS)	Those soilds that pass through the filter, and are then evaporated and dried at specified temperature. It should be noted that what is measured as TDS is comprised of colloidal and dissolved solids. Colloids are typically in the size range from 0.001 to 1 μm.
Total volatile dissolved solids (VDS)	Those solids that can be volatilized and burned off when the TDS are ignited (500 ± 50°C)
Fixed dissolved solids (FDS)	The residue that remains after TDS are ignited (500 ± 50°C)
Settleable solids	Suspended solids, expressed as milliliters per liter, that will settle out of suspension within a specified period of time (see Fig. 2–4)

[a] Adapted from Standard Methods (2012).

[b] With the exception of settleable solids, all solids values are expressed in mg/L.

Figure 2–3

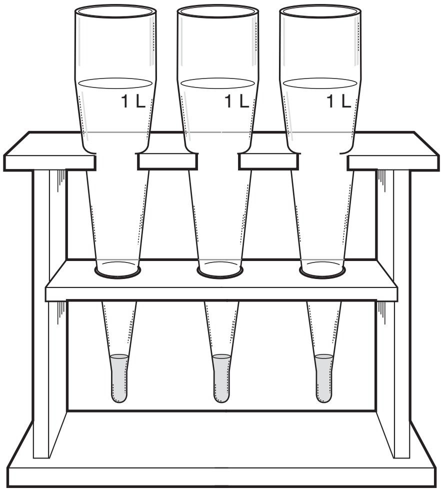
Interrelationships of solids found in water and wastewater. In much of the water quality literature, the solids passing through the filter are called dissolved solids (Tchobanoglous and Schroeder, 1985).



in a 1-liter Imhoff cone (see Fig. 2–4) and noting the volume of solids in millimeters that settle after a specified time period (1 h). Typically, about 60 percent of the suspended solids in a municipal wastewater are settleable. Total solids (TS) are obtained by evaporating a sample of wastewater to dryness and measuring the mass of the residual residue. As shown on Fig. 2–3, a filtration step is used to separate the total suspended solids (TSS) from the total dissolved solids (TDS). The apparatus used to determine TSS is shown on Fig. 2–5.

Figure 2–4

Imhoff cone used to determine settleable solids in wastewater. Solids that accumulate in the bottom of the cone after a 60-min settling time are reported as mL/L.



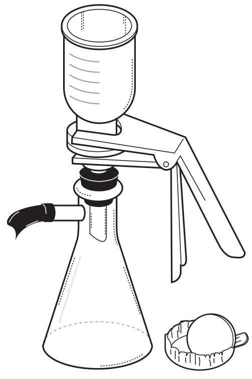


Figure 2–5

Vacuum filtration apparatus used for the determination of total suspended solids. After wastewater sample has been filtered, the preweighed filter paper is placed in an aluminum dish for drying before weighing.

Total Suspended Solids. Because a filter is used to separate the TSS from the TDS, the TSS test is somewhat arbitrary, depending on the pore size of the filter paper used for the test. Filters with nominal pore sizes varying from 0.45 μm to about 2.0 μm have been used for the TSS test (see Fig. 2–6). More TSS will be measured as the pore size of the filter used is reduced. Thus, it is important to note the pore size of the filter paper used when comparing reported TSS values.

It is also important to note that the TSS test itself has no fundamental significance. The principal reasons that the test lacks a fundamental basis are

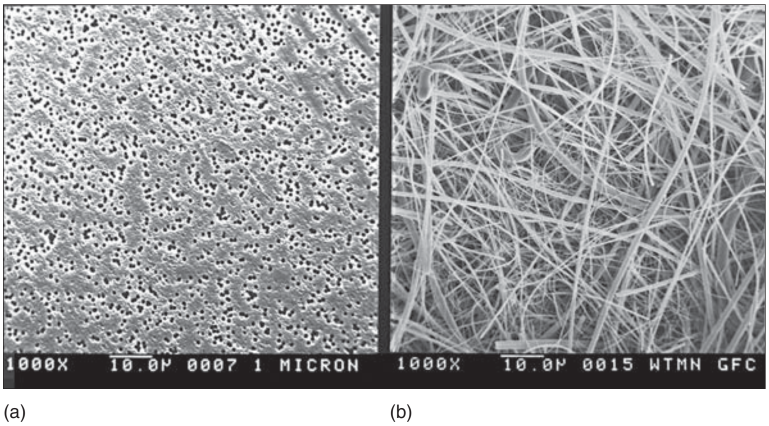
1. The measured values of TSS are dependent on the type and pore size of the filter used in the analysis.
2. Depending on the sample size used for the determination of TSS, auto filtration, where the suspended solids that have been intercepted by the filter also serve as a filter, can occur. Auto filtration will capture smaller particles than otherwise possible and cause an apparent increase in the measured TSS value over the actual value.
3. Depending on the characteristics of the particulate matter, small particles may be removed by adsorption to material already retained by the filter.
4. Because the number and size distribution of the particles that comprise the measured value is unknown, TSS is a *lumped parameter*.

Nevertheless, TSS test results are used routinely to assess the performance of conventional treatment processes and the need for effluent filtration in reuse applications. The TSS test is one of the two universally used effluent standards (along with BOD) by which the performance of treatment plants is judged for regulatory control purposes.

Total Dissolved Solids. By definition, the solids contained in the filtrate that pass through a filter with a nominal pore size of 1.2 μm or less are classified as dissolved (Standard Methods, 2012). Yet it is known that wastewater contains a high fraction of colloidal solids. The size of colloidal particles in wastewater is typically in the range of 0.01 to 1.0 μm. It should be noted that some researchers have classified the size range for colloidal particles as varying from 0.001 to 1.0 μm, others from 0.003 to 1.0 μm. The size range for colloidal particles considered in this text is from 0.01 to 1.0 μm. The number of colloidal particles in untreated wastewater and after primary sedimentation is typically in the range of 10^8 to 10^{12}/mL. Because the distinction between colloidal particles and truly dissolved material has not been made routinely, it has led to confusion in the analysis of treatment plant performance and in the design of treatment processes.

Figure 2–6

Micrographs of two laboratory filters used for the measurement of suspended solids in wastewater: (a) polycarbonate membrane filter with a nominal pore size of 1.0 μm and (b) glass fiber filter with a nominal pore size of 1.2 μm.



Volatile and Fixed Solids. Material that can be volatilized and burned off when ignited at 500 ± 50°C is classified as volatile. In general, volatile solids (VS) are presumed to be organic matter, although some organic matter will not burn, and some inorganic solids break down at high temperatures. Fixed solids (FS) comprise the residue that remains after a sample has been ignited. Thus, TS, TSS, and TDS comprise both fixed solids and volatile solids. The ratio of the VS to FS is often used to characterize the wastewater with respect to amount of organic matter present.

Particle Size and Particle Size Measurement

As noted above, TSS is a lumped parameter. In an effort to understand more about the nature of the particles that comprise the TSS in wastewater, measurement of particle size is undertaken and an analysis of the distribution of particle sizes is conducted (Tchobanoglous, 1995). Information on particle size is of importance in assessing the effectiveness of treatment processes (e.g., secondary sedimentation, effluent filtration, and effluent disinfection). Because the effectiveness of both chlorine, ozone, and UV disinfection is dependent on particle size, the determination of particle size has become more important, especially with greater effluent reuse in the western United States.

Information on the size of the biodegradable organic particles is significant from a treatment standpoint, as the biological conversion rate of these particles is dependent on size (see discussion in Sec. 2–6, which deals with biochemical oxygen demand). Methods that have been used to determine particle size are summarized in Table 2–5. As reported in Table 2–5, the methods can be divided into two general categories: (1) methods based on observation and measurement and (2) methods based on separation and analysis techniques. The methods used most commonly to study and quantify the particles in wastewater

Table 2–5

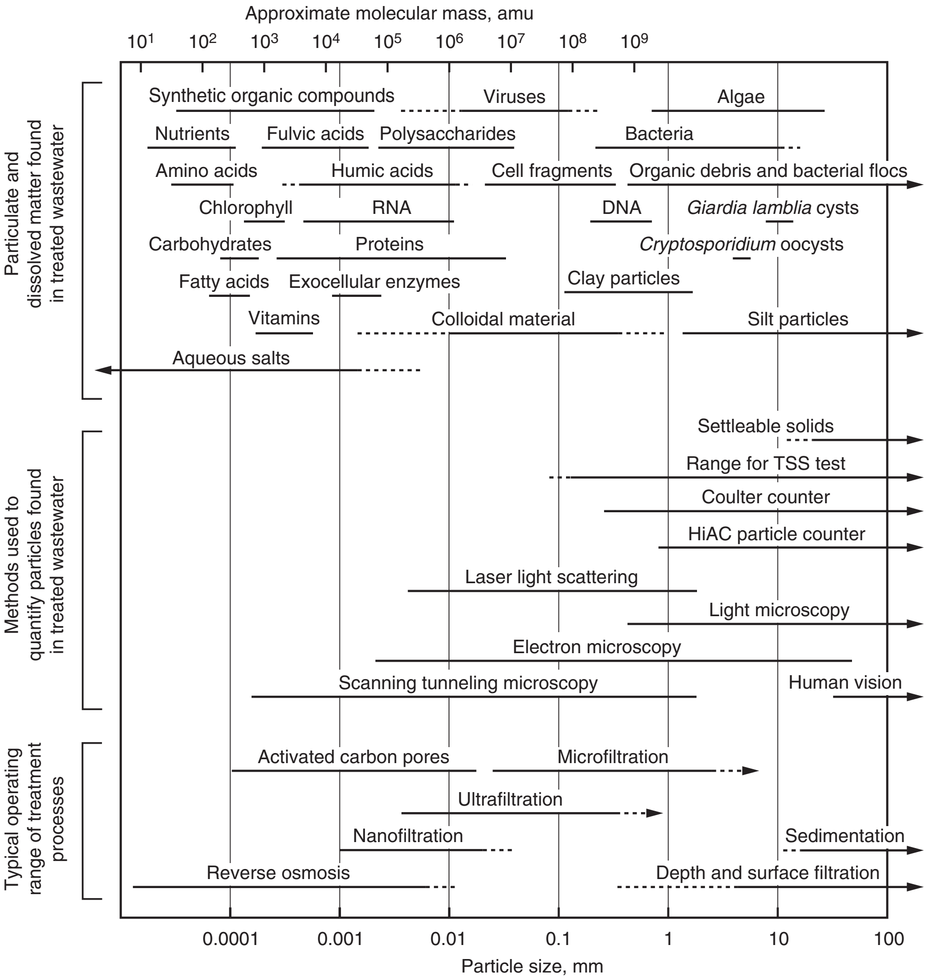
Representative analytical techniques applicable to particle size analysis of wastewater contaminants[a]

Technique	Typical size range, μm
Observation and measurement	
Microscopy	
Light	0.2–>100
Transmission electron (TEM)	0.2–>100
Scanning electron (SEM)	0.002–50
Image analysis	0.2–>100
Particle counters	
Conductivity difference	0.2–>100
Equivalent light scattering	0.005–>100
Light blockage	0.2–>100
Separation and analysis	
Centrifugation	0.08–>100
Field flow fractionation	0.09–>100
Gel filtration chromatography	<0.0001–>100
Sedimentation	0.05–>100
Membrane filtration (see Chap. 11)	0.0001–1

[a] Adapted from Levine et al. (1985).

Figure 2–7

Size ranges of organic constituents in wastewater and size separation and measurement techniques used for their quantification.



are (1) serial filtration, (2) electronic particle counting, and (3) direct microscopic observation. The principal types of materials that comprise the filterable and non-filterable solids in treated wastewater and their approximate size range are reported on Fig. 2–7.

Serial Filtration. Serial filtration may be used to determine an approximate particle size distribution of suspended solids based on mass (Levine et al., 1985). In the serial filtration method, a wastewater sample is passed sequentially through a series of membrane filters (see Fig. 2–8) with circular openings of known diameter (typically 12, 8, 5, 3, 1, and 0.1 μm), and the amount of particulate material retained in each filter is measured. Typical results from such a measurement are shown on Fig. 2–9. What is interesting to note on Fig. 2–9 is that a significant amount of colloidal material will be found between 0.1 and 1.0 μm. Although some information is gained on the size and distribution of the particles in the wastewater sample, little information is gained on the nature of the individual particles.

Electronic Particle Size Analyzers. To understand more about the nature and distribution of particles in wastewater, nondestructive measurement of particle size and particle size distribution is now quite common. However, it should be noted that electronic particle sizing and counting techniques cannot be used reliably for determining the source or type of particle (e.g., distinguishing between a viable cyst, a nonviable cyst, or a similar size silt particle).

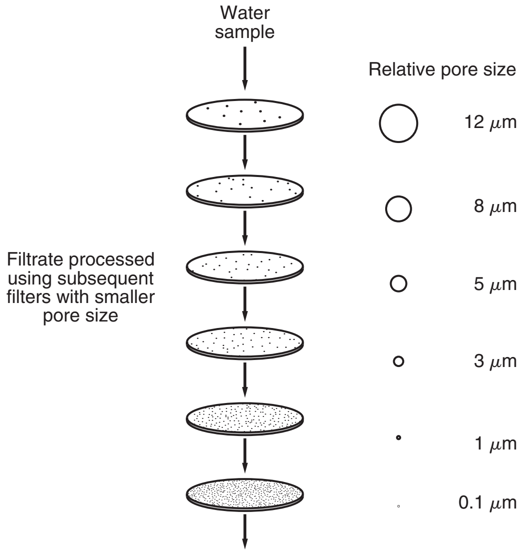


Figure 2–8

Definition sketch for the determination of the particle size distribution (by mass) using serial filtration with membrane filters.

In electronic particle size counting, particles are counted by diluting a treated wastewater sample and then passing the diluted sample through a calibrated orifice or past a laser beam [see Figs. 2–10(a) and (b), respectively]. As the particles pass through the orifice, the conductivity of the fluid changes, due to the presence of the particle. The change in conductivity is correlated to the size of an equivalent sphere. In a similar fashion, as a particle passes by a laser beam, it reduces the intensity of the laser due to light scattering. The reduced intensity is correlated to the diameter of the particle.

The typical size ranges quantifiable with different types of particle size counters were reported previously in Table 2–5. Most particle counters used in wastewater treatment facilities to assess performance have sensors available in different size ranges, such as 1.0 to 60 μm or 1 to 350 μm, depending on the manufacturer and application.

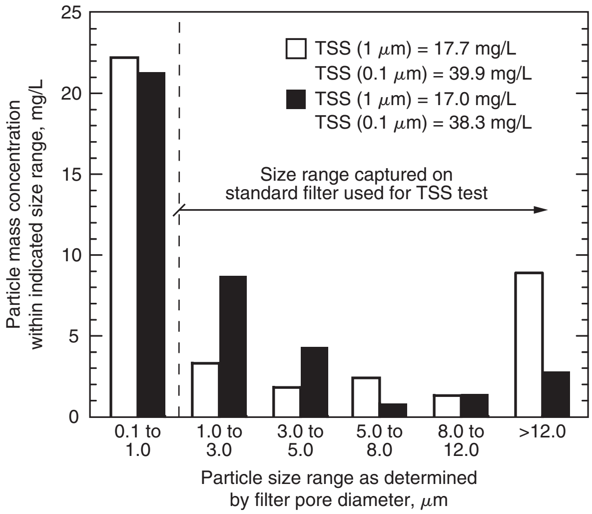

Figure 2–9

Typical data on the distribution of filterable solids obtained in two different tests by serial filtration in trickling filter effluent. Note: the large fraction of unmeasured solids between 0.1 and 1.0 μm using conventional TSS test.

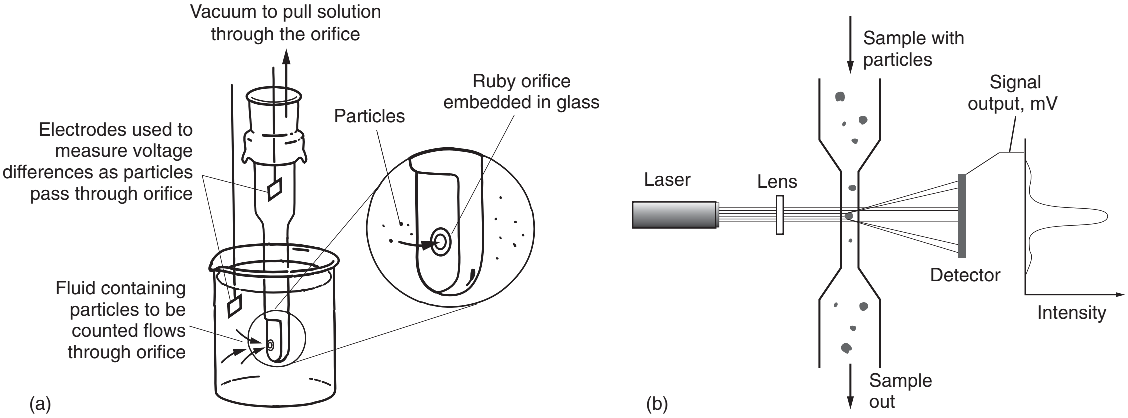

Figure 2–10

Determination of particle size distribution: (a) coulter counter, voltage difference as particle passes through the orifice is used to determine the size of an equivalent spherical particle and (b) laser particle size counter, size of equivalent spherical particle is based on reduced intensity and light scattering as particle passes through light beam.

Particle counters that do not measure particles smaller than 1 μm may be a limitation in some cases. Particle counts are typically measured and recorded in about 10 to 20 size ranges (e.g., 2 to 5 μm) called channels (or bins) of the chosen sensor range. One commonly used particle counter utilizes 128 channels. Channel sizes can be arithmetic, logarithmic, or arbitrary, depending on the measurement objective. Using a logarithmic scale, the upper channel limit is equal to the lower channel limit times a scaling factor. A typical particle size analysis with a laser type counter with 128 channels is shown on Fig. 2–11(a).

For disinfection studies, channel sizes are often selected that correspond to the size ranges of interest, for example, *Cryptosporidium* (2 to 5 μm) and *Giardia* (5 to 15 μm). With particle size counters that use large numbers of small channel sizes, the interpretation of the resulting data is more difficult. Where extremely small channel sizes are used, it is recommended that the data be aggregated into appropriate bin sizes [see Fig. 2–11(b)]. In addition to reporting particle number by size, the data can be reported in terms of surface area and volume; the volume fraction corresponding to each particle size range can also be computed, if needed (Standard Methods, 2012).

Direct Observation. For visualization of particles that are smaller than those visible to the unaided eye, microscopic techniques may be used. The use of microscopic observation allows for the determination of particle size counts and in some cases for more rigorous identification of a particle's origin than is possible with other analysis techniques. In microscopic observation, a measured volume of sample is placed in a particle counting cell, and the individual particles may be counted, often with the use of a stain to enhance the particle contrast. The size range quantifiable using a variety of microscopic techniques is reported in Table 2–5. In general, microscopic counting of particles is impractical on a routine basis, given the number of particles per mL of wastewater. Nevertheless, this method can be used to qualitatively assess the nature and size of the particles in wastewater.

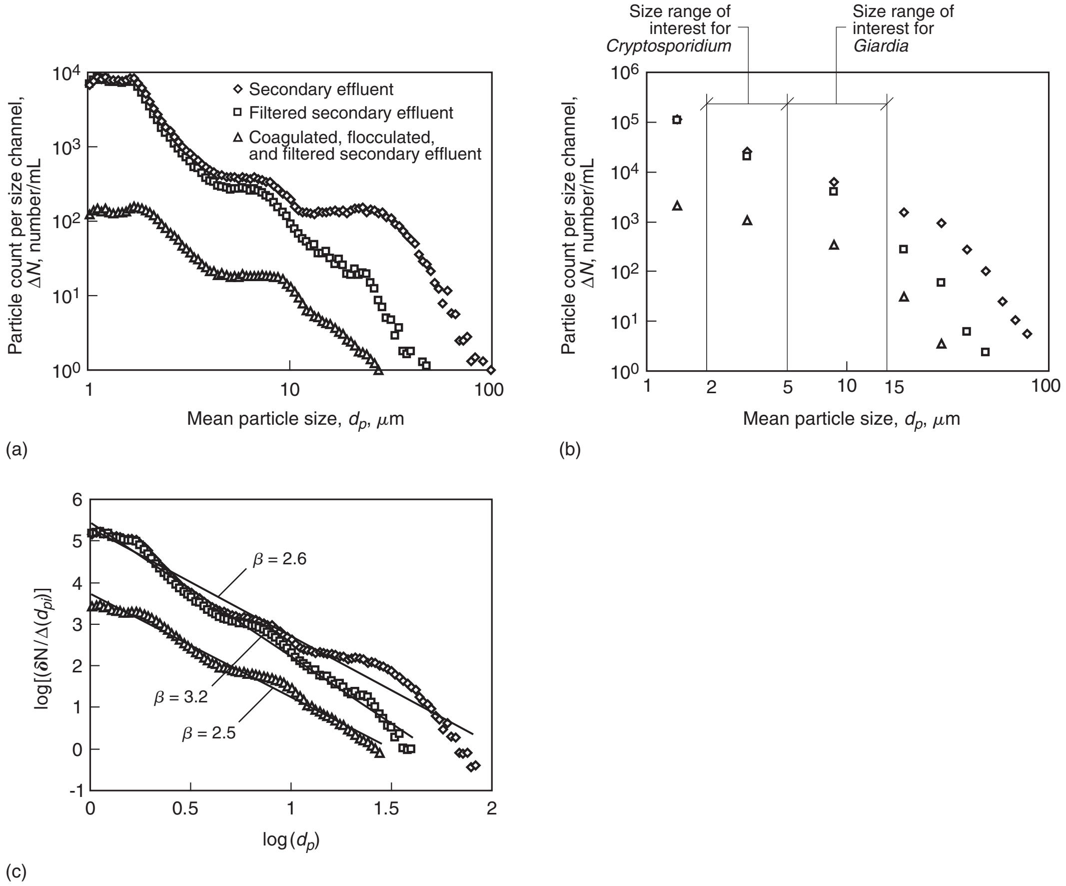

Figure 2–11

Effect the use of chemicals on filter particle size removal performance (a) original data as collected (courtesy of K. Bourgeous, 2005), (b) original data aggregated into selected channel (bin) sizes, and, (c) the original data, plotted functionally according to the power law (see Example 2–4).

Particle Size Distribution

In wastewater, it has been observed that the number of particles increases with decreasing particle diameter and that the frequency distribution typically follows a power law distribution of the form:

$$\frac{dN}{d(d_p)} = A(d_p)^{-\beta} \simeq \frac{\Delta N}{\Delta(d_{pi})} \tag{2–16}$$

where dN = the particle number concentration with respect to the incremental change in particle diameter $d(d_p)$, number/mL·μm
$d(d_p)$ = incremental change in particle diameter, μm
A = power law density coefficient, unitless
d_p = arithmetic (or geometric) mean particle diameter, depending on counter channel configuration, μm

β = power law slope coefficient
ΔN = the particle number concentration in given channel, number/mL
$\Delta(d_{pi})$ = incremental channel size, μm

In effect the right-hand term in Eq. (2–16) is used to normalize the data and allows for comparison between particle size distributions. Taking the log of both sides of Eq. (2–16) results in the following expression, which can be plotted to determine the unknown coefficients A and β:

$$\log\left[\frac{\Delta N}{\Delta(d_{pi})}\right] = \log A - \beta \log(d_p) \tag{2–17}$$

The value of A is determined when $d_p = 1\ \mu$m. As the value of A increases, the total number of particles in each size classification increases. The slope β is a measure of the relative number of particles in each size range. Thus, if β is less than one the particle size distribution is dominated by large particles, if β is equal to one all particle sizes are represented equally, and if β is greater than one the particle size distribution is dominated by small particles (Trussell and Tate, 1979). Because different slope values will be obtained, depending on the selection of the bin sizes, care must be exercised in interpreting the results. The analysis of data obtained from a particle size counter is shown on Fig. 2–11(c); the necessary computational steps are illustrated in Example 2–4.

EXAMPLE 2–4 **Analysis of Particle Size Information** Determine the coefficients A and β in Eq. (2–16) for the following particle size data obtained using a particle counter with arithmetic channel settings.

Channel size, mm	Number
1–2	20,000
2–5	6688
5–10	3000
10–15	1050
15–20	300
20–30	150
30–40	27
40–60	12
60–80	6
80–100	4
100–140	2

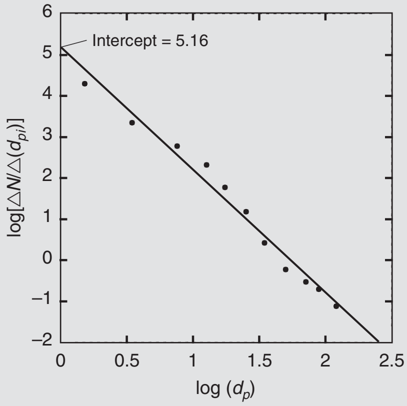
Solution

1. Set up a table to determine the information needed to plot the data

Channel size, mm	Mean diameter[a] d_p, μm	ΔN, number/mL	Channel size interval, $\Delta(d_{pi})$	$\log(d_p)$	$\log[\Delta N/\Delta(d_{pi})]$
1–2	1.50	20,000	1	0.18	4.30
2–5	3.50	6688	3	0.54	3.35
5–10	7.5	3000	5	0.88	2.78
10–15	12.5	1050	5	1.10	2.32
15–20	17.5	300	5	1.24	1.78
20–30	25.0	150	10	1.40	1.18
30–40	35.0	27	10	1.54	0.43
40–60	50.0	12	20	1.70	−0.22
60–80	70.0	6	20	1.85	−0.52
80–100	90.0	4	20	1.95	−0.70
100–140	120.0	2	40	2.08	−1.12

[a] Arithmetic mean diameter, 1.5 = [(1 + 2)/2].

2. Prepare a plot of the log of the geometric mean particle diameter, d_p, versus the normalized number of particles for the corresponding bin size, $\log[\Delta N/\Delta(d_{pi})]$.



3. Determine A and β in Eq. (2–16)
   a. Determine A

      When $\log(d_p) = 0$, $d_p = 1$, and $A = 10^{5.16}$

   b. Determine β

$$-\beta = \frac{3.65 - (-1.15)}{0.5 - 2} = -3.2$$

$$\beta = 3.2$$

Comment As the value of β is greater than one, the distribution is dominated by small particles, which is consistent with the actual data. It is important to note that the slope of the line of best fit through the plotted data will vary depending on the bin sizes selected for analysis. Also, it should be noted that the line used to define β may not be linear depending on the characteristics of the suspension and the minimum and maximum particle sizes measured, a characteristic of the specific instrument used in the analysis. The channel sizes of 2–5 and 5–15 μm were selected to determine if the number of *Cryptosporidium* or *Giardia* determined analytically can be correlated with particle size measurements.

Nanoparticles and Nanocomposites

Nanoparticles, originating from natural and anthropogenic processes, are small objects or particles, ranging in size from 1 to 100 nm, which behave as an entire unit with respect to their properties and transport. Because nanoparticles can form a variety of structures, such as nanospheres, nanotubes, or nanosheets, at least two of the three dimensions must be between 1 and 100 nm. Nanoparticles have also been referred to as ultrafine particles. Nanoparticles form a bridge between bulk materials and molecular or atomic structures. Nanocomposites, formed from two or more dissimilar materials, are developed to produce new structures with differing but controllable properties. For nanocomposites, at lease one of the materials (phases) must have a dimension in the nanoscale.

Common materials used for the production of nanoparticles, arranged alphabetically, include aluminum oxide, cerium oxide, cobalt, gold, iron, iron oxide, nickel, platinum, silica (SiO_2), silver, titanium dioxide (TiO_2), and zinc oxide. In addition to the constituents just mentioned, nanocomposites can include citrate, polyvinyl acetates (PVA), polyvinylpyrrolidone (PVP), tannic acid, and an ever expanding list of compounds. Nanoparticles are formed through natural processes and human industrial (anthropogenic) means. Natural processes include the oxidation of volatile compounds of biogenic origin. Industrially, nanoparticles are formed in the liquid and gas phase through a series of controlled chemical reactions.

Interest in nanoparticles and nanocomposites stems from the fact that they are now used extensively in the manufacture of a wide variety of consumer products such as self-cleaning glasses, clothing, scratch-resistant coatings, swimming pool cleaners, personal care products, and food production. Because of their widespread use, nanoparticles released from different household products and industrial activities are now being found in ever increasing concentrations in untreated and treated wastewater and biosolids.

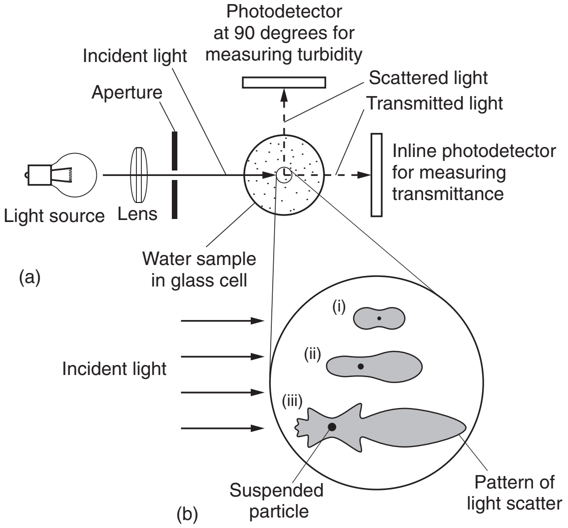
At this time, little is known about the long-term effects of nanoparticles on public health and their impacts when discharged to the environment. Also, there is some concern that nanoparticles may accumulate and that such accumulations may have health implications. In a recently completed study, it was found that the accumulation of silver nanoparticles may have a detrimental effect on nitrification and nutrient removal (Hu, 2010). Because the field of nanotechnology is evolving so rapidly, the current literature should be consulted for the latest developments including production, patterns of utilization, and the potential presence of nanoparticles in wastewater and their implications for treatment, public health, and environment. A comprehensive review of nanotechnology has been prepared by SCENIHR (2006).

Turbidity

Turbidity is a measure of the light scattering properties of a solution containing suspended and colloidal particles. Turbidity measurements require a light source (incandescent or

Figure 2–12

Determination of turbidity by light scattering: (a) schematic of turbidity apparatus and (b) typical light scattering patterns for small (i), intermediate (ii), and large (iii) particles.



light-emitting diode) and a sensor to measure the scattered light. As shown on Fig. 2–12(a), the scattered light sensor is located at 90 degrees to the light source. The measured turbidity increases as the intensity of the scattered light increases. Turbidity is expressed in nephelometric turbidity units (NTU). The spatial distribution and intensity of the scattered light, illustrated on Fig. 2–12(b), will depend on the size of the particle relative to the wavelength of the light source (Hach, 1997). For particles less than one-tenth of the wavelength of the incident light, the scattering of light is fairly symmetrical [see Fig. 2–12(b)(i)].

Limitations of Turbidity Measurements. As the particle size increases relative to the wave length of the incident light, the light reflected from different parts of the particle create interference patterns that are additive in the forward direction [see Figs. 2–12(b)(ii) and (iii)]. Also, the intensity of the scattered light varies with the wavelength of the incident light. For example, the turbidity of a solution of lamp black will essentially be equal to zero. Based on these considerations, turbidity measurements tend to be more sensitive to particles in the size range of the incident light wavelength (0.3 to 0.7 μm for visible light).

Thus, two filtered wastewater samples with nearly identical turbidity values could have very different particle size distributions. A further complication with turbidity measurements is that some particles will essentially adsorb most of the light and only scatter a minimal amount of the incident light. Also, because of the light scattering characteristics of large particles, a few large particles would not be detected in the presence of many smaller particles. Also, some online turbidity meters used to monitor the performance of microfiltration units are affected by the air used to clean the membranes.

Thus, there is no fundamental relationship between turbidity and the concentration of total suspended solids, and turbidity alone is not a good measure of whether wastewater can be disinfected effectively. As a result, it is almost impossible to compare turbidity values reported in the literature. However, turbidity readings at a given facility can be used for process control.

Relationship Between Turbidity and TSS

In general, there is no relationship between turbidity and the concentration of total suspended solids in untreated wastewater. There is, however, a reasonable relationship between turbidity and total suspended solids for the settled and filtered secondary effluent from the activated sludge process. The general form of the relationship is as follows:

$$\text{TSS, mg/L} \approx (\text{TSS}_f)(T) \tag{2–18}$$

where TSS = total suspended solids, mg/L
TSS_f = factor used to convert turbidity readings to total suspended solids, (mg TSS/L)/NTU
T = turbidity, NTU

The specific value of the conversion factor will vary for each treatment plant, depending primarily on the operation of the biological treatment process. The conversion factors for settled secondary effluent and for secondary effluent filtered with a granular-medium depth filter will typically vary from 2.3 to 2.4 and 1.3 to 1.6, respectively.

Color

Historically, the term *condition* was used along with composition and concentration to describe wastewater. Condition refers to the age of the wastewater which is determined qualitatively by its color and odor. Fresh wastewater is usually a light brownish-gray color. However, as the travel time in the collection system increases, and more anaerobic conditions develop, the color of the wastewater changes sequentially from gray to dark gray, and ultimately to black. When the color of the wastewater is black, the wastewater is often described as septic. Some industrial wastewaters may also add color to domestic wastewater. In most cases, the gray, dark gray, and black color of the wastewater is due to the formation of metallic sulfides, which form as the sulfide produced under anaerobic conditions reacts with the metals in the wastewater.

Absorption/Transmittance

The absorbance of a solution is a measure of the amount of light, of a specified wavelength, that is absorbed by the constituents in a solution. Absorbance is measured using a spectrophotometer with a fixed path length (usually 1.0 cm) at a wavelength of 254 nm. Absorbance follows the Beers-Lambert Law as given by Eq. (2–19):

$$\log\left(\frac{I}{I_o}\right) = \varepsilon(\lambda)Cx \tag{2–19}$$

Where I = light intensity at distance x from the light source, mW/cm^2
I_o = light intensity at light source, mW/cm^2
$\varepsilon(\lambda)$ = molar absorptivity (also known as the extinction coefficient) of the light-absorbing solute at wavelength λ, L/mole·cm
C = concentration of light-absorbing solute, mole/L
x = light path-length, cm

When the left-hand side of Eq. (2–19) is expressed as a natural logarithm, the right-hand side of the equation must be multiplied by 2.303 because the absorbance coefficient is determined in base 10. The term on the right-hand side of Eq. (2–19) is defined as the absorbance, $A(\lambda)$, which is unitless but is often reported in units of cm^{-1}, which corresponds to absorptivity $k(\lambda)$. If the length of the light path is 1 cm, absorptivity is equal to the absorbance.

$$k(\lambda) = e(\lambda)C = \frac{A(\lambda)}{x} \tag{2–20}$$

where $k(\lambda)$ = the absorptivity, cm^{-1}
$A(\lambda)$ = absorbance, dimensionless

Absorbance is measured using a spectrophotometer typically using a fixed sample path length of 1.0 cm.

The transmittance of a solution is defined as

$$\text{Transmittance, } T, \% = \left(\frac{I}{I_o}\right) \times 100 \tag{2–21}$$

The transmittance at a given wavelength can also be derived from absorbance measurements using the following relationship:

$$T = 10^{-A(\lambda)} \tag{2–22}$$

The term *percent transmittance,* commonly used in the literature is

$$T, \% = 10^{-A(\lambda)} \times 100 \tag{2–23}$$

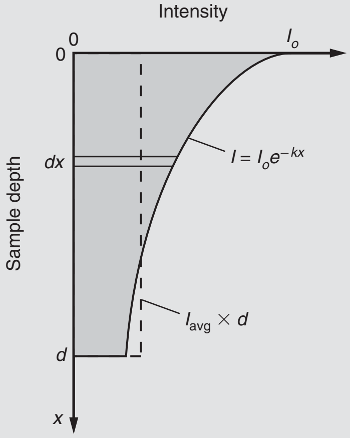
Thus, for a perfectly transparent solution $A(\lambda) = 0$, $T = 1$ and for a perfectly opaque solution $A(\lambda) \rightarrow \infty$, $T = 0$.

The principal water characteristics that affect the percent transmittance include: inorganic compounds (e.g., copper, iron), organic compounds (e.g., organic dyes, humic substances, and aromatic compounds such as benzene and toluene), and small colloidal particles ($\leq 0.45\ \mu$m). Additional details of the compounds that affect transmittance are given in the discussion of UV disinfection in Chap. 12. Typical absorbance and transmittance values for wastewater following various levels of treatment are given in Table 12–29, in Chap. 12.

EXAMPLE 2–5 **Variation of UV Intensity with Depth** If the intensity of the UV irradiation measured at the water surface in a Petri dish is 10 mW/cm^2, determine the average UV intensity to which a sample will be exposed if the depth of water in the Petri dish is 10 mm. Assume the absorptivity, $k(\lambda = 254\text{ nm})$, is equal to 1.0 cm^{-1}.

Solution

1. Use Beers-Lambert Law [Eq. (2–19)] to determine the average intensity.
   a. The definition sketch for this problem is given below.



b. Develop the required equation.

$$I_{\text{avg}} \times d = \int_0^d I_o e^{-kx} dx = -\frac{I_o}{k} e^{-kx} \Big]_0^d = -\frac{I_o}{k} e^{-kd} + \frac{I_o}{k} = \frac{I_o}{k}(1 - e^{-kd})$$

$$I_{\text{avg}} = \frac{I_o}{kd}(1 - e^{-kd})$$

2. Compute the average intensity for a depth of 10 mm (1 cm).
   a. Absorptivity, k, $= 1.0\ \text{cm}^{-1}$ (given)
   b. Solve for I_{avg}

$$I_{\text{avg}} = \frac{I_o}{kd}(1 - e^{-kd}) = \frac{(10\ \text{mW/cm}^2)}{(1/\text{cm})(1\ \text{cm})}[1 - e^{-(1/\text{cm})(1\ \text{cm})}] = 6.32\ \text{mW/cm}^2$$

Comment The equation developed in Step 1 is utilized for the analysis of UV dose in Chap. 12.

Temperature

The temperature of wastewater is commonly higher than that of the local water supply because of the addition of warm water from households and industrial activities. As the specific heat of water is much greater than that of air, the observed wastewater temperatures are higher than the local air temperatures during most of the year and are lower only during the hottest summer months. Depending on the geographic location, the mean annual temperature of wastewater in the United States varies from about 3 to 27°C (37 to 81°F); 15.6°C (60°F) is a representative value. Temperatures as high as 30 to 35°C (84 to 98°F) have been reported for countries in Africa and the Middle East. The variation that can be expected in influent wastewater temperatures is illustrated on Fig. 2–13. Depending on the location and time of year, the effluent temperatures can either be higher or lower than the corresponding influent values.

Effects of Temperature. The temperature of water is a very important parameter because of its effect on chemical reactions and reaction rates, aquatic life, and the suitability of the water for beneficial uses. Increased temperature, for example, can cause a change in the species of fish that can exist in the receiving water body. Industrial establishments that use surface water for cooling-water purposes are particularly concerned with the temperature of the intake water.

In addition, oxygen is less soluble in warm water than in cold water. The increase in the rate of biochemical reactions that accompanies an increase in temperature, combined with the decrease in the quantity of oxygen present in surface waters, can often cause serious depletions in dissolved oxygen concentrations in the summer months. When significantly large quantities of heated water are discharged to natural receiving waters, these effects are magnified. It should also be realized that a sudden change in temperature can result in a high rate of mortality of aquatic life. Moreover, abnormally high temperatures can foster the growth of undesirable water plants and wastewater fungi.

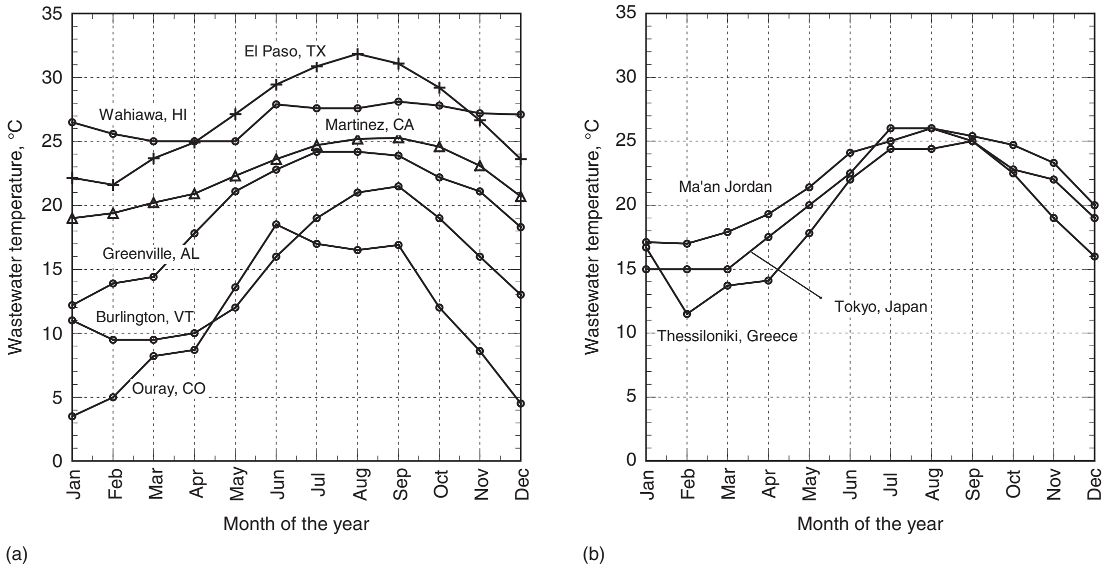


Figure 2–13

Typical variations in monthly influent wastewater temperatures (a) in various parts of the United States and (b) selected countries worldwide.

Optimum Temperatures for Biological Activity. Optimum temperatures for bacterial activity are in the range from 25 to 35°C. Aerobic digestion and nitrification stops when the temperature rises to 50°C. When the temperature drops to about 15°C, methane-producing bacteria become quite inactive, and at about 5°C, the autotrophic-nitrifying bacteria practically cease functioning. At 2°C, even the chemoheterotrophic bacteria acting on carbonaceous material become essentially dormant. The effects of temperature on the performance of biological treatment processes are considered in greater detail in Chaps. 7 and 8.

Estimation of Temperature Effects on Reaction Rates. Equilibrium constants, solubility product constants, and specific reaction-rate constants are all dependent on temperature. The temperature dependence of rate and equilibrium constants is based on the van't Hoff-Arrhenius relationship, as described in Chap. 1.

If the rate coefficient, say k_1, is known for a given temperature, the rate coefficient, k_2, at another temperature can be estimated using Eq. (1–44), repeated here for convenience. The derivation of Eq. (1–44) from the van't Hoff-Arrhenius relationship is presented in Chap. 1, Sec. 1–6.

$$\frac{k_2}{k_1} = \theta^{(T_2 - T_1)} \tag{1–44}$$

It should be noted, however, that although the value of the temperature coefficient, θ, is assumed to be constant, it will vary with temperature. Therefore, caution must be used in selecting appropriate values for θ for different temperature ranges (see Example 1–1). Typical values for various processes for different temperature ranges are given, where available, in the sections in which the individual topics are discussed.

Thermal Energy Content of Wastewater

The total energy content of wastewater is comprised of the heat and the organic constituents found in wastewater. The energy content of wastewater is an important consideration as new technologies and concepts are evaluated. Typically, the total energy content in wastewater is two to four times the energy needed to operate a WWTP. The sources of energy in wastewater are heat energy discussed below and chemical energy considered in Sec. 2–6.

The heat energy in wastewater derives from the energy added to water to heat it for a number of domestic and commercial applications. In domestic usage, the most important sources of heat in wastewater are from clothes washing, dishwashing, and bathing. The temperature of potable water typically varies from 4.5 to 10°C (40 to 50°F). The corresponding temperatures of wastewater as discharged from a residence are typically in the range from 15 to 28°C (60 to 80°F). Wastewater temperatures measured at wastewater treatment plants will vary with the season of the year and the characteristics of the collection system but are in the range from 15 to 24°C (60 to 75°F).

The heat content of wastewater can be approximated by considering the specific heat of water, which at 20°C is 4.1816 J/g·°C. Thus, for a 10°C difference, the heat content of wastewater per 1000 m^3 is equal to 41,816 MJ/10°C·10^3 m^3. Although the heat in wastewater can be recovered using a heat pump (see Chap. 17), the economic feasibility of recovering heat energy from wastewater depends on having a year-round use for the extracted heat. The heat energy extracted from wastewater can be used for drying organic materials removed by fine screening, sludge, and biosolids for subsequent processing.

Conductivity

The electrical conductivity (EC) of water is a measure of its ability to conduct an electrical current. Because the electrical current is transported by the ions in solution, the conductivity increases as the concentration of ions increases. In effect, the measured EC value is used as a surrogate measure of total dissolved solids (TDS) concentration. At present, the EC of a water is one of the important parameters used to determine the suitability of a water for irrigation. The salinity of treated wastewater to be used for irrigation is estimated by measuring its electrical conductivity.

The electrical conductivity in SI units is expressed as millisiemens per meter (mS/m) and in micromhos per centimeter (μmho/cm) in US customary units. It should be noted that 1 mS/m is equivalent to 10 μmho/cm. Equation (2–24) can be used to estimate the TDS of a water sample based on the measured EC value (Standard Methods, 2012).

$$\text{TDS (mg/L)} \cong \text{EC } (\mu\text{S/cm or } \mu\text{mho/cm}) \times (0.55 - 0.70) \tag{2–24}$$

The above relationship does not necessarily apply to raw wastewater or high-strength industrial wastewater. The above relationship can also be used to check the acceptability of chemical analyses (see Standard Methods, 2012).

The electrical conductivity can also be used to estimate the ionic strength of a solution using the following relationship (Russell, 1976)

$$I = 1.6 \times 10^{-5} \times \text{EC } (\mu\text{S/cm or } \mu\text{mho/cm}) \tag{2–25}$$

Equation (2–25) is used to estimate the ionic strength of treated wastewater in groundwater recharge applications (see Chap. 13).

Density, Specific Gravity, and Specific Weight

The density of wastewater, ρ_w, is defined as its mass per unit volume expressed as g/L or kg/m^3 in SI units and as $\text{lb}_\text{m}/\text{ft}^3$ in U.S. customary units. Density is an important physical characteristic of wastewater because of the potential for the formation of density currents in sedimentation tanks, chlorine contact tanks, and other treatment units. The density of domestic wastewater, which does not contain significant amounts of industrial waste, is essentially the same as that of water at the same temperature (see Appendix C).

In some cases the specific gravity of the wastewater s_w, is used in place of the density. The specific gravity is defined as:

$$s_w = \frac{\rho_w}{\rho_o} \tag{2–26}$$

where ρ_w = density of wastewater
ρ_o = density of water

Both the density and specific gravity of wastewater are temperature dependent and will vary with the concentration of total solids in the wastewater.

The specific weight of a fluid, γ, is its weight per unit volume. Specific weight is expressed as kN/m^3 in SI units and as lb_f/ft^3 in U.S. customary units. The relationship between γ, ρ, and the acceleration due to gravity, g, is $\gamma = \rho g$. At normal temperatures γ is about 9.81 kN/m^3 (62.4 lb_f/ft^3). Values for both density and specific weight as a function of temperature in both SI and U.S. customary units are given in Appendix C.

2–4 INORGANIC NONMETALLIC CONSTITUENTS

The chemical constituents of wastewater are typically classified as inorganic and organic. Inorganic chemical constituents of concern include nutrients, nonmetallic constituents, metals, and gases. Inorganic nonmetallic constituents considered in this section include pH, nitrogen, phosphorus, alkalinity, chlorides, sulfur, other inorganic constituents, gases, and odors. Metallic constituents are considered in Section 2–5.

Sources of Inorganic Nonmetallic Constituents

The sources of inorganic nonmetallic constituents in wastewater derive from the background levels in the water supply and from the additions resulting from domestic use, from the addition of highly mineralized water from private wells and groundwater, and from industrial use. Domestic and industrial water softeners also contribute significantly to the increase in mineral content and, in some areas, may represent the major source. Occasionally, water added from private wells and groundwater infiltration will (because of its high quality) serve to dilute the mineral concentration in the wastewater. Because concentrations of various inorganic constituents can greatly affect the beneficial uses made of the waters, the constituents in each wastewater must be considered separately.

pH

Because the concentration of the species of most chemical constituents is dependent on the hydrogen-ion concentration in solution, the hydrogen-ion concentration is an important quality parameter of both natural waters and wastewaters. The usual means of expressing the hydrogen ion concentration is as pH, which is defined as the negative logarithm of the hydrogen ion concentration:

$$\text{pH} = -\log_{10}[\text{H}^+] \tag{2–27}$$

The concentration range suitable for the existence of most biological life is quite narrow and critical (typically 6 to 9). Wastewater with an extreme concentration of the hydrogen ion is difficult to treat by biological means, and if the concentration is not altered before discharge, the wastewater effluent may alter the concentration in the natural receiving waters. For treated effluents discharged to the environment, the allowable pH range usually varies from 6.5 to 8.5.

The hydrogen ion concentration in water is connected closely with the extent to which water molecules dissociate. Water will dissociate into hydrogen and hydroxyl ions as follows:

$$H_2O \rightleftarrows H^+ + OH \tag{2–28}$$

Applying the law of mass action [Eq. (2–7)] to Eq. (2–28) yields

$$\frac{[H^+][OH^-]}{[H_2O]} = K \tag{2–29}$$

where the brackets indicate concentration of the constituents in moles per liter. Because the concentration of water in a dilute aqueous system is essentially constant, this concentration can be incorporated into the equilibrium constant K to give

$$[H^+][OH^-] = K_w \tag{2–30}$$

K_w is known as the ionization constant or ion product of water and is approximately equal to 1×10^{-14} at a temperature of 25°C. Equation (2–30) can be used to calculate the hydroxyl ion concentration when the hydrogen ion concentration is known and vice versa.

With pOH, which is defined as the negative logarithm of the hydroxyl ion concentration, it can be seen from Eq. (2–30) that, for water at 25°C,

$$pH + pOH = 14 \tag{2–31}$$

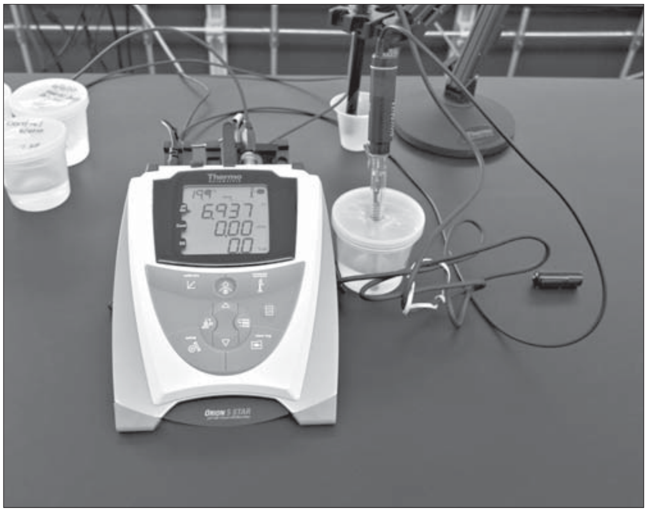
The pH of aqueous systems typically is measured with a pH meter (see Fig. 2–14). Various pH papers and indicator solutions that change color at definite pH values are also used. The pH is determined by comparing the color of the paper or solution to a series of color standards.

Chlorides

Chloride is a constituent of concern in wastewater as it can affect the final reuse applications of treated wastewater. Chlorides in natural water result from the leaching of chloride containing rocks and soils with which the water comes in contact, and in coastal areas from saltwater intrusion. In addition, agricultural, industrial, and domestic wastewaters discharged to surface waters are a source of chlorides.

Figure 2–14

Typical meter used for the measurement of pH and specific ion concentrations.



Human excreta, for example, contain about 6 g of chlorides per person per day. In areas where the hardness of water is high, home regeneration–type water softeners will also add large quantities of chlorides. Because conventional methods of waste treatment do not remove chloride to any significant extent, higher than usual chloride concentrations can be taken as an indication that a body of water is being used for waste disposal. Infiltration of groundwater into sewers adjacent to saltwater is also a potential source of high chlorides as well as sulfates.

Alkalinity

Alkalinity in wastewater results from the presence of the hydroxides $[OH^-]$, carbonates $[CO_3^{2-}]$, and bicarbonates $[HCO_3^-]$ of elements such as calcium, magnesium, sodium, potassium, and ammonia. Of these, calcium and magnesium bicarbonates are most common. Borates, silicates, phosphates, and similar compounds can also contribute to the alkalinity. The alkalinity in wastewater helps to resist changes in pH caused by the addition of acids. Wastewater is normally alkaline, receiving its alkalinity from the water supply, the groundwater, and the materials added during domestic use. The concentration of alkalinity in wastewater is important where chemical and biological treatment is to be used (see Chaps. 6 and 7, respectively), in biological nutrient removal (see Chap. 8), and where ammonia is to be removed by air stripping (see Chap. 11 and 15).

Alkalinity is determined by titrating against a standard acid; the results are expressed in terms of calcium carbonate, mg/L as $CaCO_3$. For most practical purposes alkalinity can be defined in terms of molar quantities, as

$$\text{Alk, eq/m}^3 = \text{meq/L} = [HCO_3^-] + 2[CO_3^{2-}] + [OH^-] - [H^+] \qquad (2\text{–}32)$$

The corresponding expression in terms of equivalents is

$$\text{Alk, eq/m}^3 = (HCO_3^-) + (CO_3^{2-}) + (OH^-) - (H^+) \qquad (2\text{–}33)$$

In practice, alkalinity is expressed in terms of calcium carbonate. To convert from meq/L to mg/L as $CaCO_3$ it is helpful to remember that

$$\begin{aligned}\text{Milliequivalent mass of } CaCO_3 &= \frac{(100\text{ mg/mmole})}{(2\text{ meq/mmole})} \qquad (2\text{–}34)\\ &= 50\text{ mg/meq}\end{aligned}$$

Thus 3 meq/L of alkalinity would be expressed as 150 mg/L as $CaCO_3$.

$$\begin{aligned}\text{Alkalinity, Alk as } CaCO_3 &= \frac{3.0\text{ meq}}{\text{L}} \times \frac{50\text{ mg } CaCO_3}{\text{meq } CaCO_3}\\ &= 150\text{ mg/L as } CaCO_3\end{aligned}$$

Nitrogen

The elements nitrogen and phosphorus, essential to the growth of microorganisms, plants, and animals, are known as nutrients or biostimulants. Trace quantities of other elements, such as iron, are also needed for biological growth, but nitrogen and phosphorus are, in most cases, the major nutrients of importance. Because nitrogen is an essential building block in the synthesis of protein, nitrogen data will be required to evaluate the treatability of wastewater by biological processes. Insufficient nitrogen can necessitate the addition of nitrogen to make the waste treatable. Nutrient requirements for biological waste treatment are discussed in Chaps. 7 and 8. Where control of algal growths in the receiving water is necessary, removal or reduction of nitrogen in wastewater prior to discharge may be desirable.

Sources of Nitrogen. The principal sources of nitrogen compounds are (1) the nitrogenous compounds of plant and animal origin, (2) sodium nitrate, and (3) atmospheric nitrogen. Ammonia derived from the distillation of bituminous coal is an example of nitrogen obtained from decayed plant material. Sodium nitrate ($NaNO_3$) is found principally in mineral deposits in Chile and in the manure found in sea birds' rookeries. The production of nitrogen from the atmosphere is termed *nitrogen fixation*. Because fixation is a biologically mediated process and because $NaNO_3$ deposits are relatively scarce, most sources of nitrogen in soil/groundwater are of biological origin.

Forms of Nitrogen. The chemistry of nitrogen is complex because of the several oxidation states that nitrogen can assume and the fact that changes in the oxidation state can be brought about by living organisms. To complicate matters further, the oxidation state changes brought about by bacteria can be either positive or negative depending upon whether aerobic or anaerobic conditions prevail. The oxidation states of nitrogen are summarized (Sawyer et al., 2003):

$$\begin{array}{ccccccc} -\mathrm{III} & 0 & \mathrm{I} & \mathrm{II} & \mathrm{III} & \mathrm{IV} & \mathrm{V} \\ NH_3 — & N_2 — & N_2O — & NO — & N_2O_3 — & NO_2 — & N_2O_5 \end{array} \tag{2–37}$$

The most common and important forms of nitrogen in wastewater and their corresponding oxidation state in the water/soil environment are ammonia (NH_3, $-$III), ammonium (NH_4^+, $-$III), nitrogen gas (N_2, 0), nitrite ion (NO_2^-, +III), and nitrate ion (NO_3^-, +V). The oxidation state of nitrogen in most organic compounds is $-$III.

Total nitrogen, as reported in Table 2–6, is composed of organic nitrogen, ammonia, nitrite, and nitrate. The organic fraction consists of a complex mixture of compounds including amino acids, amino sugars, and proteins (polymers of amino acids). The compounds that comprise the organic fraction can be soluble or particulate. The nitrogen in these compounds is readily converted to ammonium through the action of microorganisms in the aquatic or soil environment. Urea, readily converted to ammonium carbonate, is seldom found in untreated municipal wastewaters.

Organic nitrogen is determined analytically using the Kjeldahl method. The aqueous sample is first boiled to drive off the ammonia, and then it is digested. During digestion the organic nitrogen is converted to ammonium through the action of heat and acid. Total Kjeldahl nitrogen (TKN) is determined in the same manner as organic nitrogen, except that the ammonia is not driven off before the digestion step. Total Kjeldahl nitrogen is, therefore, the total of the organic and ammonia nitrogen. An alternative method is the perfulfate digestion procedure in which organic nitrogen is oxidized to nitrate nitrogen at high

Table 2–6

Definition of the various terms used to define various nitrogen species

Form of nitrogen	Abbrev.	Definition
Ammonia gas	NH_3	NH_3
Ammonium ion	NH_4^+	NH_4^+
Total ammonia nitrogen	TAN[a]	$NH_3 + NH_4^+$
Nitrite	NO_2^-	NO_2^-
Nitrate	NO_3^-	NO_3^-
Total inorganic nitrogen	TIN[a]	$NH_3 + NH_4^+ + NO_2^- + NO_3^-$
Total Kjeldahl nitrogen	TKN[a]	Organic N $+ NH_3 + NH_4^+$
Organic nitrogen	Organic N[a]	TKN $- (NH_3 + NH_4^+)$
Total nitrogen	TN[a]	Organic N $+ NH_3 + NH_4^+ + NO_2^- + NO_3^-$

[a] All species expressed as N.

temperatures (100–110°C in an autoclave for 1 hour) following the addition of potassium sulfate and sodium hydroxide. If the sample contains NH_4–N, NO_2–N, and NO_3–N, their concentrations are determined by other means so that these concentrations can be subtracted from the persulfate digestion total nitrogen concentration to determine the organic nitrogen concentration.

Ammonia nitrogen exists in as aqueous solution as either the ammonium ion (NH_4^+) or ammonia gas (NH_3), depending on the pH of the solution, in accordance with the following equilibrium reaction:

$$NH_4^+ \rightleftarrows NH_3 + H^+ \tag{2–38}$$

Applying the law of mass action [Eq. (2–7)] to Eq. (2–38) yields

$$\frac{[NH_3][H^+]}{[NH_4^+]} = K_a \tag{2–39}$$

where K_a = acid ionization (dissociation) constant at 25°C $= 10^{-9.25}$ or 5.62×10^{-10}

Because the distribution of the ammonia species is a function of the pH, the percentage ammonia can be determined using the following relationship:

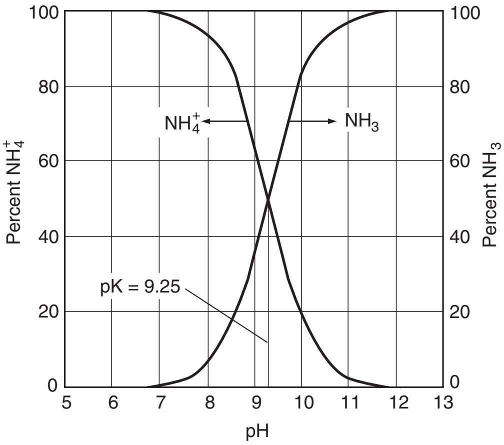
$$NH_3,\% = \frac{[NH_3] \times 100}{[NH_3] + [NH_4^+]} = \frac{100}{1 + [NH_4^+]/[NH_3]} = \frac{100}{1 + [H^+]/K_a} \tag{2–40}$$

Using Eq. (2–40) the distribution of the ammonia species as a function of pH is shown on Fig. 2–15. At pH levels above 7, the equilibrium is displaced to the left; at levels below pH 7, the ammonium ion is predominant. Ammonia is determined by raising the pH, distilling off the ammonia with the steam produced when the sample is boiled, and condensing the steam that absorbs the gaseous ammonia. The measurement is made colorimetrically, titrimetrically, or with specific-ion electrodes.

Nitrite nitrogen is relatively unstable and is easily oxidized to the nitrate form. It is an indicator of past pollution in the process of stabilization and seldom exceeds 1 mg/L in wastewater or 0.1 mg/L in surface waters or groundwaters. Although present in low concentrations, nitrite can be very important in wastewater or water pollution studies because it is extremely toxic to most fish and other aquatic species. Nitrites present in wastewater effluents are oxidized by chlorine and thus increase the chlorine dosage requirements and the cost of disinfection.

Figure 2–15

Distribution of ammonia (NH_3) and ammonium ion (NH_4^+) as a function of pH at 25°C.



Nitrate nitrogen is the most highly oxidized form of nitrogen found in wastewaters. Where secondary effluent is to be reclaimed for groundwater recharge, the nitrate concentration is important. The U.S. EPA drinking water standards (U.S. EPA, 1977) limit it to 10 mg/L as NO_3–N because of its serious and occasionally fatal effects on infants. Nitrates may vary in concentration from 0 to 20 mg/L as N in wastewater effluents. Assuming complete nitrification has taken place, the typical range found in treated effluents is from 15 to 25 mg/L as N.

Nitrous oxide (N_2O) is a greenhouse gas with an impact that is about 300 times that for CO_2 (U.S. EPA, 2008). Agriculture accounts for the main source of N_2O production due to human activity, although other anthropogenic sources include combustion of fossil fuels and manufacturing of nylon (Maier et al., 2009). Nitrous oxide can also be converted photolytically to nitric oxide (NO), which contributes to the depletion of the Earth's ozone layer. The production of N_2O and NO from biological wastewater treatment nitrification and denitrification processes is of interest and is addressed in Chapter 7. Nitrogen dioxide (NO_2) is a reddish-brown toxic gas that can be formed at high temperatures by oxidation of N_2 by oxygen, with internal combustion engines and power stations being major sources.

Nitrogen Fractions in Wastewater. As biological nutrient removal has become more common, information on the various organic nitrogen fractions has become important. The principal fractions are particulate and soluble. In biological treatment studies, the particulate and soluble fractions of organic nitrogen are fractionated further to assess wastewater treatability (see discussion in Sec. 8–2 in Chap. 8). Fractions that have been used include (1) ammonia (ionized and free), (2) biodegradable soluble organic nitrogen, (3) biodegradable particulate organic nitrogen, (4) nonbiodegradable soluble organic nitrogen, and (5) nonbiodegradable particulate organic nitrogen. The presence of nonbiodegradable forms of nitrogen often make meeting extremely low discharge limits for nitrogen difficult, if not impossible, without additional treatment steps. Unfortunately, there is little standardization on the definition of soluble versus particulate organic nitrogen (see discussion of under Solids in Sec. 2–3). Where filtration is the technique used to fractionate the sample, the relative distribution between soluble and particulate organic nitrogen will vary depending on the pore size of the filter used. In many cases, colloidal organic nitrogen has been classified as soluble or dissolved. The lack of standardized definition will also affect other aggregate constituents (i.e., chemical oxygen demand and total organic carbon).

In areas where surface water quality has been impaired due to eutrophication, more strict effluent permit requirements are imposed and an effluent total nitrogen (TN) concentration goal of less than 3.0 g/m^3 has been commonly applied. In such cases, the effluent soluble organic nitrogen (SON) concentration may account for over 40 percent of the effluent TN concentration. In addition the nondegradable SON persists in advanced biological nutrient removal processes, and has been shown to increase with increasing aeration times (Makinia et al., 2011). The inorganic forms of nitrogen are readily available for algal growth, but only recently has the SON impact on algal growth been investigated. From algal bioassay work, Haizhou et al. (2012) have shown that 20–40 percent of effluent SON is not readily available for algae growth and the nonavailable portion is likely related to more hydrophobic and possibly humic and higher molecular weight compounds

Nitrogen Pathways in Nature. The various forms of nitrogen that are present in nature and the pathways by which the forms are changed in an aquatic environment are depicted on Fig. 2–16. The nitrogen present in fresh wastewater is primarily combined in proteinaceous matter and urea. Decomposition by bacteria readily changes the organic form to ammonia. The age of wastewater is indicated by the relative amount of ammonia that is present. In an aerobic environment, bacteria can oxidize the ammonia nitrogen to nitrites and nitrates. The predominance of nitrate nitrogen in wastewater indicates that the waste has been stabilized with respect

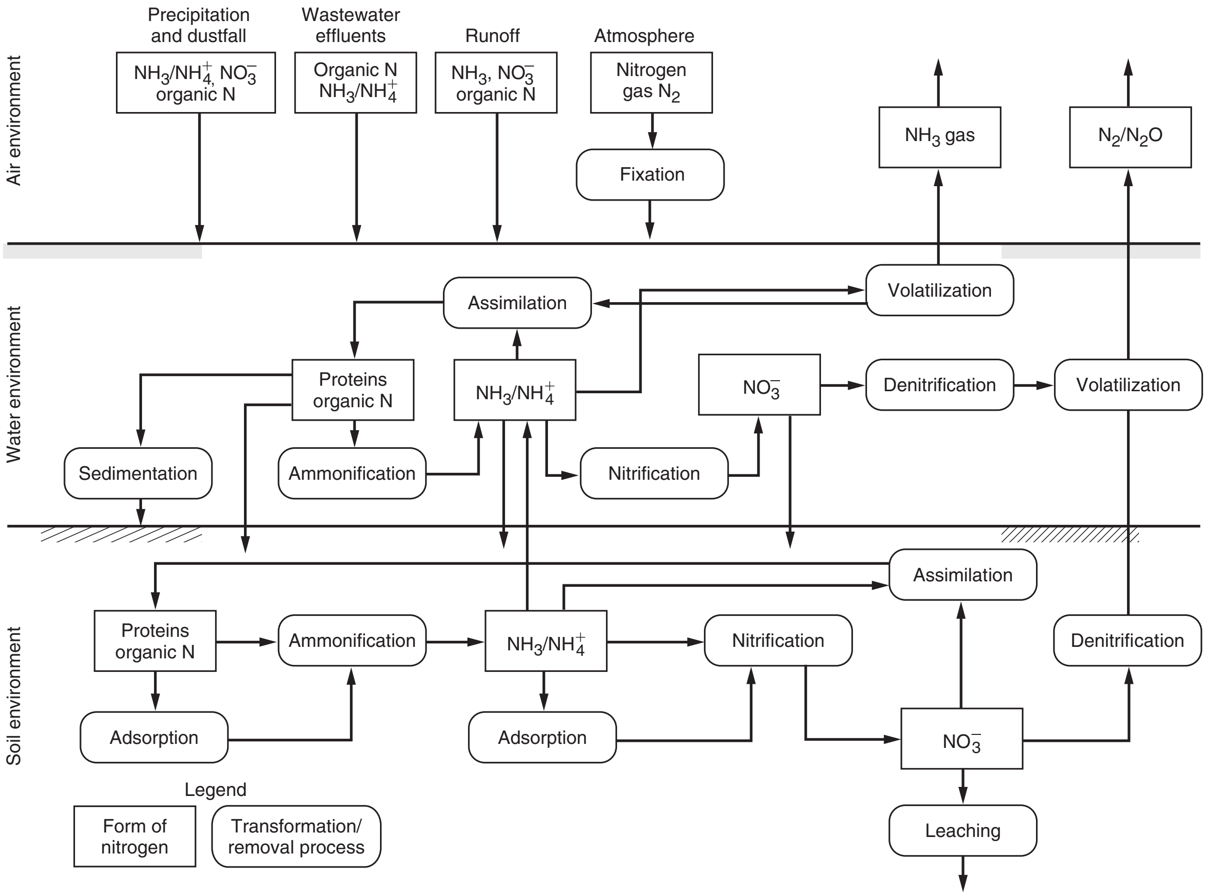


Figure 2–16

Generalized nitrogen cycle in the environment.

to oxygen demand. Nitrates, however, can be used by plants and animals to form protein. Death and decomposition of the plant and animal protein by bacteria again yield ammonia. Thus, if nitrogen in the form of nitrates can be reused to make protein by algae and other plants, it may be necessary to remove or reduce the nitrogen that is present to prevent these growths.

Phosphorus

Phosphorus is also essential to the growth of algae, agricultural crops, and other biological organisms. Unlike nitrogen, phosphorus does not have a gaseous form that can be discharged to the atmosphere. Because of noxious algal blooms that occur in surface waters, there is presently much interest in controlling the amount of phosphorus compounds that enter surface waters in domestic and industrial waste discharges and natural runoff. Further, the unsustainable nature of phosphorus mining and the potential future shortages is driving the development of processes for the recovery of phosphorus from wastewater as discussed in Chap. 15. Municipal wastewaters, for example, typically contain from 3.7 to 11 mg/L of phosphorus as P (see Table 3–18 in Chap. 3).

Phosphorus in Wastewater. Phosphorus in wastewater can be classified broadly into two fractions: particulate and dissolved. Each of these fractions can be differentiated further as reactive and nonreactive. Reactive phosphorus is defined as the forms of phosphorus that respond to colorimetric tests without preliminary hydrolysis or oxidative digestion. Note that these so-called reactive orthophosphates include both soluble forms as well as those that are loosely attached or adsorbed on to precipitates. The nonreactive forms include acid hydrolyzable and digestable forms, which may be an organic form of nonreactive phosphorus. The soluble forms of phosphorus that are found in aqueous solutions include the orthophosphates (reactive), polyphosphate (acid hydrolysable), and organic (digestable) phosphate. The orthophosphates (e.g., PO_4^{3-}, HPO_4^{2-}, $H_2PO_4^-$, H_3PO_4) are available for biological metabolism without further breakdown. The polyphosphates include those molecules with two or more phosphorus atoms, oxygen atoms, and in some cases, hydrogen atoms combined in a complex molecule. Polyphosphates undergo hydrolysis in aqueous solutions and revert to the orthophosphate forms; however, this hydrolysis is usually quite slow. The organically bound phosphorus is usually of minor importance in most domestic wastes, but it can be an important constituent of industrial wastes and wastewater sludges.

Soluble Nonreactive Forms. The soluble nonreactive forms of phosphorus are of great interest because they are not removed easily using current biological and chemical treatment processes. Effluent soluble nonreactive phosphorus concentrations in the range of 0.004 to 0.042 g/m^3 were found after high chemical dosing in tertiary filtration or membrane separation processes (Gu et al., 2011). Thus, the presence of nonreactive forms of phosphorus, as with nonbiodegradable nitrogen, can make meeting extremely low discharge permit limits difficult to achieve. As with SON, the impact of the remaining phosphorus after extensive chemical treatment and particulate removal on algal growth is also of interest. Based on algal bioassay testing of tertiary treated effluent samples with high alum dose it was found that not all of the effluent phosphorus measured was readily available to algal growth (Li and Brett, 2012). As the treatment level and alum addition increased, the percent bioavailable phosphorus for algal growth decreased from 60 percent for an effluent total phosphorus concentration of 0.50 g/m^3 to 15 percent at an effluent concentration of 0.02 g/m^3.

Sulfur

The sulfate ion occurs naturally in most water supplies and is present in wastewater as well. Sulfur is required in the synthesis of proteins and is released in their degradation. Sulfate is reduced biologically under anaerobic conditions to sulfide which, in turn, can combine with hydrogen to form hydrogen sulfide (H_2S). The following generalized reactions are typical:

$$\text{Organic matter} + SO_4^{2-} \xrightarrow{\text{bacteria}} S^{2-} + H_2O + CO_2 \tag{2–41}$$

$$S^{2-} + 2H^+ \rightarrow H_2S \tag{2–42}$$

If lactic acid is used as the precursor organic compound, the reduction of sulfate to sulfide occurs as follows:

$$\underset{\text{lactic acid}}{2CH_3CH(OH)COOH} + \underset{\text{sulfate}}{SO_4^{2-}} \xrightarrow{\text{bacteria}} \underset{\text{acetate}}{2CH_3COOH} + \underset{\substack{\text{sulfide}\\ \text{ion}}}{S^{2-}} + 2H_2O + 2CO_2 \tag{2–43}$$

Hydrogen sulfide gas, which will diffuse into the headspace above the wastewater in sewers that are not flowing full, tends to collect at the crown of the pipe. The accumulated H_2S can then be oxidized biologically to sulfuric acid, which is corrosive to concrete sewer pipes. This corrosive effect, known as "crown rot," can seriously threaten the structural integrity of the sewer pipe (ASCE, 1989; U.S. EPA, 1985a).

Sulfates are reduced to sulfides in sludge digesters and may upset the biological process if the sulfide concentration exceeds 200 mg/L. Fortunately, such concentrations are rare. The H_2S gas, which is evolved and mixed with the wastewater gas ($CH_4 + CO_2$), is corrosive to the gas piping, and if burned in gas engines, the products of combustion can damage the engine and severely corrode exhaust gas heat recovery equipment, especially if allowed to cool below the dew point.

Gases

Gases commonly found in untreated wastewater include nitrogen (N_2), oxygen (O_2), carbon dioxide (CO_2), hydrogen sulfide (H_2S), ammonia (NH_3), and methane (CH_4). The first three are common gases of the atmosphere and will be found in all waters exposed to air. The latter three are derived from the decomposition of the organic matter present in wastewater and are of concern with respect to worker health and safety. Although not found in untreated wastewater, other gases with which the environmental engineer must be familiar include chlorine (Cl_2) and ozone (O_3) (for disinfection and odor control), and the oxides of sulfur and nitrogen (in combustion processes). The following discussion is limited to those gases that are of interest in untreated wastewater. Under most circumstances, the ammonia in untreated wastewater will be present as the ammonium ion (see "Nitrogen"). However, before discussing the individual gases, it will be useful to review the ideal gas law, to consider the solubility of gases in water, and to review Henry's law as applied to the gases of interest.

Solubility of Gases in Water. The actual quantity of a gas that can be present in solution is governed by (1) the solubility of the gas as defined by Henry's law, (2) the partial pressure of the gas in the atmosphere, (3) the temperature, and (4) the concentration of the impurities in the water (e.g., salinity, suspended solids, etc.).

The Ideal Gas Law. The ideal gas law, derived from a consideration of Boyle's Law (volume of a gas is inversely proportional to pressure at constant temperature) and Charles' law (volume of a gas is directly proportional to temperature at constant pressure) is

$$PV = nRT \tag{2–44}$$

where P = absolute pressure, atm
V = volume occupied by the gas, L, m^3
n = moles of gas, mole
R = universal gas law constant, 0.082057 atm·L/mole·K
= 0.000082057 atm·m^3/mole·K
T = temperature, K (273.15 + °C)

Using the universal gas law it can be shown that the volume of gas occupied by one mole of a gas at standard temperature [0°C, (32°F)] and pressure (1.0 atm) is equal to 22.414 L.

$$V = \frac{nRT}{P}$$

$$V = \frac{(1\text{ mole})(0.082057\text{ atm}\cdot\text{L/mole}\cdot\text{K})[(273.15 + 0)\text{K}]}{1.0\text{ atm}} = 22.414\text{ L}$$

The following relationship, based on the ideal gas law, is used to convert between gas concentrations expressed in ppm_v and $\mu g/m^3$.

$$\mu\text{g/m}^3 = \frac{(\text{concentration, ppm}_v)(\text{mw, g/mole of gas})(10^6\,\mu\text{g/g})}{(22.414 \times 10^{-3}\,\text{m}^3/\text{mole of gas})} \tag{2–45}$$

The application of Eq. (2–45) is illustrated in Example 2–6.

EXAMPLE 2–6 **Conversion of Gas Concentration Units** The off gas from a wastewater force main (i.e., pressure sewer) was found to contain 9 ppm_v (by volume) of hydrogen sulfide (H_2S). Determine the concentration in $\mu g/m^3$ and in mg/L at standard conditions (0°C, 101.325 kPa).

Solution

1. Compute the concentration in $\mu g/L$ using Eq. (2–45).
   The molecular weight of $H_2S = [2(1.01) + 32.06] = 34.08$

$$9\ \text{ppm}_v = \left(\frac{9\ \text{m}^3}{10^6\ \text{m}^3}\right)\left[\frac{(34.08\ \text{g/mole H}_2\text{S})}{(22.4 \times 10^{-3}\ \text{m}^3\text{/mole of H}_2\text{S})}\right]\left(\frac{10^6\ \mu\text{g}}{g}\right) = 13{,}693\ \mu\text{g/m}^3$$

2. The concentration in mg/L is

$$13{,}693\ \mu\text{g/m}^3 = \left(\frac{13{,}693\ \mu\text{g}}{\text{m}^3}\right)\left(\frac{1\ \text{mg}}{10^3\ \mu\text{g}}\right)\left(\frac{1\ \text{m}^3}{10^3\ \text{L}}\right) = 0.0137\ \text{mg/L}$$

Comment If gas measurements, expressed in $\mu g/L$, are made at other than standard conditions, the concentration must be corrected to standard conditions, using the ideal gas law, before converting to ppm.

Henry's Law for Dissolved Gases. The equilibrium or saturation concentration of gas dissolved in a liquid is a function of the type of gas and the volume fraction or partial pressure of the gas in contact with the liquid. The relationship between the mole fraction of the gas in the atmosphere above the liquid and the mole fraction of the gas in the liquid is given by the following form of Henry's law:

$$p_g = \frac{H}{P_T} x_g \tag{2–46}$$

where p_g = mole fraction of gas in air, mole gas/mole of air

H = Henry's law constant, $\dfrac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}$

P_T = total pressure, usually 1.0 atm

x_g = mole fraction of gas in water, mole gas/mole water

$$= \frac{\text{mole gas } (n_g)}{\text{mole gas } (n_g) + \text{mole water } (n_w)}$$

In Eq. (2–46) it is helpful to remember that the mole fraction of a gas corresponds to the partial pressure or volume fraction of the gas. If the partial pressure of the gas is used, Eq. (2–46) is written as follows:

$$P_g = Hx_g \tag{2–47}$$

where P_g = partial pressure of gas, atm
other terms = as defined above

In practice and in the literature, the Henry's law constant is often reported as atm, with the mole fraction being implied. Henry's law constant is a function of the type of gas, temperature, and nature of the liquid. Values of Henry's law constants for various gases in water at 20°C are given in Table 2–7. It is important to note that reported values of the

Table 2–7

Henry's law constants at 20°C, unitless Henry's law constants at 20°C, and temperature dependent coefficients[a]

Parameter	Henry's constant, atm	Henry's constant, unitless	Temperature coefficients	
			A	*B*
Air	66,400	49.68	557.60	6.724
Ammonia	0.75	5.61×10^{-4}	1887.12	6.315
Carbon dioxide	1420	1.06	1012.40	6.606
Carbon monoxide	53,600	40.11	554.52	6.621

Oxygen	41,100	30.75	595.27	6.644
Ozone	5300	3.97	1268.24	8.05
Sulfur dioxide	36	2.69×10^{-2}	1207.85	5.68

[a] Adapted in part from Crittenden et al. (2012), Cornwell (1990), and Hand et al. (1998).

Henry's law constant found in the literature will vary depending on the date of the reference and the specific method used to estimate the constant. Use of the data in Table 2–7 is illustrated in Example 2–7.

The change in the Henry's law constant with temperature can be estimated using the following empirical equation, derived from a consideration of the van't Hoff-Arrhenius relationship:

$$\log_{10} H = \frac{-A}{T} + B \tag{2–48}$$

where H = Henry's law constant at temperature T, atm
A = empirical constant that takes into account the enthalpy change in water due to the dissolution of a component in water and the universal gas law constant
T = temperature, K = 273.15 + °C
B = empirical constant

Values of A and B for various gases of interest in wastewater treatment are presented in Table 2–7. It should be noted that the values given in Table 2–7 for A and B are approximate and will vary depending on the source and the method used to derive them.

Unitless Form of Henry's Law. In the literature, the unitless form of Henry's law is often used to compute the solubility of trace gases in water or wastewater. The unitless form is usually written as

$$\frac{C_g}{C_s} = H_u \tag{2–49}$$

where C_g = concentration of constituent in gas phase, $\mu g/m^3$, mg/L
C_s = saturation concentration of constituent in liquid, $\mu g/m^3$, mg/L
H_u = Henry's law constant, unitless

The unitless form is obtained by noting that at 1.0 atm pressure and 0°C, the volume occupied by 1.0 mole of air is 22.414 L. At other temperatures, 1.0 mole of air is equal to 0.082 T L of air, where T is temperature in Kelvin, K (273.15 + °C). Using these conversions, the unitless form of Henry's law is

$$H_u = \left[H\frac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}\right]\left(\frac{\text{mole air}}{0.082\,T\,\text{L}}\right)\left(\frac{\text{L}}{55.6\text{ mole water}}\right)$$

$$H_u = \left(\frac{H}{4.559\,T}\right) \tag{2–50}$$

For example, at 20°C, H_u equals

$$H_u = \left[\frac{H}{4.559(273.15 + 20)}\right] = H \times (7.49 \times 10^{-4}) \text{ at } 20°\text{C}$$

If atmospheric conditions prevail and Henry's constant is expressed in terms of atm·m³/mole (another form of Henry's law used commonly in the literature), the unitless form of Henry's law is obtained as follows:

$$H_u = \frac{H}{RT} \tag{2–51}$$

where H_u = Henry's law constant, unitless as used in Eq. (2–49)
H = Henry's law constant values expressed in atm·m³/mole
R = universal gas law constant, 0.00008205 atm·m³/mole·K
T = temperature, K = 273.15 + °C

EXAMPLE 2–7 **Saturation Concentration of Oxygen in Water** What is the saturation of oxygen in water in contact with dry air at 1 atm and 20°C?

Solution–Method 1 Using Eq. (2–46)

1. Dry air contains about 21 percent oxygen by volume (see Appendix B). Therefore, $p_g = 0.21$ mole O_2/mole air
2. Determine x_g.
   a. From Table 2–7, at 20°C, Henry's constant is

$$H = 4.11 \times 10^4 \frac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}$$

   b. Using Eq (2–46), the value of x_g is

$$\begin{aligned} x_g &= \frac{P_T}{H}p_g \\ &= \frac{1.0\text{ atm}}{4.11 \times 10^4 \dfrac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}}(0.21\text{ mole gas/mole air}) \\ &= 5.11 \times 10^{-6}\text{ mole gas/mole water} \end{aligned}$$

3. One liter of water contains 1000 g/(18 g/mole) = 55.6 mole, thus

$$\frac{n_g}{n_g + n_w} = 5.11 \times 10^{-6}$$
$$\frac{n_g}{n_g + 55.6} = 5.11 \times 10^{-6}$$

Because the number of moles of dissolved gas in a liter of water is much less than the number of moles of water,

$$n_g + 55.6 \approx 55.6$$

and $n_g \approx (55.6)5.11 \times 10^{-6}$

$$n_g \approx 2.84 \times 10^{-4} \text{ mole O}_2\text{/L}$$

4. Determine the saturation concentration of oxygen.

$$C_s \approx \frac{\left(\dfrac{2.84 \times 10^{-4} \text{ mole O}_2}{\text{L}}\right)\left(\dfrac{32 \text{ g}}{\text{mole O}_2}\right)\left(\dfrac{10^3 \text{ mg}}{1 \text{ g}}\right)}{(1 \text{ g}/10^3 \text{ mg})}$$
$$\approx 9.09 \text{ mg/L}$$

Solution–Method 2 Using Eq. (2–49)

1. The density of air at 20°C from Appendix B is 1204 kg/m^3.
2. The percent of oxygen in air from Appendix B is about 23.18 percent oxygen by weight.
3. Determine the saturation concentration of oxygen.
   a. From Table 2–7, at 20°C, the unitless form of Henry's constant is

   $$H_u = 30.75$$

   b. Using Eq (2–49), the value of C_s is

   $$C_s = \frac{C_g}{H_u}$$
   $$C_s = \frac{(1.204 \text{ kg/m}^3)(10^3 \text{ g/kg})(0.2318)}{30.75}$$
   $$= 9.08 \text{ g/m}^3 = 9.08 \text{ mg/L}$$

Comment The computed values (9.09 and 9.08 mg/L) are essentially the same as the value given in Appendix E (9.09 mg/L). It should be noted that the values for the Henry's law constant given in Table 2–7 will vary depending on the source and the method used to derive them. Also, the relationship at different temperatures is not linear.

Oxygen (O_2). Dissolved oxygen (DO) is required for the respiration of aerobic microorganisms as well as all other aerobic life forms. However, O_2 is only slightly soluble in water. The actual quantity of O_2 (and other gases too) that can be present in a solution is governed by (1) the solubility of the gas, (2) the partial pressure of the gas in the atmosphere, (3) the temperature, and (4) the concentration of the impurities in the water (e.g., salinity, suspended solids). The interrelationship of these variables is delineated in Chap. 6 and is illustrated in Appendix E, where the effect of temperature and salinity on DO concentration is presented.

Because the rate of biochemical reactions that use O_2 increases with increasing temperature, dissolved oxygen levels tend to be more critical in the summer months. The problem is compounded in summer months because stream flows are usually lower, and thus the total quantity of O_2 available is also lower. The presence of DO in wastewater is desirable because it prevents the formation of noxious odors. The role of O_2 in wastewater treatment is discussed in Chaps. 5, 7, 8, and 9.

Hydrogen Sulfide (H_2S). Hydrogen sulfide is formed, as mentioned previously, from the anaerobic decomposition of organic matter containing sulfur or from the reduction of mineral sulfites and sulfates. It is not formed in the presence of an abundant supply of oxygen. This gas is a colorless, inflammable compound having the characteristic odor of rotten eggs. Hydrogen sulfide is also toxic, and great care must be taken in its presence. High concentrations of H_2S can overwhelm olfactory glands, resulting in a loss of smell. This loss of smell can lead to a false sense of security that is very dangerous. The blackening of wastewater and sludge usually results from the formation of H_2S that has combined with the iron present to form ferrous sulfide (FeS). Various other metallic sulfides are also formed. Although H_2S is the most important gas formed from the standpoint of odors, other volatile compounds such as indol, skatol, and mercaptans, which may also be formed during anaerobic decomposition, may cause odors far more offensive than that of H_2S.

Methane (CH_4). The principal by-product from the anaerobic decomposition of the organic matter in wastewater is methane gas (see Chaps. 10 and 13). Methane is a colorless, odorless, combustible hydrocarbon of high fuel value. Normally, large quantities of CH_4 are not encountered in untreated wastewater because even small amounts of oxygen tend to be toxic to the organisms responsible for the production of CH_4. Occasionally, however, as a result of anaerobic decay in accumulated bottom deposits, CH_4 has been produced. Because methane is highly combustible and the explosion hazard is high, access ports (manholes) and sewer junctions or junction chambers where there is an opportunity for gas to collect should be ventilated with a portable blower during and before the time required for operating personnel to work in them for inspection, renewals, or repairs. In treatment plants, CH_4 is produced from the anaerobic treatment process used to stabilize wastewater sludges (see Chap 13). In treatment plants where CH_4 is produced, notices should be posted about the plant warning of explosion hazards, and plant employees should be instructed in safety measures to be maintained while working in and about the structures where CH_4 may be present. Methane is also a serious greenhouse gas with an impact of over 25 times that of CO_2 (U.S. EPA, 2008).

Odors

Odors in domestic wastewater are usually caused by gases produced by the decomposition of organic matter or by substances added to the wastewater. Fresh wastewater has a distinctive, somewhat disagreeable odor, which is less objectionable than the odor of wastewater which has undergone anaerobic (devoid of oxygen) decomposition. The most characteristic odor of stale or septic wastewater is that of hydrogen sulfide, which, as discussed previously, is produced by anaerobic microorganisms that reduce sulfate to sulfide. Industrial wastewater may contain either odorous compounds or compounds that produce odors during the process of wastewater treatment. The management of odors from wastewater treatment plants is considered in Chap. 16.

Public Concern. Odors have been rated as the foremost concern of the public relative to the implementation of wastewater treatment facilities. Within the past few years, the control of odors has become a major consideration in the design and operation of wastewater collection, treatment, and disposal facilities, especially with respect to the public acceptance of these facilities. In many areas, projects have been rejected because of the concern over the potential for odors. In view of the importance of odors in the field of wastewater management, it is appropriate to consider the effects they produce, how they are detected, and their characterization and measurement.

Effects of Odors. The importance of odors at low concentrations in human terms is related primarily to the psychological stress they produce rather than to the harm they do to the body. Offensive odors can cause poor appetite for food, lowered water consumption,

Table 2–8

Major odorous compounds and their corresponding odor thresholds associated with untreated wastewater[a]

Odorous compound	Chemical formula	Molecular weight	Odor threshold (typical), ppm_v[b]	Characteristic odor
Ammonia	NH_3	17.0	0.035–53 (1.5)	Ammoniacal, pungent
Chlorine	Cl_2	71.0	0.0095–4.7 (0.15)	Pungent, suffocating
Crotyl mercaptan	$CH_3—CH{=}CH—CH_2—SH$	90.19	0.00003	Skunk like
Dimethyl sulfide	$(CH_3)2^S$	62	0.0001–0.02 (0.002)	Decayed vegetables
Diphenyl sulfide	$(C_6H_5)2^S$	186	0.00005–0.005 (0.0004)	Unpleasant
Ethyl mercaptan	$CH_3(CH_2)SH$	62	0.000009–0.03 (0.0002)	Decayed cabbage
Hydrogen sulfide	H_2S	34	0.00007–1.4 (0.003)	Rotten eggs
Indole	C_8H_6NH	117	0.0001–0.0003 (0.0001)	Fecal, nauseating
Methyl amine	CH_3NH_2	31	0.02–8.7 (0.11)	Putrid, fishy
Methyl mercaptan	CH_3SH	48	0.00002–0.04 (0.0007)	Decayed cabbage
Skatole	C_9H_9N	131	0.00000007–0.05 (0.0002)	Fecal, nauseating
Sulfur dioxide	SO_2	64.07	0.009–5.0 (0.6)	Pungent, irritating
Thiocresol	$CH_3(C_6H_4)SH$	124	0.00006–0.001 (0.0002)	Skunk, rancid

[a] Adapted in part from Patterson et al. (1984) and U.S. EPA (1985a).

[b] Parts per million by volume.

impaired respiration, nausea and vomiting, and mental perturbation. In extreme situations, offensive odors can lead to the deterioration of personal and community pride, interfere with human relations, discourage capital investment, lower socioeconomic status, and deter growth. Also, some odorous compounds (e.g., H_2S) are toxic at elevated concentrations. These problems can result in a decline in market and rental property values, tax revenues, payrolls, and sales.

Detection of Odors by the Human Olfactory System. The odorous compounds responsible for producing psychological stress in humans are detected by the olfactory system, but the precise mechanism involved is at present not well understood. Since 1870, more than 30 theories have been proposed to explain olfaction. One of the difficulties in developing a universal theory has been the inadequate explanation of why compounds with similar structures may have different odors and why compounds with very different structures may have similar odors. At present, there appears to be some general agreement that the odor of a molecule must be related to the molecule as a whole as opposed to some functional group attached to a molecule. Over the years, many attempts have been made to classify odors in a systematic fashion. The major categories of offensive odors and the compounds involved are listed in Table 2–8 along with the corresponding threshold odor values. All of these compounds may be found or may develop in domestic wastewater, depending on local conditions.

Characterization of Odor. In the past, four independent factors were identified typically as being required for the complete characterization of an odor: character, detectability, hedonics, and intensity (see Table 2–9). More recently a fifth factor, persistence, has been added to the list (see Table 2–9). Detectability and persistence are considered further below.

Detectability. Odor, as shown on Fig. 2–17, can be measured (detected) by sensory methods and specific odorant concentrations can be measured by instrumental methods. The application of both methods of odor detection is considered below. In sensory methods, human subjects (often a panel of subjects) are exposed to odors that have been diluted with odor-free air, and the number of dilutions required to reduce an odor to its minimum

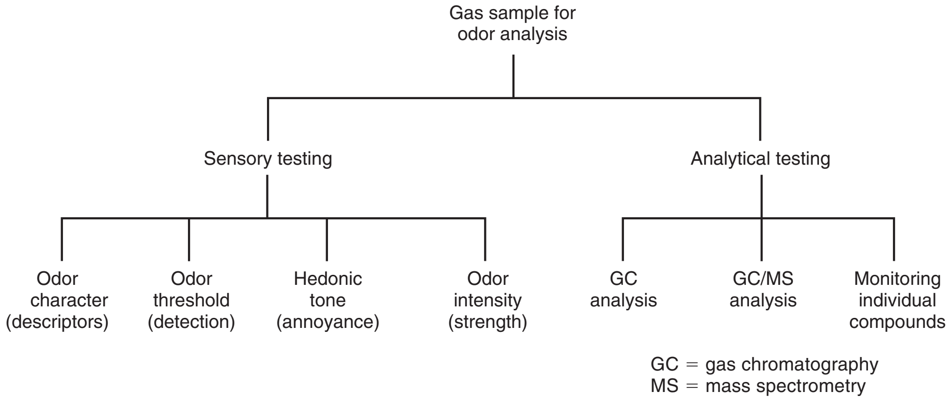
Table 2–9

Factors that must be considered for the complete characterization of an odor

Factor	Description
Character	Relates to the mental associations made by the subject in sensing the odor. Determination can be quite subjective. Typical odor descriptors are listed in the last column of Table 2–8.
Detectability (also threshold)	The number of dilutions required to reduce an odor to its minimum detectable threshold odor concentration (MDTOC).
Hedonics (tone)	The relative pleasantness or unpleasantness of the odor sensed by the subject.
Intensity	The preceived relative strength of the odor above the detection threshold. Usually measured by the butanol olfactometer or calculated from the D/T (dilutions to threshold ratio) when the relationship is established.
Persistence	The rate at which the odor intensity changes with concentration. Persistence can be represented as a dose response function.

Figure 2–17

Classification of methods used to detect odors.



detectable threshold odor concentration (MDTOC) are noted. The detectable odor concentration, reported as the dilutions to the MDTOC, commonly called *dilutions-to-threshold* (D/T) is given by the following expression:

$$\text{D/T} = \frac{\text{Volume of odor free air}}{\text{Volume of odorous air}} \tag{2–52}$$

Thus, if four volumes of odor free air must be added to one volume of odorous air to reduce the odorant to its MDTOC, the odor concentration would be reported as 4 D/T. It should be noted that a number of other measures are used to define the intensity of an odor including the ED_{50} value which represents the number of times an odorous air sample must be diluted before the average person (50 percentile) can barely detect an odor in the diluted sample. To date, detectability is the only factor that has been used in the development of statutory regulations for nuisance odors. The application of D/T values to assess odor impacts is considered in Sec. 16–3 in Chap. 16.

The threshold odor of a water or wastewater sample is determined by diluting the sample with odor-free water. Depending on the nature of the odorous constituents, the diluted sample can be heated to enhance the release of diluted odorous constituents. The "threshold odor number" (TON) corresponds to the greatest dilution of the sample with odor free water at which an odor is just perceptible. The recommended sample size is 200 mL. The numerical value of the TON is determined as follows:

$$\text{TON} = \frac{A + B}{A} \tag{2–53}$$

where TON = threshold odor number
A = mL of sample
B = mL of odor free water

The odor emanating from the liquid sample is determined as discussed above with human subjects (often a panel of subjects). Details for this procedure may be found in Standard Methods (2012).

Persistence. Persistence corresponds to the rate at which a perceived odor intensity decreases as the odor is diluted. Typically odor intensity is defined as

$$I = kC^n \tag{2–54}$$

where I = odor intensity, ppm$_v$ n-butanol
C = concentration of odor, number of dilutions
k, n = coefficients for each specific odor or combination of odors

Three odor intensity measurements at different dilutions are used to establish the dose response. When Eq. (2–54) is linearized and plotted, the slope of the line of best fit corresponds to n. Thus, as the slope of the line decreases, the odor is more persistent. The application of Eq. (2–54) is illustrated in Example 2–8.

Sensory Measurement of Odors. It has been shown that, under carefully controlled conditions, the sensory (organoleptic) measurement of odors by the human olfactory system can provide meaningful and reliable information. Therefore, the sensory method is often used to measure the odors emanating from wastewater-treatment facilities. The availability of a direct reading meter for hydrogen sulfide, described below, which can be used to detect concentrations accurately to 3 ppb and with less accuracy to 1 ppb, is a significant development.

Field Olfactometers. The sensory determination of the minimum threshold odor concentration is subject to a number of errors. Adaptation and cross adaptation, synergism, subjectivity, and sample modification (see Table 2–10) are the principal errors. To avoid errors in sample modification during storage in sample collection containers, direct reading field olfactometers have been developed to measure odors at their source without using sampling containers.

A field olfactometer is a hand-held device in which odorous air can be passed sequentially through a series of graduated orifices and mixed (diluted) with air that has been purified by passing through activated carbon. The orifices are typically sized to provide D/T values of 2, 4, 7, 15, 30, and so on. The dilution ratios are determined by the ratio of the size of the odorous to purified air inlets. Two commonly used field olfactometers, the Scentometer® (Barnebey-Cheney, 1987) and the Nasal Ranger® (St. Croix Sensory, 2006),

Table 2–10

Types of errors in the sensory detection of odors

Description	Type of error
Adaptation and cross adaptation	When exposed continually to a background concentration of an odor, the subject is unable to detect the presence of that odor at low concentrations. When removed from the background odor concentration, the subject's olfactory system will recover quickly. Ultimately, a subject with an adapted olfactory system will be unable to detect the presence of an odor to which his system has adapted.
Sample modification	Both the concentration and composition of odorous gases and vapors can be modified in sample collection containers and in odor detection devices. To minimize problems associated with sample modification, the period of odor containment should be minimized or eliminated, and minimum contact should be allowed with any reactive surfaces.
Subjectivity	When the subject has knowledge of the presence of an odor, random error can be introduced in sensory measurements. Often, knowledge of the odor may be inferred from other sensory signals such as sound, sight, or touch.
Synergism	When more than one odorant is present in a sample, it has been observed that it is possible for a subject to exhibit increased sensitivity to a given odor because of the presence of another odor.

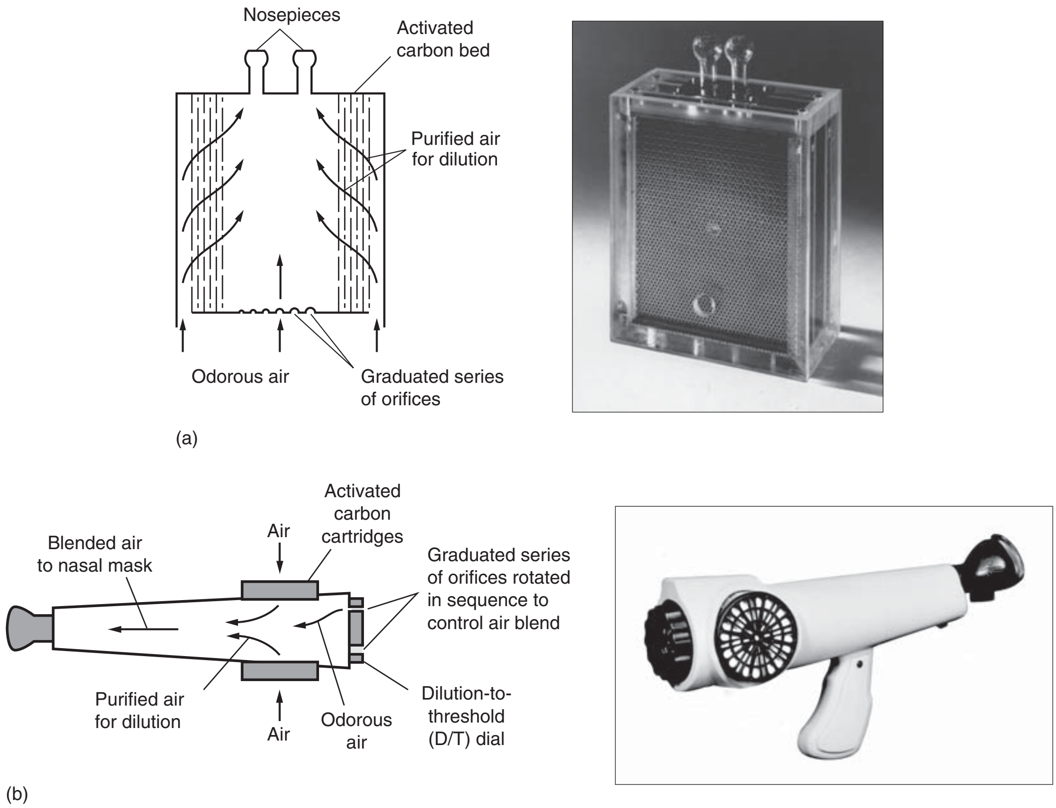


Figure 2–18

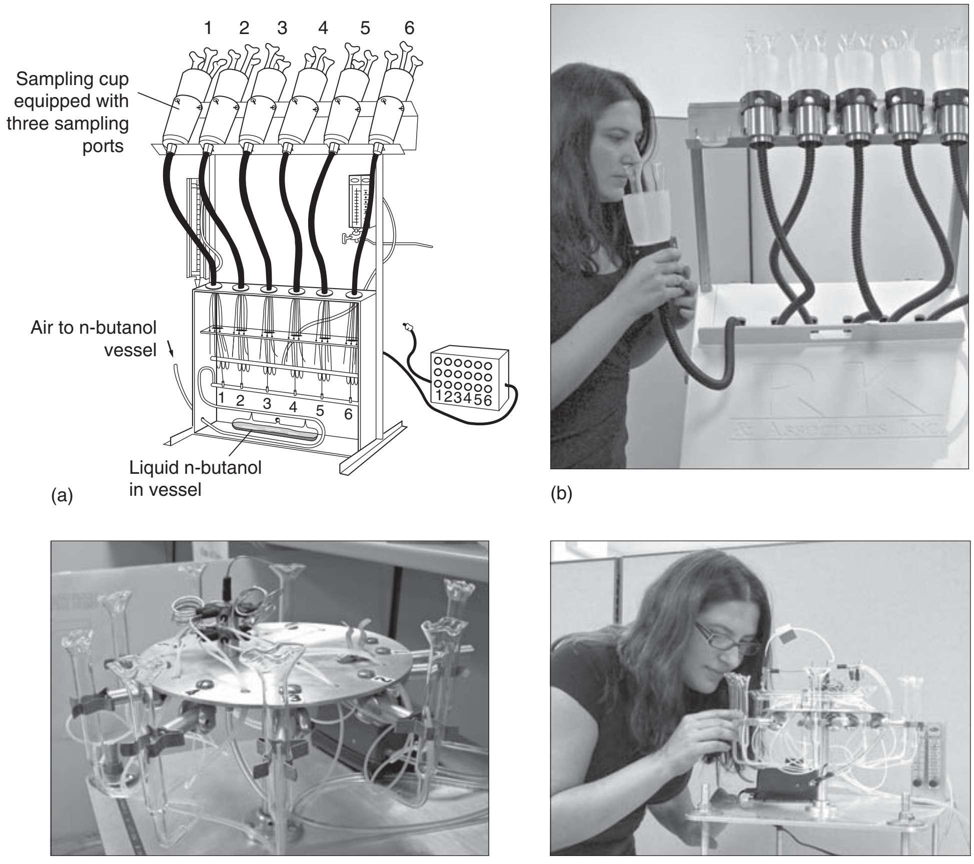
Examples of field hand-held olfactometers used for field odor studies: (a) Scentometer® schematic and front view looking at nose pieces (5 in × 6 in × 2.5 in, from Barnebey & Sutcliffe Corp.) and (b) Nasal Ranger® schematic and pictorial view (from St Croix Sensory Inc.).

are shown on Fig. 2–18. Field olfactometers are very useful for making odor determinations over a large area surrounding a treatment plant. Often a mobile odor laboratory, which contains several types of olfactory and analytical equipment in a single van type vehicle, is used for field sites.

Fixed Olfactometers. Equipment used in a laboratory setting to analyze odors includes (1) the triangle olfactometer, (2) the butanol wheel, and (3) a variety of other specialized olfactometers. The triangle olfactometer enables the operator to introduce the odorous air sample at different concentrations at five or six different cups each equipped with three sampling ports [see Fig. 2–19(a)]. At each cup, two ports contain purified air, and one port contains a diluted sample. Each odor panel member (usually six) then sniffs each of the three ports and *must* select the port he or she believes contains the sample [see Fig. 2–19(b)]. The procedure is repeated at the remaining four or five cups. The concentration of the odorous air is increased in successive cups, typically doubling in each successive cup (ASTM, 2004). The results are analyzed using a standardized statistical program based on signal detection theory (Green and Swets, 1966).

The Butanol Wheel is a device used to measure the intensity of an odor against various concentrations of n-butanol. The device comprises eight sampling ports located on a rotatable disk [see Fig. 2–19(c)]. Dilutions of n-butanol that increase by a factor of two are delivered to



(a) (b) (c) (d)

Figure 2–19

Examples of fixed olfactometers: (a) schematic of dynamic forced-choice triangle olfactometer, (b) panel member sniffing one of the three sample ports, (c) view of Butanol wheel, (d) panel member sniffing one of sample ports. [Figs. (b), (c) and (d) courtesy of RK & Associates, Inc.]

each successive port. Each odor panel member first sniffs the odorous sample being tested and then compares it to the various dilutions of n-butanol starting with Port 1 [see Fig. 2–19(d)]. The test is continued until the panelist identifies the n-butanol dilution which most closely matches the intensity of the odorous sample. The results are reported in ppmv n-butanol odor intensity. Application of Butonal Wheel test results is illustrated in Example 2–8.

EXAMPLE 2–8 **Determination of Relative Persistence** Intensity measurements were made at different dilutions for two odor samples. Using the data provided, determine which of the two odors is more persistent.

n-butanol odor intensity, ppm$_v$	Dilution-to-threshold, D/T	
	Sample A	Sample B
10,000	0	0
100	25	3.2
10	316	10
0	3160	32

Solution

1. Linearize Eq. 2–54 and log transform the given data.
   a. The linearized form of Eq. 2–54 is

      $\log I = \log k + n \log C$

   b. The log transformed data are:

	log D/T	
Log *I*	Sample A	Sample B
3	0	0
2	1.4	0.5
1	2.5	1.0
0	3.5	1.5

3. Plot log *I* versus log *C* and determine the slope *n* to determine which sample is more persistent.
   a. The required plot is given below

   b. The slopes for the two samples are

      Sample A −0.84
      Sample B −2.0

   c. Based on the slopes, Sample A is more persistent than Sample B.

Many of the specialized laboratory olfactometers are designed to work in conjunction with instrumental methods of analysis. For example, the Gerstel ODP2® is used in conjunction with a GC or MS chromatograph for the detection of compounds that as they elute from the separation column. Thus, there is a simultaneous instrumental and olfactory characterization of an odorous compounds (Agus et al., 2011).

Instrumental Measurement of Odors. It is often desirable to know the specific compounds responsible for odor. Although gas chromatography has been used successfully for this purpose, it has not been used as successfully in the detection and quantification

Figure 2–20

of odors derived from wastewater collection, treatment, and disposal facilities. Equipment developed and found useful in the chemical analysis of odors is the triple-stage quadrupole mass spectrometer. The spectrometer can be used as a conventional mass spectrometer to produce simple mass spectra or as a triple-stage quadrupole to produce collisionally activated disassociation spectra. The former operating mode provides the masses of molecular or parent ions present in samples, while the latter provides positive identification of compounds. Types of compounds that can be identified include ammonia, amino acids, and volatile organic compounds (Agus et al., 2011).

An instrumental method has been developed for the measurement of hydrogen sulfide with mid-range accuracy ranging from 0.003 to 25 ppm and with an overall range of 0.001 to 50 ppm. The portable AZI Jerome Model 631 shown on Fig. 2–20 utilizes an inline pump to pull air containing hydrogen sulfide over a gold film sensor for a fixed period of time. The sensor absorbs the hydrogen sulfide and the change in resistance of the gold film sensor is related to the mass concentration of hydrogen sulfide. The sensor is re-zeroed before the next sample cycle. Eventually, when the sensor becomes saturated, a heat cycle is initiated to remove the accumulated hydrogen sulfide from the sensor. In addition to the portable meter, the company also makes a variety of stationary units, which are designed to operate automatically.

2–5 METALLIC CONSTITUENTS

Trace quantities of many metals, such as cadmium (Cd), chromium (Cr), copper (Cu), iron (Fe), lead (Pb), manganese (Mn), and mercury (Hg), nickel (Ni), and zinc (Zn) are important constituents of most waters. Many of these metals are also classified as priority pollutants. However, most of these metals are necessary for growth of biological life, and absence of sufficient quantities of them could limit growth of algae, for example. The presence of any of these metals in excessive quantities will interfere with many beneficial uses of the water because of their toxicity; therefore, it is frequently desirable to measure and control the concentrations of these substances.

Sources of Metallic Constituents

The sources of trace metals in wastewater include the discharges from commercial and industrial activities, products used in residential applications such as cleaning agents and personal care products, and groundwater infiltration. Many of the sources of heavy metals are identified in Table 2–11. For example, cadmium, chromates, lead, and mercury are

Table 2–11

Typical metallic wastes produced by commercial, industrial, and agricultural activities that have been classified as priority pollutants

Name	Formula	Use	Concern
Arsenic	As	Alloying additive for metals, especially lead and copper, battery grids, cable sheaths, boiler tubes. High purity (semiconductor) grade	Carcinogen and mutagen. *Long term*—Sometimes can cause fatigue and loss of energy; dermatitis
Barium	Ba	Getter alloys in vacuum tubes, deoxidizer for copper, Frary's metal, lubricant for anode rotors in x-ray tubes, spark-plug alloys	Flammable at room temperature in powder form. *Long term*—Increased blood pressure and nerve block
Cadmium	Cd	Electrodeposited and dipped coatings on metals, bearing and low-melting alloys, brazing alloys, fire protection system, nickel-cadmium storage batteries power transmission wire, TV phosphors, basis of pigments used in ceramic glazes, machinery enamels, fungicide, photography and lithography, selenium rectifiers, electrodes for cadmium-vapor lamps and photoelectric cells	Flammable in powder form. Toxic by inhalation of dust or fume. A carcinogen. Soluble compounds of cadmium are highly toxic. *Long term*—Concentrates in the liver, kidneys, pancreas, and thyroid; hypertension suspected effect
Chromium	Cr	Alloying and plating element on metal and plastic substrates for corrosion resistance, chromium-containing and stainless steels, protective coating for automotive and equipment accessories, nuclear and high-temperature research, constituent of inorganic pigments	Hexavalent chromium compounds are carcinogenic and corrosive on tissue. *Long term*—Skin sensitization and kidney damage
Lead	Pb	Storage batteries, gasoline additive, cable covering, ammunition, piping, tank linings, solder and fusible alloys, vibration damping in heavy construction, foil, babbit and other bearing alloys	Toxic by ingestion or inhalation of dust or fumes. *Long term*—Brain and kidney damage; birth defects
Mercury	Hg	Amalgams, catalyst electrical apparatus, cathodes for production of chlorine and caustic soda, instruments, mercury vapor lamps, mirror coating, arc lamps, boilers	Highly toxic by skin absorption and inhalation of fume or vapor. *Long term*—toxic to central nervous system, may cause birth defects
Selenium	Se	Electronics, xerographic plates, TV cameras, photocells, magnetic computer cores, solar batteries, (rectifiers, relays), ceramics (colorant for glass) steel and copper, rubber accelerator, catalyst, trace element in animal feeds	*Long term*—Red staining of fingers, teeth, and hair; general weakness; depression; irritation of nose and mouth
Silver	Ag	Manufacture of silver nitrate, silver bromide, photo chemicals; lining vats and other equipment for chemical reaction vessels, water distillation, etc.; mirrors, electric conductors, silver plating electronic equipment; sterilant, water purification, surgical cements, hydration and oxidation catalyst, special batteries, solar cells, reflectors for solar towers, low temperatures brazing alloys, table cutlery, jewelry, dental medical and scientific equipment, electrical contacts, bearing metal, magnet windings, dental amalgams, colloidal silver used as a nucleating agent in photography and medicine, often combined with protein	Toxic metal. *Long term*—Permanent grey discoloration of skin, eyes, and mucus membranes

often present in industrial wastes. These are found particularly in metal-plating wastes and should be removed by pretreatment at the site of the industry rather than be mixed with the municipal wastewater. Fluoride, a toxic anion, is found commonly in wastewater from electronics manufacturing facilities.

Importance of Metals

Metals of importance in the treatment, reuse, and disposal of treated effluents and biosolids are summarized in Table 2–12. All living organisms require varying amounts (macro and micro) of metallic elements, such as iron, chromium, copper, zinc, and cobalt, for proper growth. Although macro and micro amounts of metals are required for proper growth, the same metals can be toxic when present in elevated concentrations. As more use is made of treated wastewater effluent for irrigation and landscape watering, the presence of a variety of

metals must be determined to assess any adverse affects that may occur. Calcium, magnesium, and sodium are of importance in determining the sodium adsorption ratio (SAR) which is used to assess the suitability of treated effluent for agricultural use (see Asano, et al., 2007). Where composted sludge is applied in agricultural applications, the concentration of arsenic, cadmium, copper, lead, mercury, molybdenum, nickel, selenium, and zinc must be determined.

Sampling and Methods of Analysis

Methods for determining the concentrations of these substances vary in complexity according to the interfering substances that may be present (Standard Methods, 2012). Metals are determined typically by flame atomic absorption, electrothermal atomic absorption, inductively coupled plasma, or IPC/mass spectrometry. Various classes of metals are defined as (1) *dissolved metals,* those metals present in unacidified samples that pass through a 0.45 μm membrane filter; (2) *suspended metals,* those metals present in unacidified samples that are retained on a 0.45 μm membrane filter; (3) *total metals,* the total of the dissolved and suspended metals or the concentration of metals determined on an unfiltered sample after digestion; and (4) *acid extractable metals,* those metals in solution after an unfiltered sample is treated with a hot dilute mineral acid (Standard Methods, 2012).

Typical Effluent Discharge Limits for Metals

Increasingly, metallic constituents in effluent discharges and in biosolids are being regulated. Typical discharge requirements for metals and other toxic constituents are reported in Table 2–13. In addition to complying with existing U.S. EPA requirements, many states have adopted more restrictive standards to protect specific beneficial uses.

2–6 AGGREGATE ORGANIC CONSTITUENTS

Organic compounds are normally composed of a combination of carbon, hydrogen, and oxygen, together with nitrogen in some cases. The organic matter in wastewater typically consists of proteins (40 to 60 percent), carbohydrates (25 to 50 percent), and oils and fats (8 to 12 percent). Urea, the major constituent of urine, is another important organic compound contributing to fresh wastewater. Because urea decomposes rapidly, urea is seldom found in other than very fresh wastewater. Because of the complex nature of wastewater, the organic characteristics of interest in wastewater are classified as aggregate and individual. Aggregate organic constituents are comprised of a number of individual compounds that cannot be or are not distinguished separately as opposed to constituents that are determined individually.

Sources of Aggregate Organic Constituents

Along with the proteins, carbohydrates, fats and oils, and urea, derived from food and human wastes, wastewater typically contains small quantities of a very large number of different synthetic organic molecules, with structures ranging from simple to extremely complex. Sources of synthetic organic molecules include unused medicine, personal care products, and household cleaning and maintenance products.

Measurement of Organic Content

In general, the analyses used to measure aggregate organic material may be divided into those used to measure gross concentrations of organic matter greater than about 1.0 mg/L and those used to measure trace concentrations in the range of 10^{-12} to 1 mg/L. Laboratory methods commonly used today to measure gross amounts of organic matter (typically

Table 2–13

Typical discharge limits for toxic constituents found in secondary effluent

Constituent	Units	Average value[a] Daily	Monthly
Arsenic	μg/L	20	
Cadmium	μg/L	1.1	
Chromium	μg/L	11	
Copper	μg/L	4.9	
Lead[b]	μg/L	5.6	
Mercury	μg/L	2.1	0.012
Nickel[b]	μg/L	7.1	
Selenium[b]	μg/L	5.0	
Silver	μg/L	2.3	
Zinc[b]	μg/L	58	
Dieldrin[c]	μg/L	0.0019	0.00014
Lindane	μg/L	0.16	0.063
Tributyltin	μg/L	0.01	0.005
PAHs[d,e]	μg/L	0.049	

[a] Limits apply to the average concentration of all samples collected during the averaging period (daily–24-h period; monthly-calendar month).

[b] Effluent limitation may be met as a 4-d average. If compliance is to be determined based on a 4-d average, then concentrations of four 24-h composite samples must be reported as well as the average of four.

[c] Compliance will be based on the practical quantification level (PQL), 0.07 μg/L.

[d] PAHs = polynuclear aromatic hydrocarbons.

[e] Compliance will be based on the practical quantification level (PQL) for each PAH, 4 μg/L.

Source: Bay Area Regional Water Quality Control Board, Oakland, CA.

greater than 1 mg/L) in wastewater include (1) biochemical oxygen demand (BOD), (2) chemical oxygen demand (COD), and (3) total organic carbon (TOC). Complementing these laboratory tests is the theoretical oxygen demand (ThOD), which is determined from the chemical formula of the organic matter.

Biochemical Oxygen Demand (BOD)

The most widely used parameter of organic pollution applied to both wastewater and surface water is the 5-d BOD (BOD_5). This determination involves the measurement of the dissolved oxygen used by microorganisms in the biochemical oxidation of organic matter. Despite the widespread use of the BOD test, it has a number of limitations, as discussed later in this section. It is hoped that, through the continued efforts of workers in the field, one of the other measures of organic content, or perhaps a new measure, will ultimately be used in its place. Why, then, if the test suffers from serious limitations, is further space devoted to it in this text? The reason is that BOD test results are now used (1) to determine the approximate quantity of oxygen that will be required to biologically stabilize the organic matter present, (2) to determine the size of waste treatment facilities, (3) to measure the efficiency of some treatment processes, and (4) to determine compliance with wastewater discharge permits. Because it is likely that the BOD test will continue to be used for some time, it is important to know the details of the test and its limitations.

Basis for BOD Test. If sufficient oxygen is available, the aerobic biological decomposition of an organic waste will continue until all of the waste is consumed. Three more or less distinct activities occur. First, a portion of the waste is oxidized to end products to obtain energy for cell maintenance and the synthesis of new cell tissue. Simultaneously, some of the waste is converted into new cell tissue using part of the energy released during oxidation. Finally, when the organic matter is used up, the new cells begin to consume their own cell tissue to obtain energy for cell maintenance. This third process is called endogenous respiration. Using the term COHNS (which represents the elements carbon, oxygen, hydrogen, nitrogen, and sulfur) to represent the organic waste and the term $C_5H_7NO_2$ to represent cell tissue, the three processes are defined by the following generalized chemical reactions:

Energy reaction (oxidation)

$$\text{COHNS} + O_2 + \text{bacteria} \rightarrow CO_2 + H_2O + NH_3 + \text{other end products} + \text{energy} \qquad (2\text{–}55)$$

Synthesis reaction

$$\text{COHNS} + O_2 + \text{bacteria} + \text{energy} \rightarrow \underset{\text{New cell tissue}}{C_5H_7NO_2} \qquad (2\text{–}56)$$

Endogenous respiration

$$C_5H_7NO_2 + 5O_2 \rightarrow 5CO_2 + NH_3 + 2H_2O \qquad (2\text{–}57)$$

If only the oxidation of the organic carbon that is present in the waste is considered, the ultimate BOD is the oxygen required to complete the three reactions given above. This oxygen demand is known as the ultimate *carbonaceous* or first-stage BOD and is usually denoted as UBOD.

As will be discussed later, the ammonia produced in the energy reaction, Eq. (2–55), can be oxidized further to nitrite and nitrate. Thus, the BOD test only represents the amount of oxygen need to oxidize the carbonaceous material in a sample.

Description of BOD Test Procedure. The standard BOD test [see Fig. 2–21(a)] involves placing a small sample of the wastewater in a BOD bottle (volume = 300 mL). The bottle is then filled with dilution water saturated in oxygen and containing the nutrients required for biological growth. To ensure that meaningful results are obtained, the sample must be suitably diluted with a specially prepared dilution water so that adequate nutrients and oxygen will be available during the incubation period. Normally, several dilutions are prepared to cover the complete range of possible values. Before stoppering the bottle, the oxygen concentration in the bottle is measured (see Fig. 2–22). When testing wastewaters with low concentrations of microorganisms, a seeded BOD test is conducted [see Fig. 2–21(b)]. The organisms contained in the effluent from primary sedimentation facilities are used commonly as the seed for the BOD test. Seed organisms can also be obtained commercially. When the sample contains a large population of microorganisms (e.g., untreated wastewater), seeding is not necessary.

The standard incubation period is usually five days at 20°C, but other lengths of time and temperatures can be used. After incubating for a period of 5-d at 20°C, the dissolved oxygen concentration is measured again. The BOD of the sample is the difference in the

Figure 2–21

Procedure for setting up BOD test bottles: (a) with unseeded dilution water and (b) with seeded dilution water (Tchobanoglous and Schroeded, 1985).

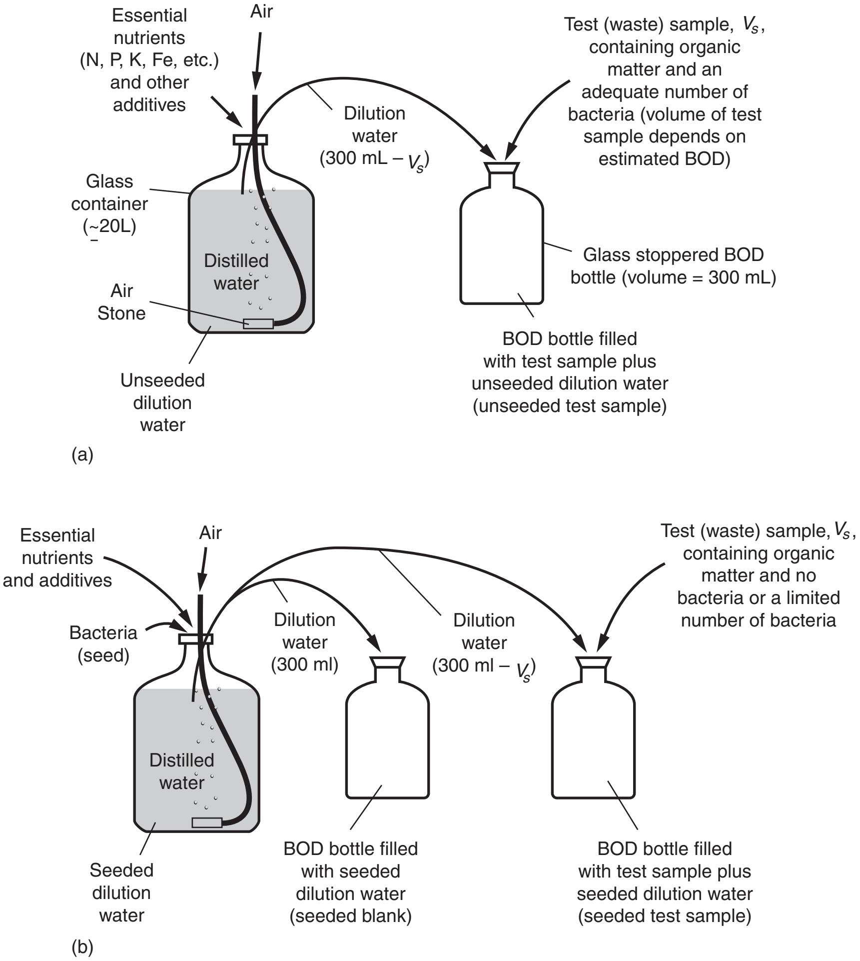

Figure 2–22

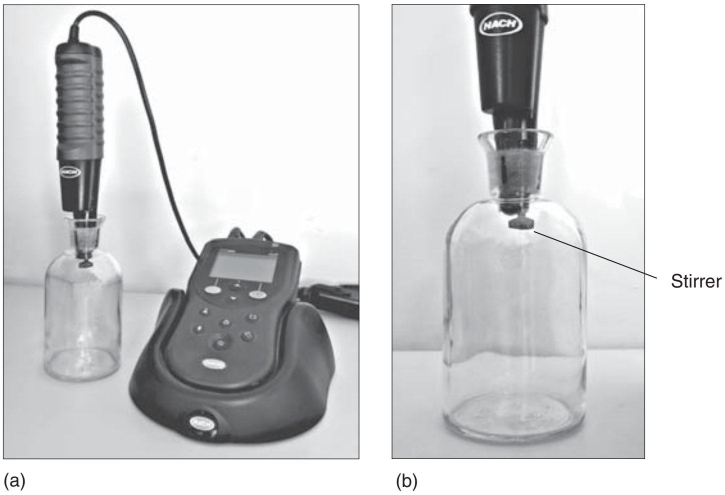
Measurement of oxygen in BOD bottle: (a) with a DO probe equipped with a stirring mechanism and (b) close up of stirrer.



dissolved oxygen concentration values, expressed in milligrams per liter, divided by the decimal fraction of sample used (Standard Methods, 2012). The computed BOD value is known as the 5-d, 20°C biochemical oxygen demand. The 5-d incubation period dates back to the use of the BOD test to assess river pollution in England the late 1800s. Because the maximum time of flow of any river in England from the headwaters to the ocean is 5 days, the 5-d period was, and is, utilized for the test.

Longer time periods (typically seven days), which correspond to work schedules, are often used, especially in small plants where the laboratory staff is not available on the weekends. The temperature, however, should be constant throughout the test. The 20°C temperature used is an average value for slow-moving streams in temperate climates and is easily duplicated in an incubator. Different results would be obtained at different temperatures because biochemical reaction rates are temperature dependent.

Modeling of BOD Reaction. The rate of BOD oxidation ("exertion") is modeled based on the assumption that the amount of organic material remaining at any time, t, is governed by a first order function (see Chap. 1).

$$\frac{d\text{BOD}_r}{dt} = k_1\text{BOD}_r \tag{2–58}$$

Integrating between the limits of UBOD and BOD_t and $t = 0$ and $t = t$ yields:

$$\text{BOD}_r = \text{UBOD}\,(e^{-k_1 t}) \tag{2–59}$$

where BOD_r = amount of waste remaining at time t (d) expressed in oxygen equivalents, mg/L
UBOD = the total or ultimate carbonaceous BOD, mg/L
k_1 = first-order reaction rate constant, 1/d
t = time, d

Thus the BOD exerted up to time t is given by

$$\text{BOD}_t = \text{UBOD} - \text{BOD}_r = \text{UBOD} - \text{UBOD}(e^{-k_1 t}) = \text{UBOD}(1 - e^{-k_1 t}) \tag{2–60}$$

Equation (2–60) is the standard expression used to define the BOD for wastewater. The basis for this equation is discussed in Sec. 1–5 in conjunction with the analysis of a batch reactor. It should be noted that in the literature dealing with the characterization of wastewater, the terms L and BOD_u are often used to denote ultimate carbonaceous BOD (UBOD).

Biochemical oxidation theoretically takes an infinite time to go to completion because the rate of oxidation is assumed to be proportional to the amount of organic matter remaining. Within a 20-d period, the oxidation of the carbonaceous organic matter is about 95 to 99 percent complete, and in the 5-d period used for the BOD test, oxidation is from 60 to 70 percent complete.

BOD Reaction Rate Coefficients. The value of k_1 for untreated wastewater is generally about 0.12 to 0.46 d^{-1} (base e), with a typical value of about 0.23 d^{-1}. The range of k_1 values for effluents from biological treatment processes is from 0.12 to 0.23 d^{-1}. For a given wastewater, the value of k_1 at 20°C can be determined experimentally by observing the variation with time of the dissolved oxygen in a series of incubated samples. If k_1 at 20°C is equal to 0.23 d^{-1}, the 5-d oxygen demand is about 68 percent of the ultimate first-stage demand. Occasionally, the first-order reaction rate constant will be expressed in log (base 10) units. The relationship between k_1 (base e) and K_1 (base 10) is as follows:

$$K_1(\text{base } 10) = \frac{k_1(\text{base } e)}{2.303} \tag{2–61}$$

As discussed above, the temperature at which the BOD of a wastewater sample is determined is usually 20°C. It is possible, however, to determine the reaction constant k at a temperature other than 20°C using the following relationship developed in the discussion on the effects of temperature in Chap. 1, Sec. 1–6:

$$\frac{k_2}{k_1} = \theta^{(T_2 - T_1)} \tag{1–44}$$

The value of the temperature coefficient θ has been found to vary from 1.056 in the temperature range between 20 and 30°C to 1.135 in the temperature range between 4 and 20°C (Schroepfer et al., 1964). A value of θ often quoted in the literature is 1.047 (Phelps, 1944), but it has been observed that this value does not apply at cold temperatures (e.g., below 20°C). Equation (2–60), along with Eq. (1–44), makes it possible to convert test results from different time periods and temperatures to the standard 5-d 20°C test, as illustrated in Example 2–9.

EXAMPLE 2–9 **Calculation of Different BOD Values** Determine the 1-d BOD and ultimate first-stage BOD for a wastewater whose 5-d, 20°C BOD is 200 mg/L. What would have been the 5-d BOD if the test had been conducted at 25°C? The reaction constant k (base e) = 0.23 d^{-1}, and $\theta = 1.047$.

Solution

1. Determine the ultimate carbonaceous BOD.

$$\text{BOD}_5 = \text{UBOD} - \text{BOD}_r = \text{UBOD}(1 - e^{-k_1 t})$$
$$200 = \text{UBOD}(1 - e^{-0.23\times 5}) = \text{UBOD}(1 - 0.317)$$
$$\text{UBOD} = 293 \text{ mg/L}$$

2. Determine the 1-d BOD.

$$\text{BOD}_t = \text{UBOD}(1 - e^{-k_1 t})$$
$$\text{BOD}_1 = 293(1 - e^{-0.23\times 1}) = 293(1 - 0.795) = 60.1 \text{ mg/L}$$

3. Determine the 5-d BOD at 25°C.

$$k_{1_T} = k_{1_{20}}(1.047)^{T-20}$$
$$k_{1_{25}} = 0.23(1.047)^{25-20} = 0.29 \text{ d}^{-1}$$
$$\text{BOD}_5 = \text{UBOD}(1 - e^{-k_1 t}) = 293(1 - e^{-0.29\times 5}) = 224 \text{ mg/L}$$

For polluted water and wastewater, a typical value of k_1 (base e at 20°C) is 0.23 d^{-1} (K_1, base 10, = 0.10 d^{-1}). The value of the reaction rate constant varies significantly, however, with the type of waste. The range may be from 0.05 to 0.3 d^{-1} (base e) or more. For the same ultimate BOD, the oxygen uptake will vary with time and with different reaction rate constant values (see Fig. 2–23).

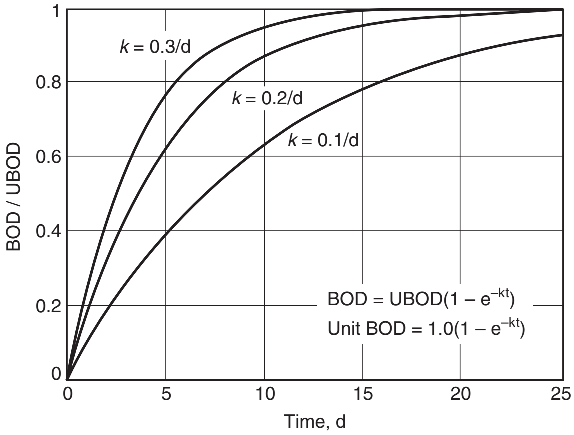
Nitrification in the BOD Test. Noncarbonaceous matter, such as ammonia, is produced during the hydrolysis of proteins. It is now known that a number of bacteria are capable of oxidizing ammonia to nitrite and subsequently to nitrate. The generalized reactions are as follows:

Conversion of ammonia to nitrite (as typified by *Nitrosomonas*):

$$NH_3 + 3/2O_2 \rightarrow HNO_2 + H_2O \tag{2–62}$$

Figure 2–23

Effect of the rate constant k_1 on BOD (for a unit UBOD value).



Conversion of nitrite to nitrate (as typified by *Nitrobacter*):

$$HNO_2 + 1/2O_2 \rightarrow HNO_3 \tag{2–63}$$

Overall conversion of ammonia to nitrate:

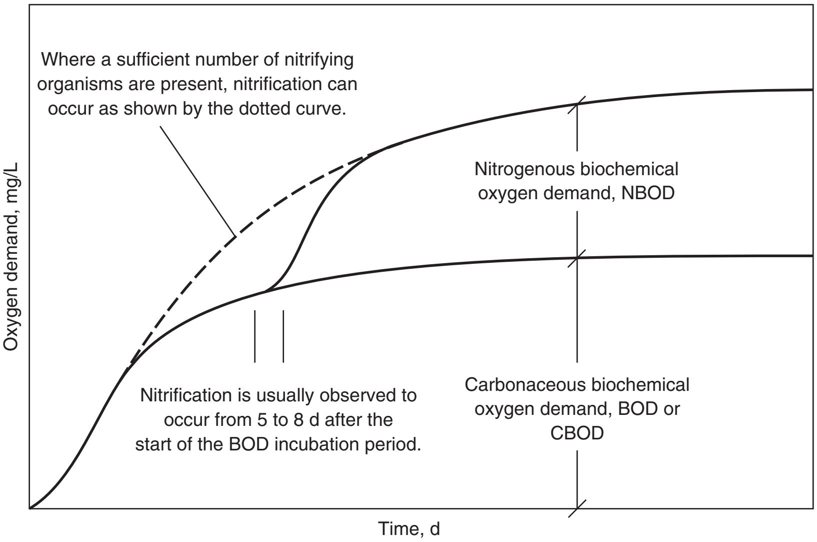
$$NH_3 + 2O_2 \rightarrow HNO_3 + H_2O \tag{2–64}$$

The oxygen demand associated with the oxidation of ammonia to nitrate is called the nitrogenous biochemical oxygen demand (NBOD). The normal exertion of the oxygen demand in a BOD test for a domestic wastewater is shown on Fig. 2–24. Because the reproductive rate of the nitrifying bacteria is slow, it normally takes from 6 to 10 d for them to reach significant numbers to exert a measurable oxygen demand. However, if a sufficient number of nitrifying bacteria is present initially, the interference caused by nitrification can be significant.

When nitrification occurs in the BOD test, erroneous interpretations of treatment operating data are possible. For example, assume the effluent BOD from a biological treatment process is 20 mg/L without nitrification and 40 mg/L with nitrification. If the influent BOD to the treatment process is 200 mg/L, then the corresponding BOD removal efficiency

Figure 2–24

Definition sketch for the exertion of the carbonaceous and nitrogenous biochemical oxygen demand in a waste sample.

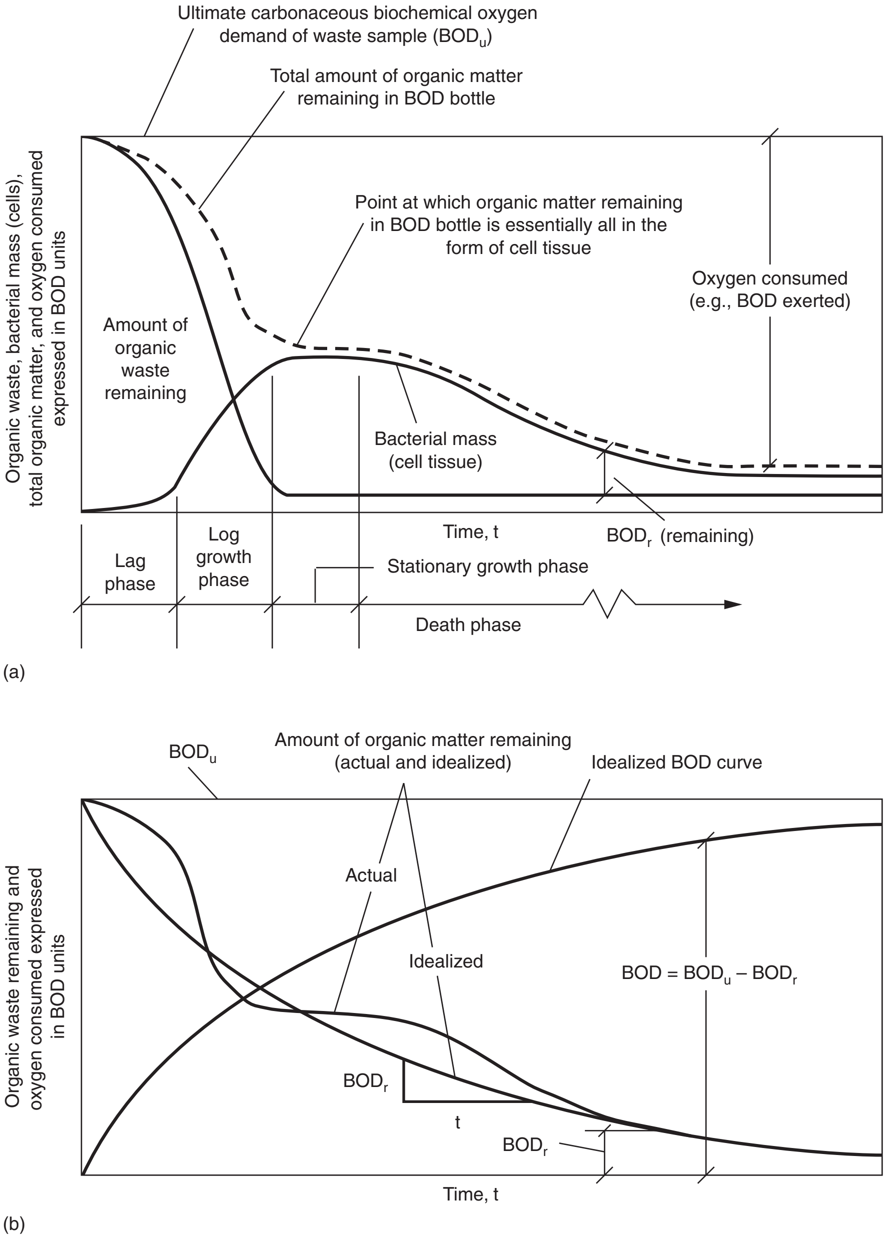


would be reported as 90 and 80 percent without and with nitrification, respectively. Thus, if nitrification is occurring but is not suspected, it might be concluded the treatment process is not performing well, when in actuality it is performing quite well.

Carbonaceous Biochemical Oxygen Demand. When nitrification occurs, the measured BOD value will be higher than the true value due to the oxidation of carbonaceous material (see Fig. 2–25). If a given percentage of carbonaceous biochemical oxygen demand (CBOD) removal must be achieved to meet regulatory permit limits, early nitrification can pose a serious problem. The effects of nitrification can be overcome either by using

Figure 2–25

Functional analysis of the BOD test: (a) interrelationship of organic waste, bacterial mass (cell tissue), total organic waste, and oxygen consumed in BOD test and (b) idealized representation of the BOD test (Tchobanoglous and Schroeder, 1985).



various chemicals to suppress the nitrification reactions, or by treating the sample to eliminate the nitrifying organisms (Young, 1973). Pasteurization and chlorination/dechlorination are two methods that have also been used to suppress the nitrifying organisms.

When the nitrification reaction is suppressed, the resulting BOD is known as the carbonaceous biochemical oxygen demand (CBOD). In effect, the CBOD is a measure of the oxygen demand exerted by the oxidizable carbon in the sample. The CBOD test, in which the nitrification reaction is suppressed chemically, should only be used on samples that contain small amounts of organic carbon (e.g., treated effluent). Errors have sometimes been observed in the measured BOD values when the CBOD test is used on wastewater containing significant amounts of organic matter such as untreated wastewater.

Analysis of BOD Data. The value of k is needed if the BOD_5 is to be used to obtain UBOD, the ultimate or 20-d BOD. The usual procedure followed when these values are unknown is to determine k_1 and UBOD from a series of BOD measurements. There are several ways of determining k_1 and UBOD from the results of a series of BOD measurements, including the method of least-squares, the method of moments (Moore et al., 1950), the daily-difference method (Tsivoglou, 1958), the rapid-ratio method (Sheehy, 1960), the Thomas method (Thomas, 1942, 1950) and the Fujimoto method (Fujimoto, 1961). The least-squares and Fujimoto method are illustrated in the 4th edition of this textbook (Tchobanoglous et al., 2003).

Effect of Particle Size on BOD Reaction Rates. If a separation and analysis technique, such as membrane filtration (see Figs. 2–4 and 2–8), is used to quantify the size distribution of the solids in the influent wastewater, the various size fractions can be correlated to observed oxygen (BOD) uptake rates, determined using a respirometer. As reported in Table 2–14, the observed BOD reaction rate coefficients are affected significantly by the size of the particles in wastewater. Based on the data given in Table 2–14, it is clear that the treatment of a wastewater can be affected by modifying the particle size distribution. Further, wastewaters with significantly different particle size distributions will respond differently, depending on the method of treatment (e.g., in constructed wetlands).

Limitations in the BOD Test. The limitations of the BOD test are as follows: (1) a high concentration of active, acclimated seed bacteria is required; (2) pretreatment is needed when dealing with toxic wastes, and the effects of nitrifying organisms must be reduced; (3) only the biodegradable organics are measured; (4) the test does not have stoichiometric validity after the soluble organic matter present in solution has been used (see Fig. 2–25); and (5) the relatively long period of time required to obtain test results. Of the above, perhaps the most serious limitation is that the 5-d period may or may not correspond to the point where the soluble organic matter that is present has been used. The lack of stoichiometric validity at all times reduces the usefulness of the test results.

Table 2–14

Effect of the size of the biodegradable particles found in wastewater on observed BOD reaction rates[a]

Fraction	Size range μm	k (base 10), d^{-1}
Settleable	>100	0.08
Supracolloidal	1–100	0.09
Colloidal	0.1–1.0	0.22
Soluble	<0.1	0.39

[a] Adapted from Balmat (1957).

Total and Soluble Chemical Oxygen Demand (COD and SCOD)

The COD test is used to measure the oxygen equivalent of the organic material in wastewater that can be oxidized chemically using dichromate in an acid solution, as illustrated in the following equation when the organic nitrogen is in the reduced state (oxidation number $= -3$) (Sawyer et al., 2003).

$$C_nH_aO_bN_c + dCr_2O_7^{2-} + (8d + c)H^+ \rightarrow nCO_2 + \frac{a + 8d - 3c}{2}H_2O + cNH_4^+ + 2dCr^{3+} \tag{2–65}$$

where $d = \frac{2n}{3} + \frac{a}{6} - \frac{b}{3} - \frac{c}{2}$

Although it would be expected that the value of the ultimate carbonaceous BOD would be as high as the COD, this is seldom the case. Some of the reasons for the observed differences are as follows: (1) many organic substances which are difficult to oxidize biologically, such as lignin, can be oxidized chemically, (2) inorganic substances that are oxidized by the dichromate increase the apparent organic content of the sample, (3) certain organic substances may be toxic to the microorganisms used in the BOD test, and (4) high COD values may occur because of the presence of inorganic substances with which the dichromate can react. From an operational standpoint, one of the main advantages of the COD test is that it can be completed in about 2.5 h, compared to 5 or more d for the BOD test. To reduce the time further, a rapid COD test that takes only about 15 min has been developed.

As new methods of biological treatment have been developed, especially with respect to biological nutrient removal, it has become more important to fractionate the COD. The principal fractions are particulate and soluble COD. In biological treatment studies, the particulate and soluble fractions are fractionated further to assess wastewater treatability (see discussion in Chap. 8, Sec. 8–2). Fractions that have been used include (a) readily biodegradable soluble COD, (b) slowly biodegradable colloidal and particulate (enmeshed) COD, (c) nonbiodegradable soluble COD, and (d) nonbiodegradable colloidal and particulate COD. The readily biodegradable soluble COD is often fractionated further into complex COD that can ferment to volatile fatty acids (VFAs) and short chain VFAs (see Fig. 8–4 in Chap. 8). Unfortunately, as noted previously, there is little standardization on the definition of soluble versus particulate COD. Where filtration is the technique used to fractionate the sample, the relative distribution between soluble and particulate COD will vary greatly depending on the pore size of the filter. An alternative method used to determine the soluble COD involves precipitation of the suspended solids and a portion of the colloidal material. The COD of the clarified liquid corresponds to the soluble COD.

Total and Dissolved Organic Carbon (TOC and DTOC)

The TOC test, done instrumentally, is used to determine the total organic carbon in an aqueous sample. The test methods for TOC utilize heat and oxygen, ultraviolet radiation, chemical oxidants, or some combination of these methods to convert organic carbon to carbon dioxide which is measured with an infrared analyzer or by other means. The TOC of a wastewater can be used as a measure of its pollution characteristics and in some cases it has been possible to relate TOC to BOD and COD values. The TOC test is also gaining in favor because it takes only 5 to 10 min to complete. If a valid relationship can be established between results obtained with the TOC test and the results of the BOD test for a given wastewater, use of the TOC test for process control is recommended.

A continuous online TOC analyzer has been developed, in conjunction with the space program, which can be used to detect TOC concentrations in the ppb (parts per billion) range.

Such instruments are used to detect the residual TOC in the treated effluent from microfiltration and reverse osmosis (RO) treatment units. Continuous TOC measurements may be used to monitor the performance of the full-scale RO units, to be used in conjunction with repurification projects in which repurified effluent is proposed to be blended with other waters.

Along with COD, it has also become more important to fractionate the TOC. The principal fractions are particulate TOC and dissolved (soluble) TOC (DTOC). As with COD, the particulate and soluble TOC fractions are fractionated further to assess treatability. It should be noted that the pore size of the filter paper recommended in Standard Methods (2012) for differentiating between dissolved and particulate TOC is 0.45 μm, in contrast to the pore size (2.0 μm or less) used to define TSS and TDS. Again, because of the pore size of the filter paper used, the colloidal material that passes through the filter will be classified as dissolved. Because of the interest in the chemical constituents that make up the DTOC, advanced methods of analysis have been developed to quantify the constituent groupings as illustrated on Fig. 2–26.

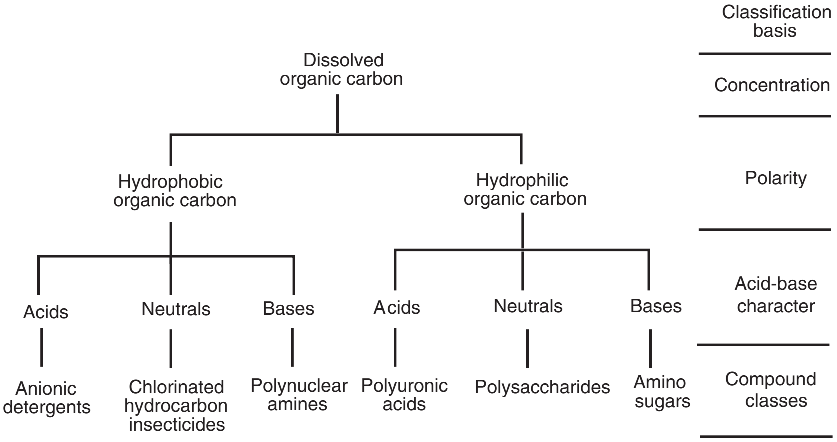
UV-Absorbing Organic Constituents

A number of organic compounds are found in wastewater including humic substances, lignin, tannin, and various aromatic compounds, that strongly absorb ultraviolet (UV) radiation. As a result, UV absorption has been used as a surrogate measure for the organic compounds cited above. The UV wavelengths at which adsorption is determined are typically in the range from 200 to 400 nm, with the value of 254 nm being reported most commonly. The results of UV absorption measurements are reported in units of cm^{-1}, along with the pH and the UV wavelength (e.g., $\text{UV}_\lambda^{\text{pH}}$ where λ is the UV wavelength). This method has proven useful in assessing the aggregate presence of UV absorbing compounds in wastewater, although interfering compounds can render the test invalid.

The results of UV absorption measurements at a wavelength of 254 nm are also correlated to the amount of dissolved organic carbon (DOC) present in a sample that has been filtered through a filter with a pore size of 0.45 μm. The results are reported as the *specific ultraviolet adsorption* (SUVA) per mg/L of DOC. It should be noted that although the UV measurement is correlated to the DOC, SUVA is in fact a measure of the nature of the carbon in the sample being analyzed, more specifically the extent to which the carbon is aromatic. Thus, the SUVA test is used most commonly to distinguish between different water samples. The SUVA test has also been used to assess the potential for the formation of trihalomethanes (THMs) (see Sec. 2–7).

Figure 2–26

Procedure for the characterization of the organic fractions that comprise the TOC.



Theoretical Oxygen Demand (ThOD)

Organic matter of animal or vegetable origin in wastewater is generally a combination of carbon, hydrogen, oxygen, and nitrogen. The principal groups of these elements present in wastewater are, as previously noted, carbohydrates, proteins, oils and grease, and products of their decomposition. The biological decomposition of these substances is discussed in Chap. 7. If the chemical formula of the organic matter is known, the ThOD may be computed as illustrated in Example 2–10.

EXAMPLE 2–10 **Calculation of ThOD** Determine the ThOD for glycine [$CH_2(NH_2)COOH$] using the following assumptions:

1. In the first step, the organic carbon and nitrogen are converted to carbon dioxide (CO_2) and ammonia (NH_3), respectively.
2. In the second and third steps, the ammonia is oxidized sequentially to nitrite and nitrate.
3. The ThOD is the sum of the oxygen required for all three steps.

Solution

1. Write balanced reaction for the carbonaceous oxygen demand.

$$CH_2(NH_2)COOH + 3/2O_2 \rightarrow NH_3 + 2CO_2 + H_2O$$

2. Write balanced reactions for the nitrogenous oxygen demand.

$$\begin{array}{ll} \text{(a)} & NH_3 + 3/2O_2 \rightarrow HNO_2 + H_2O \\ \text{(b)} & \underline{HNO_2 + 1/2O_2 \rightarrow HNO_3 \qquad\quad} \\ & NH_3 + 2O_2 \quad \rightarrow HNO_3 + H_2O \end{array}$$

3. Determine the ThOD.

$$\begin{aligned} \text{ThOD} &= (3/2 + 4/2) \text{ mole } O_2/\text{mole glycine} \\ &= 7/2 \text{ mole } O_2/\text{mole glycine} \times 32 \text{ g/mole } O_2 \\ &= 112 \text{ g } O_2/\text{mole glycine} \end{aligned}$$

Interrelationships between BOD, COD, and TOC

Typical values for the ratio of BOD/COD for untreated municipal wastewater are in the range from 0.3 to 0.8 (see Table 2–15). If the BOD/COD ratio for untreated wastewater is 0.5 or greater, the waste is considered to be easily treatable by biological means. If the ratio is below about 0.3, either the waste may have some toxic components or acclimated microorganisms may be required in its stabilization. The corresponding BOD/TOC ratio for untreated wastewater varies from 1.2 to 2.0. In using these ratios it is important to remember

Table 2–15

Comparison of ratios of various parameters used to characterize wastewater

Type of wastewater	BOD/COD	BOD/TOC
Untreated	0.3–0.8	1.2–2.0
After primary settling	0.4–0.6	0.8–1.2
Final effluent	0.1–0.3[a]	0.2–0.5[b]

[a] CBOD/COD.

[b] CBOD/TOC.

that they will change significantly with the degree of treatment the waste has undergone, as reported in Table 2–15. The theoretical basis for these ratios is explored in Example 2–11.

EXAMPLE 2–11 **Determination of BOD/COD, BOD/TOC, and TOC/COD ratios** Determine the theoretical BOD/COD, BOD/TOC, and TOC/BOD ratios for the compound $C_5H_7NO_2$. Assume the value of the BOD first-order reaction rate constant is 0.23/d (base *e*) (0.10/*d* base 10).

Solution

1. Determine the COD of the compound using Eq. (2–57).

$$C_5H_7NO_2 + 5O_2 \rightarrow 5CO_2 + NH_3 + 2H_2O$$

$$\text{mw } C_5H_7NO_2 = 113, \text{ mw } 5O_2 = 160$$

$$\text{COD} = 160/113 = 1.42 \text{ mg } O_2/\text{mg } C_5H_7NO_2$$

2. Determine the BOD of the compound.

$$\frac{\text{BOD}}{\text{UBOD}} = (1 - e^{-k_1 t}) = (1 - e^{-0.23 \times 5}) = 1 - 0.32 = 0.68$$

$$\text{BOD} = 0.68 \times 1.42 \text{ mg } O_2/\text{mg } C_5H_7NO_2 = 0.97 \text{ mg BOD/mg } C_5H_7NO_2$$

3. Determine the TOC of the compound.

$$\text{TOC} = (5 \times 12)/113 = 0.53 \text{ mg TOC/mg } C_5H_7NO_2$$

4. Determine BOD/COD, BOD/TOC, and TOC/BOD ratios.

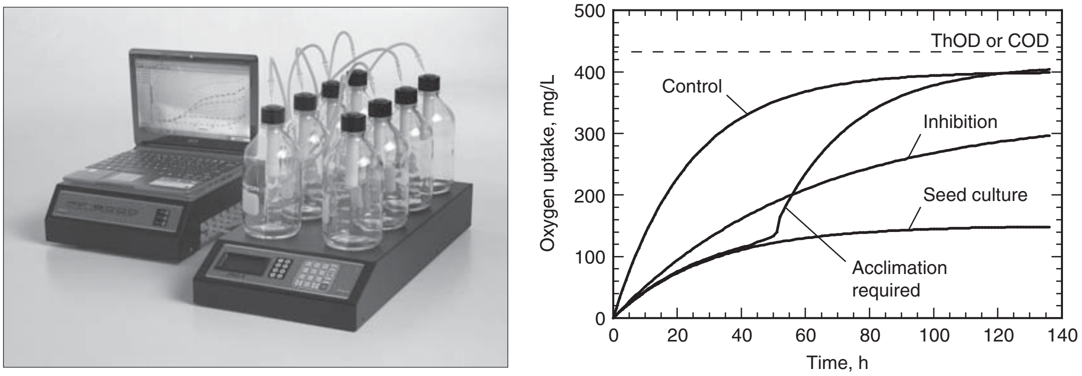
$$\frac{\text{BOD}}{\text{COD}} = \frac{0.68 \times 1.42}{1.42} = 0.68$$

$$\frac{\text{BOD}}{\text{TOC}} = \frac{0.68 \times 1.42}{0.53} = 1.82$$

$$\frac{\text{TOC}}{\text{COD}} = \frac{0.53}{1.42} = 0.37$$

Respirometric Characterization of Aggregate Organic Constituents. Determination of the BOD value and the corresponding rate constant k_1 can be accomplished more effectively using a respirometer as compared to using the bottle technique as described above (Young and Baumann, 1976a, 1976b; Young, et al., 2003). Respirometers are devices that are used to measure the rate of respiration of living microorganisms in aerobic, anoxic, and anaerobic environments.

Description. Modern headspace-gas respirometers work by maintaining a constant oxygen pressure over a sample containing microorganisms that are in the process of metabolizing an organic substrate by replacing the oxygen as it is consumed by the microorganisms. Oxygen replacement is accomplished by means of an electrolysis cell, a bubble-type flow cell, or by transducer-controlled pneumatic injection. An example of a



(a) (b)

Figure 2–27

View of respirometer and response curves: (a) commercial headspace-gas respirometer (courtesy of Respirometer Systems and Applications, LLC) and (b) typical oxygen uptake curves for wastewater samples having different biodegradation characteristics (Young and Cowan, 2004).

typical commercially available respirometer is shown on Fig. 2–27(a). The principal advantages of modern headspace-gas respirometers over manometric respirometers, such as Gilson or Warburg respirometers (Tchobanoglous and Burton, 1991), are (1) the use of a large (1-L) sample that minimizes the errors of grab sampling and pipetting in dilutions and (2) oxygen consumption is measured continuously, thereby providing much more detail about the progress of the biological reaction.

Respirometric Applications. Used initially for the determination of the BOD and rate constants, respirometry is now used in a number of different applications in the field of wastewater treatment, including (1) monitoring oxygen uptake rates in activated sludge mixed liquors, (2) assessing biodegradability and treatability of industrial wastewaters, (3) assessing toxicity of industrial chemicals to wastewater treatment processes, and (4) assessing nutrient deficiencies (Young and Cowan, 2004). Biodegradation characteristics can vary among chemical types and wastewater sources, as illustrated on Fig. 2–27(b). The curve labeled "control" represents oxygen uptake of readily biodegradable substances. The curve labeled "inhibition" is characteristic of the oxygen uptake for chemicals that may be toxic or have low rates of biodegradation. When acclimation is required, a delay in oxygen uptake will occur, but the initial rates of oxygen uptake will be similar to that of the seed culture. Other patterns can occur depending on the type of stresses imposed on the seed culture.

Oil and Grease

The term *oil and grease,* as commonly used, includes the fats, oils, waxes, and other related constituents found in wastewater. The term *fats, oil, and grease* (FOG) used previously in the literature has been replaced by the term oil and grease. The oil and grease content of a wastewater can be determined by several methods based on liquid-liquid extraction and solid phase adsorption followed by liquid extraction (Standard Methods, 2012). Following the extraction step, the solvent used in the extraction is evaporated and the residual oil and grease content is determined gravimetrically. Other extractable substances include mineral oils, such as kerosene and lubricating and road oils. Oil and grease are quite similar chemically; they are compounds (esters) of alcohol or glycerol (glycerin) with fatty acids. The glycerides of fatty acids that are liquid at ordinary temperatures are called oils, and those that are solids are called grease (or fats).

If grease is not removed before discharge of treated wastewater, it can interfere with the biological life in the surface waters and create unsightly films. The thickness of oil required to form a translucent film on the surface of a water body is about 0.0003048 mm (0.0000120 in.), as given in the following table.

	Film thickness		**Quantity spread**	
Appearance	**in.**	**mm**	**gal/mi²**	**L/ha**
Barely visible	0.0000015	0.0000381	25	0.365
Silvery sheen	0.0000030	0.0000762	50	0.731
First trace of color	0.0000060	0.0001524	100	1.461
Bright bands of color	0.0000120	0.0003048	200	2.922
Colors begin to dull	0.0000400	0.0010160	666	9.731
Colors are much darker	0.0000800	0.0020320	1332	19.463

Source: Eldridge (1942).

Fats and oils are contributed to domestic wastewater in butter, lard, margarine, and vegetable fats and oils. Fats are also commonly found in meats, in the germinal area of cereals, in seeds, in nuts, and in certain fruits. The low solubility of fats and oils reduces their rate of microbial degradation. Mineral acids attack them, however, resulting in the formation of glycerin and fatty acid. In the presence of alkalies, such as sodium hydroxide, glycerin is liberated, and alkali salts of the fatty acids are formed. These alkali salts are known as soaps. Common soaps are made by saponification of fats with sodium hydroxide. They are soluble in water, but in the presence of hardness constituents, the sodium salts are changed to calcium and magnesium salts of the fatty acids, or so-called mineral soaps. These are insoluble and are precipitated.

Kerosene, lubricating, and road oils are derived from petroleum and coal tar and contain essentially carbon and hydrogen. These oils sometimes reach the collection system in considerable volume from shops, garages, and streets. For the most part, they float on the wastewater, although a portion is carried into the sludge on settling solids. To an even greater extent than fats, oils, and soaps, the mineral oils tend to coat surfaces. The particles interfere with biological action and cause maintenance problems.

Surfactants

Surfactants, or surface-active agents, are large organic molecules that are slightly soluble in water and cause foaming in wastewater treatment plants and in the surface waters into which the waste effluent is discharged. Surfactants are composed most commonly of a strongly hydrophobic group combined with a strongly hydrophilic group. Typically, the hydrophobic group is a hydrocarbon radical (R) made up of 10 to 20 carbon atoms. Two types of hydrophobic groups are used: those that will and those that will not ionize in water. Anionic surfactants are negatively charged [e.g., $(RSO_3N)^-Na^+$], whereas cationic surfactants are positively charged [e.g., $(RMe_3N)^+Cl^-$]. Nonionizing (nonionic) surfactants commonly contain a polyoxyethylene hydrophilic group ($ROCH_2CH_2OCH_2CH_2 \ldots OCH_2CH_2OH$, often abbreviated RE_n, where n is the average number of $—OCH_2CH_2—$ units in the hydrophilic group). Hybrids of these types also exist. In the United States, ionic surfactants amount to about two-thirds of the total surfactants used and nonionics to about one-third (Standard Methods, 2012).

Surfactants tend to collect at the air-water interface with the hydrophilic group in the water and the hydrophobic group in the air. During aeration of wastewater, these compounds collect on the surface of the air bubbles and thus create a very stable foam. Before 1965, the type of surfactant present in synthetic detergents, called alkyl-benzene-sulfonate (ABS), was especially troublesome because it resisted breakdown by biological means. As a result of legislation in 1965, ABS has been replaced in detergents by linear-alkyl-sulfonate (LAS), which is biodegradable. Because surfactants come primarily from synthetic detergents, the foaming problem has been greatly reduced. It should be noted that so called “hard” synthetic detergents are still used extensively in many foreign countries.

Two tests are now used to determine the presence of surfactants in water and wastewater. The MBAS (methylene blue active substances) test is used for anionic surfactants. The determination of surfactants is accomplished by measuring the color change in a standard solution of methylene blue dye. Nonionic surfactants are measured using the CTAS (cobalt thiocyanate active substances) test. Nonionic surfactants will react with the CTAS to produce a cobalt containing product which can be extracted into an organic liquid and then measured. It should be noted that the CTAS method requires sublimation to remove nonsurfactants and ion exchange to remove the cationic and anionic surfactants (Standard Methods, 2012).

Chemical Energy in Wastewater and Biosolids

The chemical energy content of the organic constituents in untreated wastewater, primary sludge, and biosolids can be determined by (1) using a full-scale boiler as a calorimeter, (2) using a laboratory bomb calorimeter, and (3) by calculation, if the elemental composition is known. Because of the difficulty in instrumenting a full-scale boiler, most of the experimental data on the energy content of the organic constituents of wastewater, sludge, and biosolids are based on the results of bomb calorimeter tests (Shizas and Bagley, 2004; Zanoni and Mueller, 1982).

The energy content of wastewater can be estimated from an elemental analysis of the constituents in organic compounds using the following expression, which is a modified form of the DuLong formula developed by Channiwala (1992), also Channiwala and Parikh (2002).

$$\text{HHV (MJ/kg)} = 34.91\,C + 117.83\,H - 10.34\,O - 1.51\,N + 10.05\,S - 2.11A \tag{2–66}$$

Where HHV is the high heating value and C is the weight fraction of carbon; H of hydrogen; O of oxygen; N of nitrogen; S of sulfur; and A of ash as derived from an ultimate analysis or from the chemical formula, if known. When the HHV is used, it is assumed that the water component is in liquid state at the end of combustion. Another estimate of the heating value of a combustible material is the lower LHV (lower heating value), in which it is assumed that latent heat of vaporization is not recovered. In general, the LHV is about 6 to 8 percent lower than the corresponding HHV. For stationary combustion units with exhaust heat recovered, use of the HHV is the most appropriate. Where exhaust heat is not recovered, use of the LHV is most appropriate. Also, in most of the European literature, LHVs are reported, whereas HHVs are reported in the American literature. The application of Eq. 2–66 is illustrated in Example 2–12.

EXAMPLE 2–12 **Estimate the Chemical Energy Content of Untreated Wastewater and Biosolids** Estimate the chemical energy content, on a COD basis, of (1) the organic fraction of untreated wastewater, composed of 50, 40, and 10 percent proteins, carbohydrates, and fat, respectively and (2) biosolids comprised of bacterial cell biomass. Assume the chemical composition of untreated wastewater is $C_{7.9}H_{13}O_{3.7}NS_{0.04}$ with an ash content of 3 percent. The composition of the cell biomass is $C_5H_7O_2N$ (Hoover and Porges, 1952) with an ash content of 3 percent. Express results on the basis of MJ/kg organic fraction or biosolids COD.

Solution-Part 1 Untreated Wastewater

1. Determine the energy content of the wastewater using Eq. 2–66.
   a. Determine the weight fractions of the elements and ash comprising the wastewater.

Component	Coefficient	Molecular weight	Molecular mass	Weight fraction
Carbon	7.9	12	94.8	0.50[a]
Hydrogen	13	1	13	0.07
Oxygen	3.7	16	59.2	0.31
Nitrogen	1	14	14	0.08
Sulfur	0.04	32	1.28	0.01
Ash	0			0.03
			182.28	1.00

[a] (94.8/182.28) × 0.97 = 0.50.

   b. The energy content of the organic fraction using Eq. 2–66 is:

$$\text{HHV (MJ/kg organic fraction)} = 34.91\,(0.50) + 117.83\,(0.07) - 10.34\,(0.31) - 1.51\,(0.08) + 10.05(0.01) - 2.11\,(0.03)$$

$$\text{HHV (MJ/kg organic fraction)} = 17.45 + 8.25 - 3.21 - 0.12 + 0.10 - 0.06 = 22.41$$

2. Determine the COD of the organic fraction.
   a. Write a balanced reaction for the chemical oxidation of the biomass neglecting sulfur.

$$\underset{182.28}{C_{7.9}H_{13}NO_{3.7}} + \underset{8.55(32)}{8.55O_2} \rightarrow 7.9CO_2 + NH_3 + 5H_2O$$

   b. The COD of the organic fraction is

$$\text{COD} = 8.55(32\text{ g }O_2\text{/mole})/(182.28\text{ g organic fraction/mole})$$

$$= 1.50\text{ g }O_2\text{/g organic fraction}$$

3. Determine the energy content of the biomass in terms of MJ/kg biosolids COD

$$\text{HHV (MJ/kg organic fraction COD)} = \frac{(22.77\text{ MJ/kg of organic fraction})}{(1.50\text{ kg }O_2\text{/kg of organic fraction})}$$

$$= 15.1\text{ MJ/kg of organic fraction COD}$$

Solution-Part 2 Biosolids

1. Determine the energy content of the biosolids using Eq. 2–66.
   a. Determine the weight fractions of the elements and ash comprising the biosolids.

Component	Coefficient	Molecular weight	Molecular mass	Weight fraction
Carbon	5	12	60	0.52[a]
Hydrogen	7	1	7	0.06
Oxygen	2	16	32	0.27
Nitrogen	1	14	14	0.12
Sulfur	0	32	0	0
Ash	0			0.03
			113	1.00

[a] (60/113) × 0.97 = 0.52.

b. The energy content of the biosolids using Eq. 2–66 is

$$\text{HHV (MJ/kg biosolids)} = 34.91\,(0.52) + 117.83\,(0.06) - 10.34\,(0.27) - 1.51(0.12) - 2.11\,(0.03)$$

$$\text{HHV (MJ/kg biosolids)} = 18.15 + 7.07 - 2.79 - 0.18 - 0.06 = 22.19$$

2. Determine the COD of the biosolids.

a. Write a balanced reaction for the chemical oxidation of the biomass.

$$\underset{113}{C_5H_7NO_2} + \underset{5(32)}{5O_2} \rightarrow 5CO_2 + NH_3 + 2H_2O$$

b. The COD of the biosolids is

$$\begin{aligned}\text{COD} &= 5(32\text{ g }O_2\text{/mole})/(113\text{ g/mole biosolids})\\ &= 1.42\text{ g }O_2\text{/g biosolids}\end{aligned}$$

3. Determine the energy content of the biomass in terms of MJ/kg biosolids COD.

$$\begin{aligned}\text{HHV (MJ/kg biosolids COD)} &= \frac{(22.19\text{ MJ/kg of biosolids})}{(1.42\text{ kg }O_2\text{/kg of biosolids})}\\ &= 15.63\text{ MJ/kg of biosolids COD}\end{aligned}$$

Comment In practice, because the HHV is difficult to recover, the LHV is often used in place of the HHV. If the difference between the HHV and LHV is assumed to be eight percent, the corresponding LHV of the organic fraction and biosolids is 13.74 MJ/kg organic fraction and 14.38 MJ/ kg biosolids COD.

2–7 INDIVIDUAL ORGANIC COMPOUNDS

Individual organic compounds are determined to assess the presence of priority pollutants identified by the U.S. Environmental Protection Agency (U.S. EPA) and a number of new emerging compounds of concern (for which regulations have not been written). Priority pollutants (both inorganic and organic) have been and are continuing to be selected on the basis of their known or suspected carcinogenicity, mutagenicity, teratogenicity, or high acute toxicity. As the techniques used to identify specific compounds continue to improve, several other organic compounds have been detected in public water supplies and in treated wastewater effluents.

Sources of Individual Organic Compounds

The individual compounds of concern can be grouped into several categories: (1) priority pollutants, (2) volatile organic compounds (VOCs), (3) disinfection byproducts, (4) pesticides and agricultural chemicals, and (5) unregulated trace organic compounds. The sources of priority pollutants are primarily from commercial and industrial discharges and, to a very limited extent, from products used in domestic applications. Volatile organic compounds are derived primarily from commercial and industrial sources. Pesticides and agricultural chemicals found in wastewater are primarily from surface runoff from agricultural, vacant, and park lands. Unregulated trace organic compounds in question are derived, in large part, from (1) human and veterinary antibiotics, (2) human prescription and nonprescription drugs, (3) industrial and household wastewater products, and (4) sex and steroidal hormones.

Priority Pollutants

The U.S. EPA initially identified 129 priority pollutants in 65 classes to be regulated by categorical discharge standards; three were removed in 1981 (Federal Register, 1982). Priority pollutants (both inorganic and organic) were selected on the basis of their known or suspected carcinogenicity, mutagenicity, teratogenicity, or high acute toxicity. Many of the organic priority pollutants are also classified as volatile organic compounds (VOCs). Two types of standards are used to control pollutant discharges to public-owned treatment works (POTWs). The first, "prohibited discharge standards," applies to all commercial and industrial establishments which discharge to POTWs. Prohibited standards restrict the discharge of pollutants that may create a fire or explosion hazard in collection systems or treatment works, are corrosive ($pH < 5.0$), obstruct flow, upset treatment processes, or increase the temperature of the wastewater entering the plant to above 40°C. "Categorical Standards" apply to industrial and commercial discharges in 25 industrial categories ("categorical industries") and are intended to restrict the discharge of priority pollutants. It is anticipated that this list will continue to be updated in future.

Volatile Organic Compounds (VOCs)

Organic compounds that have a boiling point less than or equal to 100°C or a vapor pressure greater than 1 mm Hg at 25°C are generally considered to be volatile organic compounds (VOCs). For example, vinyl chloride, which has a boiling point of -13.9°C and a vapor pressure of 2548 mm Hg at 20°C, is an example of an extremely volatile organic compound. Volatile organic compounds are of great concern because (1) once such compounds are in the vapor state they are much more mobile and, therefore, more likely to be released to the environment; (2) the presence of some of these compounds in the atmosphere may pose a significant public health risk; and (3) they contribute to a general increase in reactive hydrocarbons in the atmosphere, which can lead to the formation of photochemical oxidants. The release of these compounds in collection systems and at treatment plants, especially at the headworks, is of particular concern with respect to the health of the collection system and treatment plant workers. The physical phenomena involved in the release and control of VOCs is considered in more detail in Chap. 16.

Disinfection Byproducts

It has been found that when chlorine is added to water containing organic matter several organic compounds containing chlorine are formed. Collectively, these compounds, along with others, are known as disinfection byproducts (DBPs). Although generally present in low concentrations, they are of concern because many of them are known or suspected potential human carcinogens. Typical classes of compounds include trihalomethanes (THMs), haloacetic acids (HAAs), trichlorophenol, and aldehydes.

In the last decade N-Nitrosodimethylamine (NDMA) has been found in the effluent from wastewater treatment plants. The reason for concern over this compound is because as a group of compounds, nitrosamines are among the most powerful carcinogens known (Snyder, 1995). These compounds are also known to be carcinogenic to various fish species at low concentrations. The U.S. EPA action limit for NDMA is two parts per trillion. Based on the results of recent studies, NDMA appears to be formed during the chlorination process. In treated effluent, the nitrite ion can react with hydrochloric acid, present as result of the use of chlorine for disinfection, to form nitrous acid. In turn, nitrous acid can react with dimethylamine to form NDMA (Hill, 1988). The compound dimethylamine is common in wastewater and surface waters, being found in urine, feces, algae, and plant tissues. Dimethylamine is also part of some polymers used for water treatment (such as polydiallyl dimethylamine) and for ion exchange resins. The formation of NDMA under basic and alkaline conditions has been reported by Wainwright (1986).

Because of the concern over the formation of DBPs and NDMA, considerable attention has been focused on the use of ultraviolet (UV) disinfection as a possible replacement for chlorine. In addition, considerable attention has been focused on the modifications to conventional treatment processes to improve the treatment of these compounds and to advanced treatment processes for the removal of these substances. The use of UV radiation for disinfection and the destruction of NDMA is considered in Chap. 12.

Pesticides and Agricultural Chemicals

Pesticides, herbicides, and other agricultural chemicals, are toxic to many organisms and, therefore, can be significant contaminants of surface waters. Concentrations of these chemicals can result in fish kills, in contamination of the flesh of fish that decreases their value as a source of food, and in impairment of water supplies. These chemicals are not common constituents of domestic wastewater.

Unregulated Trace Organic Compounds

In addition to the compounds discussed above for which requirements have been established, varieties of new unregulated (often referred to as emerging, trace or micropollutant compounds) compounds have been identified in many of the nation's water supplies and in treated wastewater effluents at low ng/L or low ug/L concentrations. The compounds in question are derived, in large part, from (1) human and veterinary antibiotics, (2) human prescription and nonprescription drugs, (3) industrial and household wastewater products, and (4) sex and steroidal hormones. Typical examples of types of compounds involved are reported in Table 2–16. As more becomes known about the health impacts of these compounds, it is anticipated that discharge limits may be developed for a number of these compounds. Given that over 30 million organic compounds are known to exist, it is clear that the list of emerging compounds will continue to grow as analytical techniques continue to improve.

Analysis of Individual Organic Compounds

The analytical methods used to determine individual organic compounds require the use of sophisticated instrumentation capable of measuring trace concentrations in the range of 10^{-12} to 10^{-3} mg/L. Gas chromatographic (GC) and high-performance liquid chromatographic (HPLC) methods are used most commonly to detect individual organic compounds. Different types of detectors are used with each method, depending on the nature of the compound being analyzed. Typical detectors used in conjunction with gas chromatography include electrolytic conductivity, electron capture (ECD), flame ionization (FID),

Table 2–16

Representative organic constituents found in wastewater and in streams[a]

Veterinary and human antibiotics

Carbadox
Chlortetracycline
Ciprofloxacin
Dolcycline
Enrofloxacin
Erythromycin
Erythromycin-H_2O
Ivermectin
Lincomycin
Norfioxacin
Oxytetracycline
Roxarsone
Roxithromycin
Sarafloxacin
Spectinomycin
Sulfachlorpyridazine
Sulfadimethoxine
Sulfamethazine
Sulfamethazine
Sulfamethiazole
Sulfathiazole
Sulfamethoxazole
Tetracycline
Trimethoprim
Tylosin
Virginiamycin

Sex and steroidal hormones

Cis-androsternone
3-β-coprostanol
Cholesterol
Equilenin
Equilin
Estrone
Estriol
17α-estradiol
17β-estradiol
17α-ethynylestradiol
Mestranol
19-norethisterone
Progesterone
Testosterone

Human prescription and non-prescription drugs (general use)

Acetominophen (antipyretic)
Albuterol (antiasthmatic)
Amoxicillin (antibiotic)
Caffeine (stimulant)
Carbamazepine (anticonvulsant)
Cimetidine (antacid)
Codeine (analgesic)
Cotinine (nicotine metabolite)
Dehydronifedipine (antianginal)
Digoxigenin (digoxin metabolite)
Diltiazem (antihypertensive)
Diphenhydramine (antihistamine)
Enalaprillat (antihypertensive)
Fluoxetine (antidepressant)
Furosemide (diuretic)
Gemfibrozil (lipotropic agent)
Ibuprofen (anti-inflammatory)
Mefformin (antidiabetic agent)
Paroxetine (paxil metabolite)
Paraxanthine (caffeine metabolite)
Ranitidine (antacid)
Salbutamol (antiasthmatic)
Sulfamethoxazole (antibiotic)
Trimethoprim (antibiotic)
Warfarin (anticoagulant)

Industrial and Household Wastewater Products (general use)

Acetophenone (fragrance)
Anthracene (PAH)[b]
Benzo(a)pyrene (PAH)
Benzophenone (used in plastics)
2,6-di-tert-para-benzoquinone (antioxidant)
5methyl 1 H benzotriazole (antioxidant)
Lindane (pesticide)
Methyl parathion (pesticide)
Napthalene (PAH)
NPEO1 – total (detergent metabolite)
NPEO2 – total (detergent metabolite)
OPEO1 (detergent metabolite)

(*continued*)

Table 2–16 (*Continued*)

Industrial and household wastewater products (continued)	
Bisphenol A (used in polymers)	OPEO2 (detergent metabolite)
Bis(2-ethylhexyl)phthalate (plasticizer)	Pentachlorophenol (wood preservative)
2,6-di-te-butylphenol (antioxidant)	Phenanthrene (PAH)
Butylated hydroxyanisole (antioxidant)	Phenol (disinfectant)
Butylated hydroxytoluene (antioxidant)	Para–nonylphenol-total (detergent metabolite)
Caffeine (stimulant)	Phthalic anhydride (used in plastics)
Cholesterol (plant/animal steroid)	Pyrene (PAH)
Codeine (analgesic)	Stigmastanol (plant sterol)
Cotinine (nicotine metabolite)	Tetrachloroethylene (solvent)
3b-coprostanol (carnivore fecal indicator)	Tributyl phosphate (fire retardant)
Para-cresol (wood preservative)	Triclosan (antimicrobial disinfectant)
Diethylphthalate (plasticizer)	Tri(2-butoxyethyl) phosphate (plasticizer)
1,4-dichorobenzene (fumigant)	Tri(2-chloroethyl) phosphate (fire retardant)
Ethanol, 2-butoxy-, phosphate (plasticizer)	Tri(dichlorisipropyl) phosphate (fire retardant)
Fluoranthene (PAH)	Triphenyl phosphate (plasticizer)
Fungicide, herbicides, insecticides, and pesticides (general use)	
Bromacil (herbicide)	Diazinon (insecticide)
Carbazole (insecticide)	Dieldrin (pesticide)
Carbraryl (insecticide)	Metolachlor (herbicide)
Chlorpyrifos (insecticide)	N,N-diethyltoluamide (DEET) (insecticide)
Chlorpyrifos (pesticide)	Prometon (herbicide)
Cis-chlordane (pesticide)	Thiabendazole (fungicide)
Other compounds (general use)	
Anthraquinone (aromatic organic compound used in manufacturing)	1,3,4,6,7,8-hexahydro-4,6,6,7,8,8,-hexamethylcyclopenta-γ-2-benzopyran (fragrances)
β-sitostrol (plant steroid)	
β-stigmastanol (plant steroid)

[b] PAH = polynuclear aromatic hydrocarbon.

photoionization (PID) and mass spectrometer (GCMS). Typical detectors for high-performance liquid chromatography include photodiode array (PDAD) and post column reactor (PCR). It should also be noted that many of the individual organic constituents can be determined by two or more of the above methods (Standard Methods, 2012).

Over 180 individual organic compounds the can be determined using one or more of the methods cited above. The principal categories containing the individual organic compounds are reported in Table 2–17. As instrumental methods of analysis have improved, the detection limits for these compounds have become increasingly small, typically below 10 ng/L. The specific organic compounds that are analyzed for will depend on the application. For example, for indirect reuse applications, scans of disinfection by-products may be required where chlorine is used for disinfection.

Table 2–17

Typical classes of organic compounds whose members are identified as individual compounds

Name	Occurrence/source	Concern
Volatile organic compounds	Found in ground and surface waters	Potential for tetratogenesis or carcinogenesis in humans
1,2-Dibromoethane (EDB) and 1,2-Dibromo-3-Chloropropane (DBCP)	Found in groundwater supplies, especially where these compounds have been used as fumigants	Detrimental effects on human health
Trihalomethanes (THMs)	Found in most chlorinated water supplies	Disinfection byproduct. Potential human carcinogen
Chlorinated organic solvents	Found in raw water supplies resulting from industrial contamination	Potential human carcinogen
Halocetic acids (HAAs)	Form from the chlorination of natural organic matter (humic and fulvic acids)	Disinfection byproduct. Potential human carcinogen
Trichlorophenol	Form from the chlorination of natural organic matter (humic and fulvic acids)	Disinfection byproduct. Dichloacetic acid and trichloroacetic acid are animal carcinogens
Aldehydes	Formed from the application of ozone to water containing organic matter	Disinfection byproduct
Extractable base/neutral and acids	Many semivolitile compounds including polynuclear aromatic hydrocarbons, phthalates, phenolics, organochlorine pesticides, and PCBs	Many of the listed compounds are toxic or carcinogenic
Phenols	Generally traceable to industrial discharges or landfills	Impart a taste to water at low levels. May have detrimental impact on human health at higher levels
Polychlorinated biphenyls (PCB)	Found in water supplies contaminated by transformer oils	These compounds are toxic, bioaccumulative, and extremely stable in water
Polynuclear aromatic hydrocarbons (PAHs)	Byproducts of petroleum processing or combustion	Many compounds in this group are highly carcinogenic at relatively low levels
Carbamate pesticides	Found in water supplies contaminated by pesticides	
Organochlorine pesticides	Found in water supplies contaminated by pesticides	Many compounds in this group are bioaccumulative, and relatively stable, as well as toxic or carcinogenic
Acidic herbicide compounds	Used for weed control these compounds are found in aquatic systems	
Glyphosphate herbicide	Broad spectrum nonselective post emergence herbicide. Water supplies can become contaminated through runoff and spray drift	

2–8 RADIONUCLIDES IN WASTEWATER

Radionuclides are unstable atoms that are transformed through the process of radioactive decay. Radioactive decay is the spontaneous disintegration of an element, resulting in greater atomic stability through change of electron orbits or release of radioactive particles or radiation (Crittenden et al., 2012). Radionuclides are of interest because of the health effects resulting from exposure to radioactive particles and their occurrence in natural waters. Radionuclides are being detected in wastewater and are of concern when wastewater containing radionuclides is reused or discharged to the environment. Wastewater treatment plant processes also have the potential to concentrate radioactive materials in biosolids.

Sources of Radionuclide

Radioactive materials may be present in wastewater from natural occurring sources, medical facilities, and regulated users of Atomic Energy Act radioactive materials. Natural radionuclides are the most common sources of radioactivity in the environment and are formed from the dissolution of rock formations containing uranium ore and gases released from deep in the earth's crust. The principal source of natural radionuclides is uranium ore (U_3O_8), and its abundance in the earth's crust is 1 part per 10^{12} parts. Natural occurring radionuclides can enter the collection system from (1) community water supplies, principally those with predominant amounts of groundwater; (2) water infiltrating into the sewer system; and (3) residuals from water purification systems. Runoff into storm sewers can also occur from global radioactive fallout such as that resulting from the nuclear power plant disaster in Japan in 2011.

The anthropogenic radionuclides come from sources such as a nuclear power plants used to supply electrical energy, medical facilities that provide nuclear medicines and x-ray services, academic and research facilities using nuclear materials for research, commercial products such as televisions and smoke detectors, and nuclear weapons (Crittenden et al., 2012). The National Research Council (NRC) estimates that more than 9000 out of 22,000 regulated users have the potential to release radioactive materials to domestic collection systems (Bastian, 2011).

Units of Expression

The life span of a radionuclide in water and wastewater is measured by its half-life. A half-life is defined in terms of probability. It is the time when the expected value of a number of entities that have decayed is equal to half of the original number. The units of expression for radionuclide concentrations in water are picocuries per liter (pCi/L).

Description of Isotopes Found in Wastewater and Sludge

The primary forms of radioactive decay are (1) alpha (particle) radiation, (2) beta (particle) radiation, and (3) gamma (ray) radiation. The release of alpha and beta particles transforms an isotope into a different element, while the release of gamma radiation reduces the energy of the element. Alpha, beta, and gamma radiation are known as ionizing radiation because of their ability to free electrons from their orbit in adjacent atoms (Crittenden et al., 2012). In an environmental radiation program conducted by the State of Washington, for example, several isotopes as well as total uranium were detected in wastewater and wastewater sludge samples from six wastewater treatment plants. The decay mode in most cases was found to be either beta or gamma. The isotopes identified in the sampling study, their half-life, and possible sources are given in Table 2–18 (WDOH 1997).

Recently, radioactive tritium, which occurs naturally in lakes, rivers, and public water supplies, has been detected near nuclear testing facilities and nuclear power plants. Tritium at very low concentrations has been detected in tertiary effluents. In a report by the U.S. EPA, the levels of radioactive materials found in biosolids and ash samples from most wastewater treatment plants indicated that radiation exposure to workers and the general public is very low and is not likely of concern (Bastian, 2011).

Treatment Technologies for the Removal of Radionuclides

No technologies have been reported in the literature for the removal of radionuclides in wastewater. However, technologies that have been investigated for the removal of radionuclides from drinking water that can be considered for wastewater are presented in Table 2–19. Laboratory analyses and bench- and pilot-plant testing are required to determine feasible methods of treatment.

Table 2–18

Isotopes Found in Wastewater and Sludge in the State of Washington

Isotope	Half-life	Decay mode	Possible sources
Beryllium-7 (Be-7)	53 d	Gamma	Be-7 is a naturally occurring radioisotope produced by the interactions of cosmic radiation and the upper atmosphere. Be-7 could enter the wastewater system through the water supply, from runoff in a combined system, or in washwater which has picked up dust
Cesium-137 (Cs-137)	30 y	Beta, Gamma	Cs-137 is a fission product produced in nuclear reactors and explosions. It is encountered virtually everywhere in the world as the result of atmospheric testing of nuclear weapons. Cs-137 can be found in wastewater systems from the water supply (if not supplied by wells), runoff in combined systems, and people via the food chain
Cobalt-57 (Co-57)	270 d	Gamma	Co-57 is produced by accelerators. The source of Co-57 detected in sludge is not apparent although Co-57 is used in some medical procedures
Cobalt-58 (Co-58)	71 d	Gamma	See Co-57
Cobalt-60 (Co-60)	5.2 y	Beta, Gamma	Co-60 is produced usually in nuclear reactors when neutrons are by Co-59 atoms in the steel. It is not readily apparent where Co-60 in collection systems comes from
Gross Beta	NA	Beta	Gross Beta is a screening tool to determine if further analyses of Beta emitting isotopes are needed. Subsequent testing of isotopes is expensive and time consuming
Iodine-131 (I-131)	8 d	Beta, Gamma	I-131 can be created as a fission product of a nuclear reactor or weapon, or by irradiating material in a reactor accelerator. It is also used in a number of medical procedures. I-131 found in sludge is likely from medical procedures
Manganese-54 (Mn-54)	312 d		Mn-54 is an activation product produced in nuclear reactors
Potassium-40 (K-40)	1.2×10^9 y	Beta, Gamma	K-40 is an naturally occurring radioisotope; approximately 0.01% of all potassium is K-40. The K-40 in sludge is attributed principally to excrement although it could be from runoff of fertilizer used in landscape and agricultural applications
Strontium-89 (Sr-89)	51 d	Beta	Sr-89 is a fission fragment produced in nuclear reactors or weapon explosions. It is sometimes used in medical procedures
Strontium-90 (Sr-90)	230 y	Beta	Sr-90 is a fission fragment produced in nuclear reactors or weapon explosions. Sr-90 is found in the environment from weapons test fallout and can travel up the food chain
Technetium-99 (Tc-99)	213,000 y	Beta	Tc-99 is created as a fission fragment when a uranium atom is split. It also has several medical uses
Thallium-201 (Tl-201)	3 d	Gamma	Th-201 is produced in accelerators and used in examining heart functions
Total Uranium (Total U)			Total U can occur is a natural form or from processing in a nuclear reactor. Uranium in the wastewater system can arrive from the water supply (especially wells) or from runoff in combined systems and washwater from uranium processing facilities
Zinc-65 (Zn-65)	243.9 d		Zn-65 is a neutron activation product, usually associated with nuclear reactors

[a] Adapted from WDOH (1997).

Table 2–19

Possible treatment technologies considered for the removal of radionuclides[a]

Treatment technology	Application
Activated alumina	Activated alumina has been used to remove fluoride and arsenic in full-scale drinking water applications and may be suitable for the removal of uranium. Removal rates for uranium are reported to be about 90 percent.
Aeration	Radon-222 gas has a very high Henry's law constant and is very amenable to aeration. Aeration methods such as diffused air and packed towers are reported to be very effective in removing radon-222. Removal rates for radon are reported to be up to 99 percent.
Coagulation-filtration	Conventional coagulation-filtration using alum or iron salts can be effective in removing uranium from drinking water. Removal rates are reported to be in the range of 80 to 98 percent. Enhanced coagulation-filtration with alum or ferric can be used in large applications for the removal of uranium.
Ion exchange	Strong-acid cation (SAC) resins in the sodium form and weak acid cation (WAC) resins can be used to remove radium-226 and radium-228 from aqueous systems. The advantages of WAC resins are that they are easier to regenerate and require less regenerate then SAC resins; the disadvantages are the resin tends to swell and corrosion resistant materials are required if HCl is the regenerant solution. Reported removal rates are from 81 to 100 percent for radium and 90 to 100 percent for uranium.
Reverse osmosis	Reverse osmosis has been found to be an excellent treatment technology for the removal of radionuclides from drinking water. Several types of membranes have been effective in removing natural uranium from groundwater in Florida. Reported removal rates are 90 to 95+ percent for radium and 90 to 99 percent for uranium.

[a] Adapted from Crittenden et al. (2012) and Malcolm Pirnie Inc. (2008).

2–9 BIOLOGICAL CONSTITUENTS

The biological characteristics of wastewater are of fundamental importance in the control of diseases caused by pathogenic organisms of human origin and, because of the extensive and fundamental role played by bacteria and other microorganisms in the decomposition and stabilization of organic matter and the transformation of inorganic compounds, both in nature and in wastewater treatment plants. To develop a general understanding of the microbial constituents in wastewater, the material presented in this section has been organized into the following subsections: (1) the sources of the microorganisms found in wastewater, (2) the general classification of the microorganisms found in wastewater, (3) the enumeration and detection microorganisms, (4) the pathogenic microorganisms associated with human disease, (5) the use of indicator organisms, and (6) a brief discussion of evolving pathogenic microorganisms. Following the general introduction presented in subsections (1) and (2), the remainder of the section is devoted to consideration of the pathogenic microorganisms found in wastewater. The growth, metabolic, and environmental requirements of microorganisms responsible for the treatment of wastewater are considered in Chap. 7. The use of microorganisms for the treatment of wastewater is considered in Chaps. 8, 9, and 10. The biological conversion of waste sludge to biosolids is considered in Chap. 13.

Sources of Microorganisms in Wastewater

Microorganisms found in untreated wastewater include bacteria, fungi, algae, protozoa, helminthes, viruses, and other microscopic plants and animals. The principal source of these organisms is from human waste. Other sources include commercial and industrial activities and surface water infiltration and inflow. While a large number of microorganisms are always present in wastewater, others may only be present during disease outbreaks resulting from a specific disease or specific events or occurrences. The concentration of microorganisms resulting from a disease outbreak will depend on the number of persons shedding microorganisms (in feces) and the duration of the shedding.

General Classification. In 1990, a three domain system for classifying microoganisms was proposed (Woese et al., 1990). The three domains proposed are *Bacteria, Archaea,* and *Eucarya (*or *Eukarya*). The relationship between these three domains along with the principal phyla within each domain are illustrated on Fig. 7–8 in Chap. 7. The Bacteria and Archaea are single-cellular organisms and classified as prokaryotes, which do not contain their chromosome inside a nucleus. The Eucarya can be single or multicellular organisms and have their chromosome inside a nucleus. The Archaea are separated from Bacteria due to their deoxyribonucleic acid (DNA) composition and unique cellular chemistry, such as differences in the cell wall and ribosome structure. Many Archaea can grow under extreme conditions of temperature and salinity and also include methanogenic-producing microorganisms within the phylum Euryarchaeota, important in anaerobic treatment processes, and ammonia-oxidizing populations within the phylum Crenarchaetota. There are no known pathogenic microorganisms within the Archaea. Some of the key differences between bacteria and Archaea (prokaryotes) and eukaryote microorganisms are summarized in Table 2–20, and a schematic of their cell structures is shown on Fig. 2–28. Clearly, the eukaryotes are much more complex and encompass both multicellular and single-cell plants and animals including algae, protozoa, and fungi. Also, the eukaryote organisms are generally much larger than the prokaryotes. Additional information on prokaryote cell structure and composition and the role and importance of DNA and ribonucleic nucleic acid (RNA) are discussed in Chap. 7.

Viruses are obligate *intracellular infectious* agents that are able to direct the metabolic machinery of a host cell to duplicate their molecular structure. Although viruses contain the genetic information (either DNA or RNA) needed to replicate themselves, they are unable to reproduce outside of a host cell. Viruses are composed of a nucleic acid core (DNA or RNA) surrounded by an outer coat of protein and glycoprotein. In the past, viruses were often classified according to the host infected. Bacteriophage, as the name implies, are viruses that infect bacteria and are common microbial constituents found in wastewater.

General Description. A general description of the microorganisms found in wastewater is given in Table 2–21 using the terminology introduced in the previous paragraphs. Data on the shape, resistant form, and size of the microorganisms of interest are presented in Table 2–22. Information on the size of the microorganisms, especially the resistant form, is needed to determine the type of treatment that will be required to treat or remove them.

An important feature of some microorganisms is their ability to generate resistant cell forms. For example, selected species of bacteria can form endospores (formed within the cell), the structure of which is extremely complex. The endospore contains all of the information necessary for reproduction and is coated with several layers of proteins. Endospores are extremely resistant to heat, dessication, and disinfecting chemicals. It has been speculated that endospores may remain dormant for decades, and perhaps even centuries. A spore can become viable in a suitable environment in a three step process: activation,

Table 2–20

Comparison of prokaryote and eucaryote cells[a]

Cell characteristic	Prokaryote	Eukaryote (Eukarya)
Phylogenetic group	Bacteria, blue-green algae (cyanobacteria), archaea	Single cell: algae, fungi, protozoan Multicell: plants, animals
Size[b]	Small, 0.2 to 3.0 μm	2–100 μm for single cell organisms
Cell wall	Composed of petidoglycan (bacteria), other polysaccharides, protein, glycoprotein (archaea)	Absent in animals and most protozoan, present in plants, algae, fungi: usually polysaccharide
Nuclear structure		
Nuclear membrane	Absent	Present
DNA	Single molecular, plasmids	Several chromosomes
Internal membranes	Simple, limited	Complex, endoplasmic reticulum, golgi, mitochondria several present
Membrane organelles	Absent	Several present
Photosynthetic pigments	In internal membranes chloroplasts absent	In chloroplasts
Respiratory system	Part of cytoplasmic membrane	Mitochondria

[a] Adapted from Ingraham and Ingraham (1995), Madigan et al. (2009), and Stanier et al. (1986).

[b] For additional size information see Table 2–20.

Figure 2–28

Typical structure of microorganism cells: (a) prokaryotic and (b) eukaryotic.

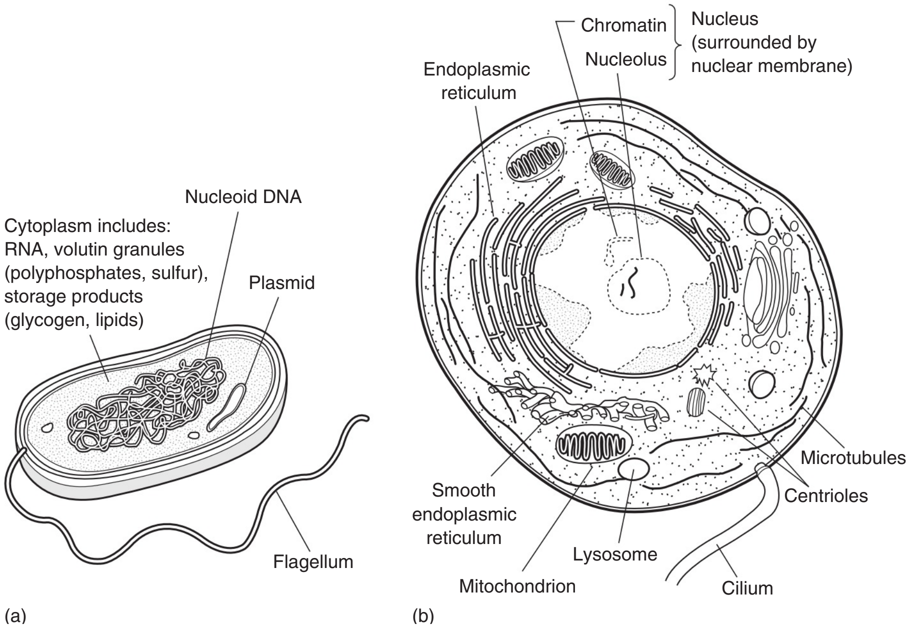

Table 2–21

Typical descriptions of the microorganisms found in natural waters, wastewater, and wastewater treatment processes

Organism	Description
Bacteria	Bacteria are single-cell prokaryotic organisms. The interior of the cell contains a colloidal suspension of proteins, carbohydrates, and other complex organic compounds, called the cytoplasm. The cytoplasmic area contains ribonucleic acid (RNA), whose major role is in the synthesis of proteins. Also within the cytoplasm is deoxyribonucleic acid (DNA). DNA contains all the information necessary for the reproduction of all the cell components and may be considered to be the blueprint of the cell. Their usual mode of reproduction is by binary fission or by budding.
Archaea	Similar to bacteria in size and basic cell components. Their cell wall, cell material, and RNA composition is different. Important in anaerobic processes and also found under extreme conditions of temperature and chemical composition.
Fungi/ yeast	Fungi are multicellular, non-photosynthetic, heterotrophic eukaryotes. Most fungi are either strict or facultative aerobes which reproduce sexually or asexually, by fission, budding, or spore formation. Molds or "true fungi" produce microscopic units (hyphae), which collectively form a filamentous mass called the mycelium. Yeasts are fungi that cannot form a mycelium and are therefore unicellular. Fungi have the ability to grow under low-moisture, low nitrogen conditions and can tolerate an environment with a relatively low pH. The ability of the fungi to survive under low pH and nitrogen-limiting conditions, coupled with their ability to degrade cellulose, makes them very important in the composting of sludge.
Protozoa	Protozoa are motile, microscopic eukaryotes that are usually single cells. The majority of protozoa are aerobic heterotrophs, some are aerotolerant anaerobes and a few are anaerobic. Protozoa are generally an order of magnitude larger than bacteria and often consume bacteria as an energy source. In effect, the protozoa act as polishers of the effluents from biological waste treatment processes by consuming bacteria and particulate organic matter.
Helminths	Helminth is a general term used to describe worms collectively. Classified as invertebrates, helminths are usually elongated, flat, or round. The three stages of helminth development are eggs, larval, adult. Worldwide, worms are one of the principal causative agents of human disease.
Rotifers	Rotifers are aerobic heterotrophic animal eukaryotes. The name is derived from the fact that they have two sets of rotating cilia on their head which are used for motility and capturing food. Rotifers are very effective in consuming dispersed and flocculated bacteria and small particles of organic matter. Their presence in an effluent indicates a highly efficient aerobic biological purification process.
Algae	Algae are unicellular or multicellular, autotrophic, photosynthetic eukaryotes or prokaryotes. They are of importance in biological treatment processes. In wastewater treatment lagoons, the ability of algae to produce oxygen by photosynthesis is vital to the ecology of the water environment. The blue-green algae cyanobacteria is a prokaryotic organism.
Viruses	Viruses are composed of a nucleic acid core (either DNA or RNA) surrounded by an outer shell of protein called a capsid. Viruses are infectious agents that only multiply within a host cell, where they redirect the cell's biochemical system to reproduce themselves. Viruses can also exist in an extracellular state in which the virus particle (known as a viron) is metabolically inert. Bacteriaphages are viruses that infect bacteria as the host; they have not been implicated in human infections.

Table 2–22

Typical data on the shape, size, and resistant forms of classes of microorganisms and selected species found in wastewater

Microorganism	Shape	Size, μm[a]	Environmentally resistant form
Bacteria			
Bacilli	rod	0.3–1.5 D × 1–10 L	endospores or dormant cells
Bacillus (*E. coli*)	rod	0.6–1.2 D × 2–3 L	dormant cells
Cocci	spherical	0.5–4	dormant cells
Spirilla	spiral	0.6–2 D × 20–50 L	dormant cells
Vibrio	rod, curved	0.4–2 D × 1–10 L	dormant cells
Protozoa			
Cryptosporidium[b]			
Oocysts	spherical	3–6	oocysts
Sporozite	tear drop	1–3 W × 6–8 L	
Entamoeba histolytica			
Cysts	spherical	10–15 D	cysts
Trophozite	semi-spherical	10–20	
Giardia lamblia[c]			
Cysts	ovid	6–8 W × 8–14 L	cysts
Trophozite	pear or kite	6–8 W × 12–16 L	
Helminths			
Ancylostoma duodenale (hookworm) eggs	elliptical or egg	36–40 W × 55–70 L	filariform larva
Ascaris lumbricoides (roundworm) eggs	lemon or egg	35–50 W × 45–70 L	embryonated egg
Trichuris trichiura (whipworm) eggs	elliptical or egg	20–24 W × 50–55 L	embryonated egg
Viruses			
MS2	spherical	0.022–0.026	virion
Enterovirus	spherical	0.020–0.030	virion
Norwalk	spherical	0.020–0.035	virion
Polio	spherical	0.025–0.030	virion
Rotavirus	spherical	0.070–0.080	virion

[a] D = diameter, L = length, and W = width.

[b] Member of the phylum Apicomplexa.

[c] Member of the phylum Sarcomastigophora, order Diplomonadida.

germination, and outgrowth (Madigan et al., 2009). The resistant forms in protozoans are known as cysts or oocycts. Resistant forms in helminths are eggs and oocysts.

The term *parasite* is used to describe an organism that lives at the expense of another. Parasites that live on the surface of a host organism are *ectoparasites*. Parasites that live internally within the host are known as *endoparasites* (Roberts and Janovy, 1996).

Enumeration and Identification of Microorganisms

In terms of wastewater treatment, the most dramatic change that has occurred is in the identification of the microorganisms found in water and wastewater. The methods now used include a combination of traditional and newer molecular-based methods. The principal methods used for microorganism identification include (1) observational, (2) culture methods, (3) physiological methods, (4) immunological methods, and (5) nucleic-acid based methods. To describe all of the individual tests used within each method would encompass several books, and that is not the purpose here. The principal methods used to enumerate various microorganisms in wastewater treatment are summarized in Table 2–23. These methods are considered briefly in the following discussion. An appreciation of the methods used to both enumerate and identify microorganisms is important in assessing the significance of the data reported in the literature. Additional details on the methods listed in Table 2–23 may be found in Standard Methods (2012) and Maier et al. (2009). Also, because the methods are evolving so rapidly, especially the newer molecular-based methods, the current literature should be consulted for the latest methods.

Observational Methods. The direct observation of microorganisms dates back to the mid-1600s when the microscope was developed. Leeuwenhoek, a Dutch merchant, is credited with providing the first accurate descriptions of bacteria, protozoa, and fungi between 1670 and 1723. Observational methods are still very much in use for algae, fungi, and protozoa as well as other observable microorganisms, such as the filamentous microorganisms common in activated sludge treatment systems (see Chap. 8).

Culture Methods. The traditional culture-based methods of analysis that have been used to enumerate bacteria, as reported in Table 2–23, include (1) pour and spread plate method, (2) membrane filtration, (3) multiple tube fermentation, (4) enzyme substrate coliform tests, (5) heterotrophic plate count, and (6) presence absence test. Because of the widespread use of these tests, they are described further below. Details on these methods, and many others, may be found in Standard Methods (2012).

Pour and Spread Plate Method. Robert Koch, a German scientist regarded as the father of clinical bacteriology, first reported the use of a gel (solid medium) for the culture of microorganisms in 1873. Use of a Petri dish with a solid medium was first reported in 1877, by Petri who worked in Koch's laboratory (Madigan et al., 2009). The pour and spread plate methods are illustrated on Fig. 2–29. The separate distinct bacterial colonies formed on the petri dish after incubation are counted, and the results reported as colony forming units (cfu) per unit volume of sample (typically cfu/mL). In the past, it was assumed that each colony developed from a single bacterium, but use of the term cfu does not assume that one bacteria formed each colony. The use of the pour plate method for the enumeration of bacteriophage is illustrated on Fig. 2–30.

Membrane Filtration. The membrane filtration (MF) method (see Fig. 2–31) evolved from the pour and spread plate methods. Bacteria are retained on the filter because they are larger than the size of the pores of the membrane filter (typically 0.45 μm). After incubation, the colonies formed on the surface of the filter can be counted and the concentration in the original water sample determined. The membrane filter technique has the advantage of being faster than the MPN procedure and of giving a direct count of the number of organisms (e.g., coliform organisms). The results are reported as colony forming units per 100 milliliters (CFU/100 mL).

Multiple Tube Fermentation. The multiple tube method (see Fig. 2–32) for enumerating the number of microorganisms was first proposed by Theobald Smith in the United States

Table 2–23

Representative methods used to enumerate and identify microorganisms and to assess performance of various treatment processes[a]

Test	Description	Typical application
Observational		
Conventional light microscopy	Used for observation of cell morphology and size. Various dyes and stains can be used to enhance visualization and identification. Direct counts can be obtained using a Petroff-Hauser counting chamber.	Cell counts, characterization of filamentous bacteria
Flow cytometry	Light scattering and fluorescence detection with flow of single particles through detector allows for rapid cell counts. Number and size of cells related to change in electric conductivity. Common for algae enumeration.	Cell counts
Electron microscopy	Electron microscopes include transmission and scanning types and are capable of magnification around 10,000,000x. However, the process of obtaining images with electron microscopes can be time consuming and expensive.	Visualization of microorganisms
Culture methods		
Pour and spread plate method	Diluted sample is mixed with agar and poured into culture dish. Agar is allowed to solidify and the dish incubated. After incubation, colonies formed on the agar are counted. Results are reported as colony forming units per milliliter (cfu/mL). In the spread plate method, diluted sample is spread on a surface culture dish containing a suitable culture medium.	Bacterial counts
Membrane filter technique	Sample is passed through a membrane filter and the filter placed right side up in contact with an agar or other solid media. After incubation, colonies formed on the surface of the filter are counted.	Bacterial counts
Multiple-tube fermentation	Sample is diluted serially and added to fermentation tubes and incubated. Positive tubes (cloudy) are counted. Based on the principle of dilution to extinction, as illustrated on Fig. 2–33, *the most probable number per 100 mL* (MPN/100 mL) is computed using the Poisson distribution for extreme values.	Bacterial counts
Enzyme substrate coliform test	Enzyme based methods used to simultaneously determine total coliform bacteria and *E. coli*. Bacterial enzymes present in total coliform group hydrolyze an added substrate resulting in a color change (yellow). *E. coli* cleave a fluorogenic substrate, resuling in the release of fluorogen, which fluoresces under ultraviolet light.	Total coliform bacteria and *E. coli*
Heterotrophic plate count (HPC)	Pour plate, spread plate, or membrane filter method, as described above, can be used to determine HPC. Colonies of bacteria, derived from pairs, chains, clusters, or single cells, are measured. The results are reported as colony forming units per milliliter (CFU/mL).	Bacterial counts

(*continued*)

Table 2–23 (*Continued*)

Test	Description	Typical application
Culture methods (continued)		
Presence-absence (P-A) test	A single 100 mL sample is tested for the P-A of coliform organisms using a selective media. The P-A test is used for highly treated samples such as effluent from a water treatment plant.	Presence of bacteria
Agar overlay method	Sample is mixed with agar and *E. coli*. Solution poured onto solid agar plate and incubated. If colifphage are present, the bacterial cells will lyse resulting in the presence of clear spots. Clear spots, called plaques, are reported as plaque forming units (e.g., pfu/100 mL).	Coliphage counts[b]
Tissue culture (agar overlay method)	Virus assays are performed in the laboratory by inoculating sample concentrate onto monolayers of cultured cells (hence the name tissue culture). Buffalo Green Monkey Kidney (GBMK) is most common cell line for enteroviruses. Virus destroy the infected cells. The destroyed cells appear as a hole or plaque in the cell monolayer. Each plaque (plaque forming unit or PFU) is the result of the presence of a single or a clump of viruses.	Virus counts
Physiological methods		
Respiration gases	Measurement of the rate of gas consumption or production, i.e., oxygen consumption, carbon dioxide evolution, and methane evolution.	Microbial activity and substrate conversion
Microelectrodes	Ulta-fine probes are inserted into a microbial sample followed by continuous measurement of various cell activities, including oxygen uptake and nitrate reduction.	Microbial activity
Labeled constituents	Introduction of a radiolabeled constituents into a microbial sample, including (a) labeled substrate followed by measurement of labeled carbon within the cell, liquid, and evolved as carbon dioxide and (b) labeled thymidine followed by the measurement of the rate of incorporation into DNA.	Microbial activity and substrate conversion
Cell products	Methods include measurement of (a) proteins expressed under variable conditions, (b) enzyme activity through the production of fluorescent products generated by the hydrolysis of fluorescein diacetate, (c) dehydrogenase activity through the reduction of tetrazolium salts, and (d) metabolically active biomass through the adenylate energy charge, or ratio of ATP to total adenylates.	Microbial activity
Immunological methods		
Fluorescent immunolabeling	An antibody is tagged with a fluorescent dye. Once tagged, an antibody becomes attached to an antigen associated with a microorganism; the sample can then be examined using fluorescence microscopy. Fluorescein isothiocyanate (FITC) is the most commonly used fluorescent dye.	Spatial distribution of antigen, detection of bacteria, virus, protozoa, helminths
Enzyme-linked immunosorbent assay (ELISA)	An enzyme-antibody probe is added to a sample containing an antigen. After attachment, the substrate for the enzyme is added to the sample, resulting in a color change.	Quantification of biomass in biofilms, various assays

(*continued*)

Table 2–23 (*Continued*)

Test	Description	Typical application
Nucleic-acid methods		
Cloning	The process of cloning consists of the insertion of an isolated fragment of DNA of interest into a host cell, typically *E. coli*. The host cell, or clone, then generates identical replicates of the DNA fragment. The DNA fragments are typically analyzed by sequencing.	Replication of genetic material
Nucleic acid probes	A nucleic acid probe is a molecule having a strong interaction with a known complementary genomic sequence unique to the targeted organism(s) and possessing a means for detection. Typical methods include (a) fluorescent in-situ hybridization (FISH), (b) detection of DNA or RNA on gels following electrophoresis, and (c) screening gene expression using an array of gene probes known as microarrays.	Identification of specific microorganisms, including spatial distribution in flocs and biofilms
Polymerase chain reaction (PCR)	Amplification of the DNA of the genome of the microorganisms being tested by using complementary DNA fragments known as primers to bind to target DNA of virus The primer triggers a reaction which results in the production of many millions of copies of the microorganism DNA. Examples include reverse transcription PCR (RT-PCR), nested PCR, multiplex PCR, integrated cell culture PCR (ICC-PCR), and real-time quantitative PCR (qPCR).	Amplification of genetic material
Sequencing	The coding of genetic material can be determined through the process of sequencing, which usually takes place at commercial laboratories. The DNA sequence can then be compared to databases to determine the relationship of the genetic material to other organisms that have had their DNA sequenced. The 16S rRNA region of the sequence has been found to be the most useful for determining the identity of isolated microorganisms.	Identification of isolated microorganisms
Restriction fragment length polymorphism (RFLP)	A method that uses enzymes to cut purified DNA or PCR products into small fragments at specific segments of the genome. The fragments are then analyzed by gel or capillary electrophoresis to obtain a microbial community fingerprint.	Microbial community fingerprint
Gel gradient electrophoresis	A method that subjects PCR fragments to an increasing concentration of denaturant (DGGE) or temperature (TGGE) to allow for visualization of diversity in the genetic material resulting from differential melting or denaturing of the PCR fragments.	Microbial community diversity
Metagenomics	The analysis of the collective genetic material recovered from an environment sample.	Microbial community diversity and metabolism

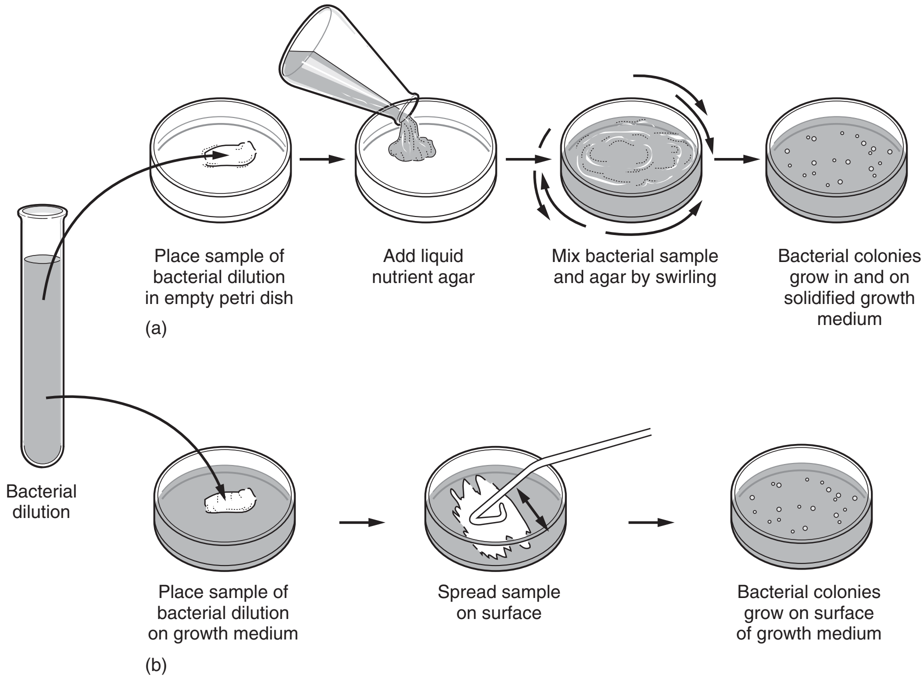
[b] A bacteriophage is a virus that infects and replicates within bacteria. A coliphage is a type of bacteriophage that infects *E. coli*.

Figure 2–29

Schematic of plate culture methods used for the enumeration of bacteria: (a) pour plate and (b) spread plate.



in 1893 (Smith, 1893). The method is based on the principle of dilution to extinction as illustrated on Fig. 2–32. Initially, the results obtained with the multiple tube method were identified as the *indicated number*. The name was changed to multiple tube method in the 1930s. Concentrations of total coliform bacteria are typically reported as the *most probable number per 100 mL* (MPN/100mL). The MPN is based on the application of the Poisson distribution for extreme values to the analysis of the number of positive and negative results obtained when testing multiple portions of equal volume and in portions constituting a geometric series. It is emphasized that the MPN is not the absolute concentration of organisms that are present, but only a statistical estimate of that concentration.

Enzyme Substrate Coliform Tests. In addition to the modified MPN test, several commercial enzymatic assays have been developed that can be used for the simultaneous detection of both total coliform bacteria and *E. coli*. In the enzymatic assays, powdered ingredients

Figure 2–30

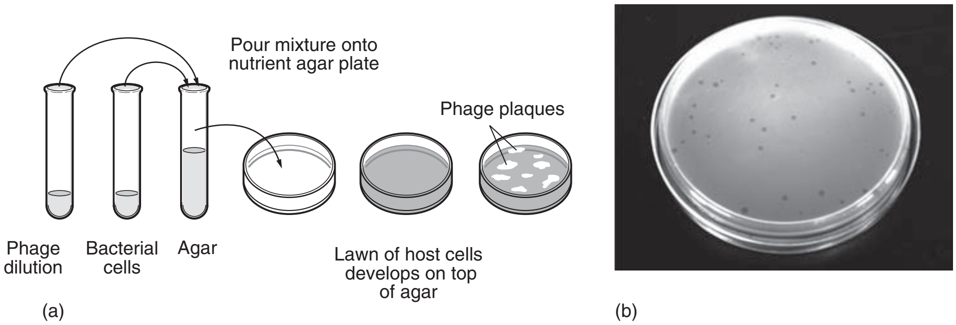

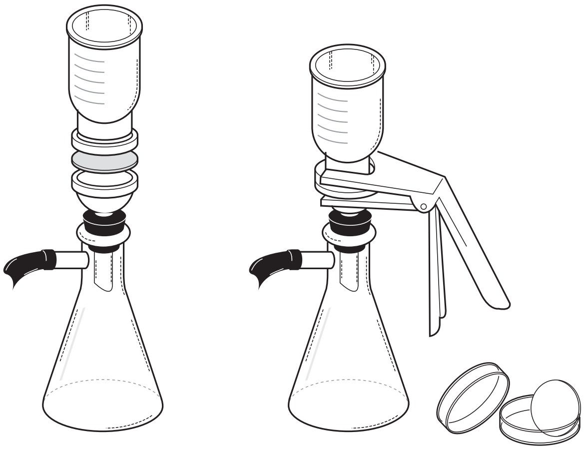

Figure 2–31

Membrane filter apparatus used to test for bacteria in relatively clean waters. After centering the membrane filter on the filter support, the funnel top is attached and the water sample to be tested is poured into the funnel. To aid in the filtration process, a vacuum line is attached to the base of the filter apparatus. After the sample has been filtered, the membrane filter is placed in a petri dish containing a culture medium for incubation and subsequent bacterial enumeration.

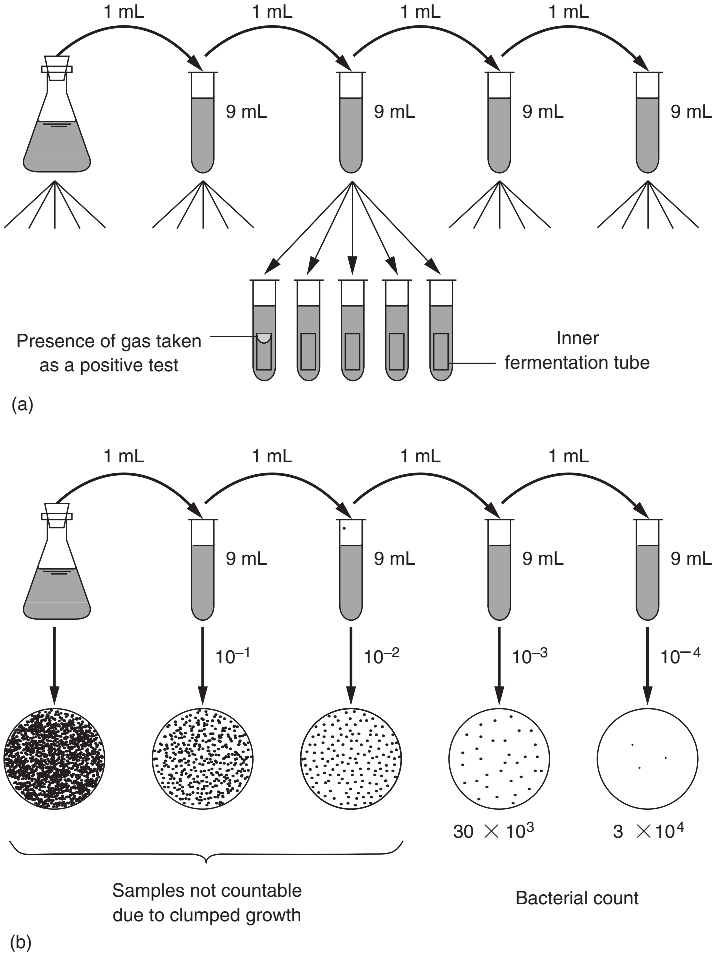

Figure 2–32

comprised of salts and specific enzyme substrates that serve as the sole carbon source are added to various wastewater samples. When metabolized by total coliform and *E coli*, the specific enzyme substrates produce a yellow color and or fluoresce. After incubation, samples containing coliform organisms turn yellow, and samples containing *E. coli* will fluoresce when exposed to long-wave UV illumination [see Fig. 2–33(a)]. The enzymatic test can be used in two different modes: presence/absence and quantification. In the presence/absence mode the chemical ingredients are added to 100 mL bottles containing the sample to be analyzed. The quantification mode can be carried out using the multiple-tube method or specialized apparatus such as the Colilert-18/Quanti-Tray method [see Fig. 2–33(b)]. The results are reported as present or absent in a 100 mL sample and as MPN/100mL in the quantification test.

Heterotrophic Plate Count. The heterotrophic plate count (HPC) is a procedure for estimating the number of live heterotrophic bacteria in wastewater samples. The HPC method

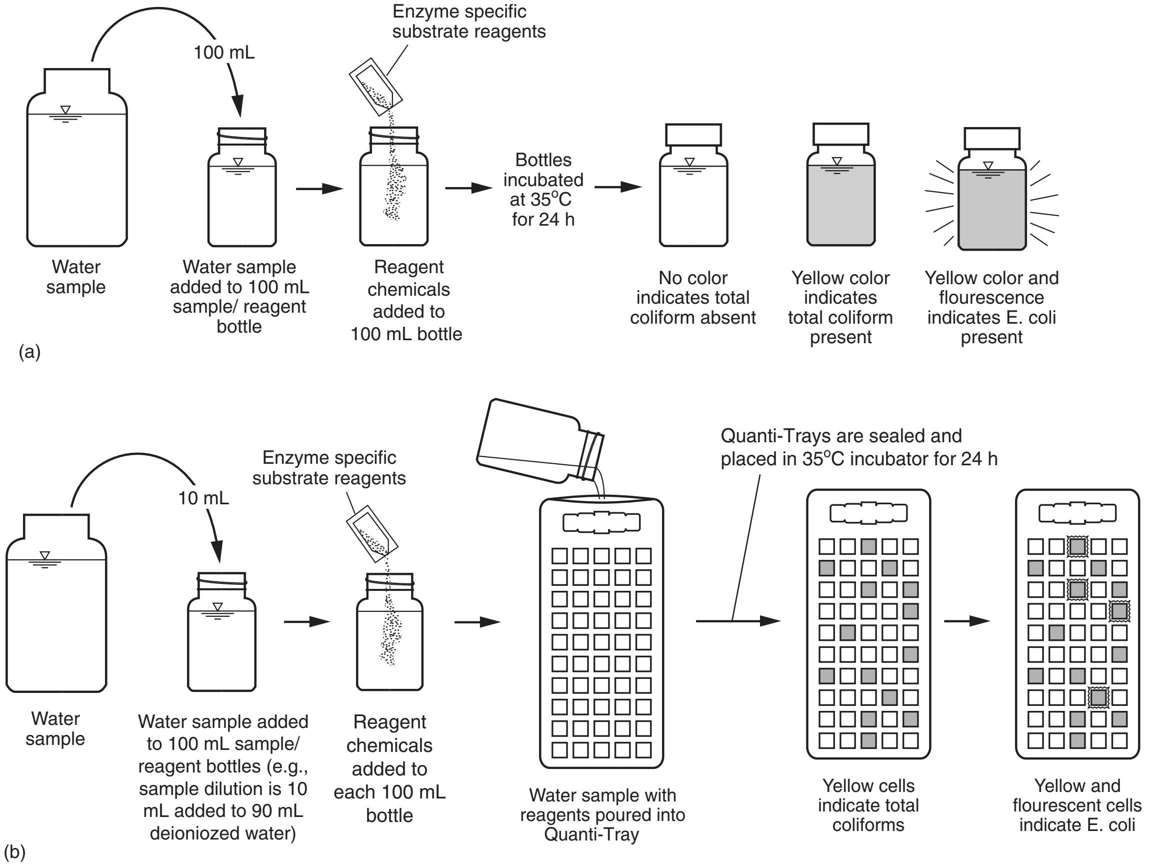

Figure 2–33

Schematic of the enzyme specific substrate coliform test for total coliform and *E coli:* (a) presence absence test using 100 mL bottles and (b) quantification test using Quanti-Tray apparatus. Note that sample dilutions can be prepared as necessary for a given sample (dilution shown is for example only). When using the Quanti-Tray, the number of total coliform or *E. coli* organisms present in the sample can be determined by counting the positive wells and then using IDEXX most probable number (MPN) tables.

evolved from first plate count method which was included in the first edition of Standard Methods (Standard Methods, 1905). The HPC can be determined using the (1) pour plate method, (2) spread plate method, or (3) membrane filter method as described above. In the HPC test, colonies of bacteria, which may be derived from pairs, chains, clusters, or single cells, are measured. The results are reported as colony forming units per milliliter (CFU/mL).

Presence Absence Test. The presence-absence (P-A) test for coliform organisms is a modification of the multiple tube fermentation technique described above. The test is used intended for use for samples collected from water distribution systems or water treatment plants. Rather than using multiple dilutions, a single 100 mL sample is tested for the P-A of coliform organisms using lauryl sulfate tryptose lactose broth as used in the MPN test. Coliform organisms are present if a distinct yellow color forms, indicating that lactate fermentation has occurred in the sample. The test is based on the rationale that no organisms should be present in 100 mL. It has been used in wastewater for highly treated samples. Enzymatic methods are also used in the P-A test.

Physiological Methods. Physiological methods are used to address the metabolic processes carried out by a microbial community, Measurement of microbial activity can be used to estimate the amount of active biomass, the response of a microbial system to a disturbance, and for determination of the status of an engineered biological process, such as biological wastewater treatment or composting of organic wastes. Common examples of physiological methods include measurement of the rate and type of substrate utilization, the rate of oxygen uptake, or the formation of respiration products.

Immunological Methods. Analytical methods that utilize an antibody for the detection or quantification of a target antigen are known as immunoassays. A key element of immunoassays is the visualization of the antibody-antigen interaction. The visualization step is accomplished typically through the use of signal molecules, which can be designed to allow for detection by various mechanisms, including color change, fluorescence, and radioactivity. Signal molecules can be attached to the antibody directly, known as direct labeling, or the signal molecule may be added after the antibody-antigen attachment has taken place, known as indirect labeling. Indirect labeling uses a secondary antibody to attach with the primary antibody, which is already attached to the target antigen. While nonspecific attachment is a key disadvantage for many immunoassays, the ability to observe the spatial arrangement of target microorganisms is a powerful advantage.

Nucleic-Acid-Based Methods. Molecular methods are based on the use of specific (DNA or RNA) sequences to identify microorganisms, and the use of DNA or RNA amplification procedures (e.g., polymerase chain reaction, PCR) to detect extremely low concentrations of nucleic acid. The PCR technique was developed by Dr. Kary B. Mullis in 1983 while he worked as chemist at the Cetus Corporation. He won the Nobel Prize in 1993 for his invention. Since 1983, the original procedure has been improved and modified to include a number of procedures such as those reported in Table 2–21. Additional details may be found in Madigan et al. (2009) and Maier et al. (2009). Application of some of these procedures to identify and follow specific microbial populations and activity are presented in Chap. 7.

Pathogenic Organisms and Prions

Pathogenic organisms and agents found in wastewater may be excreted by human beings and animals who are infected with disease or who are carriers of a particular infectious disease. The pathogenic organisms found in wastewater can be classified into four broad categories: bacteria, protozoa, helminths, and viruses. The principal pathogenic organisms found in untreated wastewater are reported in Table 2–24, along with the diseases and

Table 2–24

Infectious agents potentially present in untreated domestic wastewater[a]

Organism	Disease	Remarks/symptoms
Bacteria		
Campylobacter jejuni	Gastroenteritis	Diarrhea
Escherichia coli (Enteropathogenic)	Gastroenteritis	Diarrhea
Legionella pneumophila	Legionnaires disease	Malaise, myalgia, fever, headache, respiratory illness
Leptospira (spp.)	Leptospirosis	Jaundice, fever (Weil's disease)
Salmonella typhi	Typhoid fever	High fever, diarrhea, ulceration of small intestine
Salmonella ($\approx$2,100 serotypes)	Salmonellosis	Food poisoning
Shigella (4 spp.)	Shigellosis	Bacillary dysentery
Vibrio cholera	Cholera	Extremely heavy diarrhea, dehydration
Yersinia enterolitica	Yersinosis	Diarrhea
Protozoa		
Balantidium coli	Balantidiasis	Diarrhea, dysentry
Cryptosporidium parvum	Cryptosporidiosis	Diarrhea
Cyclospora cayetanensis	Cyclosporasis	Severe diarrhea, stomach cramps, nausea, and vomiting lasting for extended periods
Entamoeba histolytica	Amebiasis (Amoebic dysentery)	Prolonged diarrhea with bleeding, abscesses of the liver and small intestine
Giardia lamblia	Giardiasis	Mild to severe diarrhea, nausea, indigestion
Helminths[b]		
Ascaris lumbricoides	Ascariasis	Roundworm infestation
Enterobius vermicularis	Enterobiasis	Pinworm
Fasciola hepatica	Fascioliasis	Sheep liver fluke
Hymenolepis nana	Hymenolepiasis	Dwarf tapeworm
Taenia saginata	Taeniasis	Beef tapeworm
T. solium	Taeniasis	Pork tapeworm
Trichuris trichiura	Trichuriasis	Whipworm
Viruses		
Adenovirus (31 types)	Respiratory disease and gastrointestinal illness	
Enteroviruses (more than 100 types, e.g., polio, echo, and coxsakie viruses)	Gastroenteritis, heart anomalies, meningitis	
Hepatitis A virus	Infectious hepatitis	Jaundice, fever
Norovirus	Gastroenteritis	Vomiting
Pavrovirus (2 types)	Gastroenteritis	
Rotavirus	Gastroenteritis	

[a] Adapted from Feachem et al. (1983), Madigan et al. (2009), and Crook (1998).

[b] The helminths listed are those with a worldwide distribution.

Table 2–25

Microorganism concentration found in untreated wastewater and septic tank effluent and the corresponding infectious dose[a]

Organism	Concentration in raw wastewater[b] MPN/100 mL	Infectious dose, number of organisms[c]
Bacteria		
Bacteroides	10^7–10^{10}	
Colifom, total	10^7–10^9	
Colifom, fecal	10^6–10^8	10^6–10^{10}
Coliform, *E coli.*	10^5–10^7	
Clostridium perfringens	10^3–10^5	1–10^{10}
Enterococci	10^4–10^5	
Fecal streptococci	10^4–10^7	
Pseudomonas aeruginosa	10^3–10^6	
Shigella	10^0–10^3	10–20
Salmonella	10^2–10^4	
Protozoa		
Cryptosporidium parvum oocysts	10^1–10^3	1–10
Entamoeba histolytica cysts	10^{-1}–10^1	10–20
Giardia lamblia cysts	10^3–10^4	<20
Helminth		
Ova	10^1–10^3	
Ascaris lumbricoides	10^{-2}–10^0	1–10
Viruses		
Enteric virus	10^3–10^4	1–10
Coliphage	10^3–10^4	

[a] Adapted in part from Crook (1998) and Feacham et al. (1983).
[b] Value will vary with portion of population shedding at any given time.
[c] Infections dose will vary with serotype or strain of organism, and the individual's general health.

disease symptoms associated with each pathogen. Bacterial pathogenic organisms of human origin typically cause diseases of the gastrointestinal tract, such as typhoid and paratyphoid fever, dysentery, diarrhea, and cholera. Because these organisms are highly infectious, they are responsible for many thousands of deaths each year in areas with poor sanitation, especially in the tropics. It has been estimated that that up to 4.5 billion people are or have been infected with some parasite (Madigan et al., 2009). Typical data on the quantity of selected pathogenic organisms found in wastewater and the corresponding concentration needed for an infectious dose are reported in Table 2–25.

Bacteria. Many types of harmless bacteria colonize the human intestinal tract and are routinely shed in the feces. Because pathogenic bacteria are present in the feces of infected individuals, domestic wastewater contains a wide variety and concentration range of nonpathogenic and pathogenic bacteria. One of the most common bacterial pathogens found in domestic wastewater is the genus *Salmonella.* The *Salmonella* group contains a wide variety of species that can cause disease in humans and animals. Typhoid fever, caused by *Salmonella typhi*, which is specific to humans, is the most severe and serious. The most common disease associated with *Salmonella* is food poisoning identified as salmonellosis. *Shigella*, a less common genus of bacteria, is responsible for an intestinal disease known as bacillary dysentery or shigellosis. Waterborne outbreaks of shigellosis have been reported from recreational swimming areas and where wastewater has contaminated wells used for drinking water (Crook, 1998; Maier et al., 2009).

Other bacteria isolated from raw wastewater include *Vibrio, Mycobacterium, Clostridium, Leptospira* and *Yersinia* species. *Vibrio cholerae* is the disease agent for cholera, which is not common in the United States but is still prevalent in other parts of the world. Humans are the only known hosts, and the most frequent mode of transmission is through water. *Mycobacterium tuberculosis* has been found in municipal wastewater, and outbreaks have been reported among persons swimming in water contaminated with wastewater (Crook, 1998; Maier et al., 2009).

Waterborne gastroenteritis of unknown cause is frequently reported, with the suspected agent being bacterial. One potential source of this disease is certain gram-negative bacteria normally considered to be nonpathogenic. These include the enteropathogenic *Escherichia coli* and certain strains of *Pseudomonas,* which may affect the newborn and have been implicated in gastrointestinal disease outbreaks. *Campylobacter jejuni* has been identified as the cause of a form of bacterial diarrhea in humans. While it has been well established that this organism causes disease in animals, it has also been implicated as the etiologic agent in human waterborne disease outbreaks (Crook, 1998).

Protozoa. Of the disease causing organisms reported in Table 2–24, the protozoans *Cryptosporidium parvum, Cyclospora, Entamoeba histolytica,* and *Giardia lamblia* (see Fig. 2–34) are of great concern because of their significant impact on individuals with compromised immune systems, including very young children, the elderly, persons undergoing treatment for cancer, and individuals with acquired immune deficiency syndrome (AIDS). The life cycle of *Cryptosporidium parvum* and *Giardia lamblia* is illustrated on Fig. 2–35. As shown, infection is caused by the ingestion of water contaminated with oocycts and cysts. It is also important to note that numerous nonhuman sources of *Cryptosporidium parvum* and *Giardia lamblia* are present in the environment. Further, not all of the oocycsts and cysts that are present are viable in terms of their ability to cause disease. To determine the potential risk from these microorganisms, infectivity studies must be conducted.

Pathogenic protozoan disease outbreaks have been significant, highlighted by the 1993 outbreak of cryptosporidiosis in Milwaukee in which it is estimated that more than 400,000 persons became ill and that there were outbreaks of cyclosporiasis in ten other

Figure 2–34

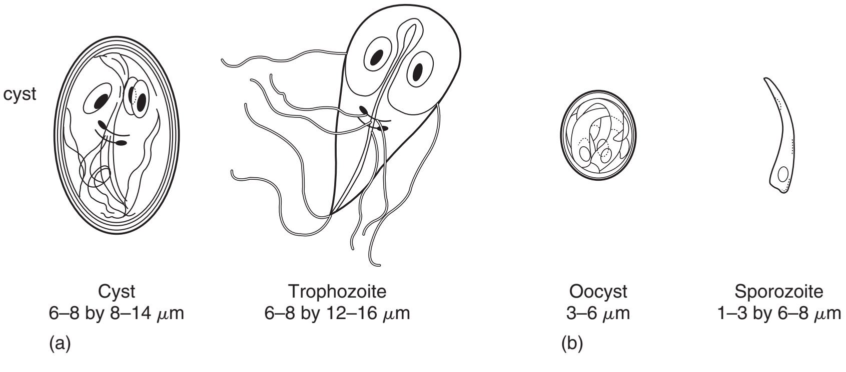

Figure 2–35

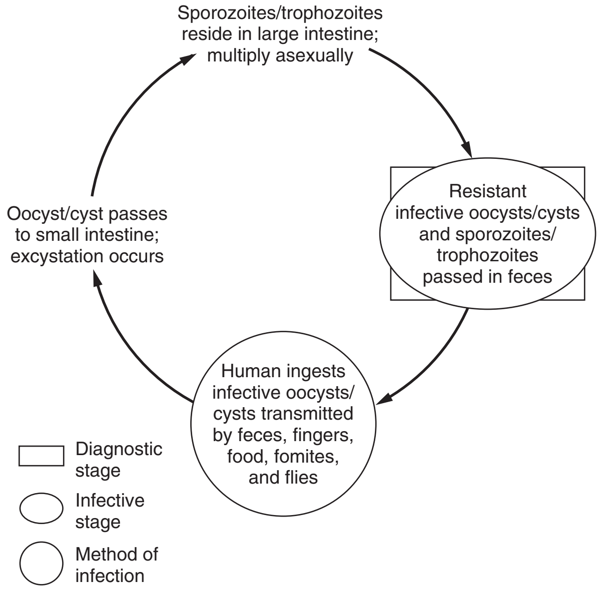
Life cycle of *Cryptosporidium parvum* and *Giardia lamblia.*



states. As noted in Table 2–22, these protozoan organisms may cause symptoms which can include severe diarrhea, stomach cramps, nausea, and vomiting lasting for extended periods. Despite intensive trials in humans and animals, no effective treatment has been found for cryptosporidiosis (Roberts and Janovy, 1996). The oocysts of *Cryptosporidium parvum* and the cysts of *Giardia lamblia* are the most resistant forms (see Table 2–22). These organisms are of particular concern because they are found in almost all wastewaters and because conventional disinfection techniques using chlorine have not proven to be effective in their inactivation or destruction. However, it has been found that UV disinfection is extremely effective in the inactivation of oocysts of *Cryptosporidium parvum* and the cysts of *Giardia lamblia*.

Helminths. The term *helminths* is used to describe parasitic worms collectively. In the United States, as result of the improvements in the provision of sanitation and wastewater treatment facilities and in food handling practices, the prevalence of helminth infections has decreased dramatically over the last century. Nevertheless, due to increased levels of immigration to the United States of persons from countries where worms are endemic, the transmission of helminths by wastewater and particularly by biosolids remains a concern. In fact, the eggs of worms are found in wastewater throughout the United States. In particular, small, nonparasitic nematodes are universally present, even in finished drinking water at the tap (Cooper, 2012). As noted in Table 2–21, worldwide, worms are one of the principal causative agents of human disease. It is estimated that the number of human infections caused by helminths collectively is on the order of 4.5 billion (Roberts and Janovy, 1996).

Most of the helminths fall into three major phyla: Nematoda (roundworms), Platyhelminths (flatworms), and Annelida (segmented worms). Most human infections are associated with nematodes and flat worms, while the segmented worms are primarily ectoparisitic, such as leaches. The phylum Nematoda collectively represents one of the most abundant animal groups on earth, most of which are harmless to humans. Included among its pathogenic members are the large round worm *Ascaris lumbricoides,* the whipworm *Trichuris trichiura,* the hookworms *Necator americanus* and *Ancylostoma duodenale,* and the threadworm *Strongyloides stercoralis*. *Ascaris lumbricoides* is considered to be the most prevalent parasitic infection worldwide with over one and a half billion persons infected (Crompton, 1999; Maier et al., 2009; Roberts and Janovy, 1996). It has been estimated that there are on the order of 4 million cases in the United States (Khuroo, 1996).

The phylum platyhelminths includes the tapeworms *Taenia saginata* (beef tapeworm), *Taenia solium* (pork tapeworm), and *Schistosoma* species. *Taenia saginata*, transmitted primarily by the ingestion of infected beef products, is the most common tapeworm found in humans. The trematodes *Schistosoma mansoni*, *S. haematobium, and S. japonicum,* also known as blood flukes, are medically important members of the trematoda class. More than 200 million infections are ascribed to these worms worldwide. It is estimated that more than 400,000 infected individuals, most of whom were infected outside of the United States, live in the United States (West and Olds, 1992).

The human infective stage of helminths varies; in some species it is either the adult organism or larvae, while in other species it is the eggs, but it is primarily the eggs that are present in wastewater. Helminth eggs, which range in size from about 10 μm to more than 100 μm, can be removed by many commonly used wastewater treatment processes such as sedimentation, filtration, and stabilization ponds. However, some helminth eggs are extremely resistant to environmental stresses and may survive usual wastewater and sludge disinfection procedures. Chlorine disinfection and mesophilic anaerobic digestion, for example, are not effective at inactivating many helminth eggs. It has been found that the eggs of *Ascaris* can survive for up to ten years in the sediments of oxidation ponds (Nelson, 2011). The long survival times of *Ascaris* and other worm eggs are of particular importance in the management of biosolids.

Viruses. More than 100 different types of enteric viruses capable of producing infection or disease are excreted by humans. Enteric viruses multiply in the intestinal tract and are released in the fecal matter of infected persons. From the standpoint of health, the most important human enteric viruses are the enteroviruses (polio, echo, and coxsackie), caliciviruses including noroviruses (formally known as Norwalk agents), rotaviruses, reoviruses, adenoviruses, and hepatitis A virus. Of the viruses that cause diarrheal disease, only the Norwalk virus and rotavirus have been shown to be major waterborne pathogens. The reoviruses and adenoviruses, known to cause respiratory illness, gastroenteritis, and eye infections, have been isolated from wastewater. There is no evidence that the human immunodeficiency virus (HIV), the pathogen that causes the acquired immunodeficiency syndrome (AIDS), can be transmitted via the waterborne route (Crook, 1998; Madigan et al., 2009; Maier et. al., 2009; Rose and Gerba, 1991). The biology of viruses is delineated in Voyles (1993).

Prions. Prions consist of small protein molecules that have a distinct extracellular form but do not contain either DNA or RNA. Interest in prions stems from the fact that they can cause disease in animals, such as mad cow disease and scrapie in sheep, and can also infect humans. Prions can exist in two forms: healthy or pathogenic. The healthy form is found in most animals. The pathogenic form enters the host, which contains healthy prions, and replicates by converting the healthy prions present in the host to the pathogenic form. To date, no model has been put forth to explain how the pathogenic prion subverts the healthy prion to become pathogenic. A public health assessment of prion diseases in humans may be found in Belay and Schonberger (2005).

One form of prion disease has been observed in humans that have consumed contaminated meat from cattle infected with pathogenic prions (Johnson et al., 2011). Pathogenic prions may also be transferred in animal manures, thus there is potential for prions to be present in the waste from animal facilities such as slaughterhouses where infected tissues may be present. In wastewater treatment, concern centers on the fact that prions are

Table 2–26

Typical pathogen survival times at 20–30°C in various environments[a]

Pathogen	Survival time, d Fresh water and wastewater	 Crops	 Soil
Bacteria			
Fecal coliforms[b]	<60 but usually <30	<30 but usually <15	<120 but usually <50

[a] Adapted from Feacham et al. (1983).

[b] In seawater, viral survival is less, and bacterial survival is very much less than in fresh water.

[c] *V. cholerae* survival in aqueous environments is a subject of current uncertainty.

[d] Includes polio, echo, and coxsackie viruses.

difficult to inactivate by conventional means. Temperatures exceeding 100°C have been found to be an effective treatment strategy (Kirchmayer et al., 2006). Because they have been found in digested biosolids, there is also concern about their potential impacts on farm animals as a result of land application.

Survival of Pathogenic Organisms. Of great concern in the management of disease-causing organisms is the survival of these organisms in the environment. Typical data on the survival of microorganisms in the environment are presented in Table 2–26. Although the data given in Table 2–26 can be used as a rough guide, numerous exceptions have been reported in the literature.

Use of Indicator Organisms. Because the numbers of pathogenic organisms present in wastes and polluted waters are usually few and difficult to isolate and identify, microorganisms, which are more numerous and more easily tested for, are commonly used as surrogate (i.e., indicator) organisms for the target pathogen(s). The general features of an ideal indicator organism and the use of bacterial and other indicators is considered briefly in the following discussion.

Characteristics of an Ideal Indicator Organism. An ideal organism should have the following characteristics (adapted from Cooper 2012; Maier et al., 2009):

1. The indicator organism must be present when fecal contamination is present.
2. The numbers of indicator organisms present should be equal to or greater than those of the target pathogenic microorganism.
3. The indicator organism must exhibit the same or greater survival characteristics in the environment as the target pathogen organism for which it is a surrogate.

4. The isolation and quantification procedure for the indicator organism must be faster, simpler, and less expensive than that of the target pathogen.
5. The organism should be a member of the intestinal microflora of warm-blooded animals.

Some authors have stated the first characteristic as "the indicator organism must be present when the target pathogen is present." Unfortunately, the target pathogen(s) may not be present during the entire year because the shedding rate of pathogenic organisms is not uniform throughout the year. Thus, it is important that the indicator organism be present when fecal contamination is present if public health is to be protected. To date, no ideal indicator organism has yet been found. Microorganisms that have been proposed for use as indicators of fecal contamination are summarized in Table 2–27. Indicator organisms that have been used to establish performance criteria for various water uses are reported in Table 2–28.

Table 2–27

Specific organisms that have been used or proposed for use as indicators of fecal contamination

Indicator organism	Characteristics
Total coliform bacteria	Species of gram-negative rods which ferment lactose with gas production (or produce a distinctive colony within 24 ± 2 h to 48 ± 3 h incubation on a suitable medium) at 35 ± 0.5°C. There are strains which do not conform to the definition. The total coliform group includes four genera in the *Enterobacteriaceae* family: *Escherichia*, *Citrobactor*, *Enterobacter*, and *Klebisella*. Of the group, the *Escherichia* genus (*E. coli* species) appears to be most representative of fecal contamination.
Fecal coliform bacteria	A fecal coliform bacteria group was established based on the ability to produce gas (or colonies) at an elevated incubation temperature (44.5 ± 0.2°C for 24 ± 2 h).
Klebisella	The total coliform population includes the genera *Klebisella*. The thermotolerant *Klebisella* are also included in the fecal coliform group. This group is cultured at 35 ± 0.5°C for 24 ± 2 h.
E. coli	The *E. coli* is one of the coliform bacteria population and is more representative of fecal sources than other coliform genera.
Bacteroides	Bacteroides, an anaerobic organism, has been proposed as a human specific indicator.
Fecal Streptococci	This group had been used in conjunction with fecal coliforms to determine the source of recent fecal contamination (man or farm animals). Several strains appear to be ubiquitous and cannot be distinguished from the true fecal streptococci under usual analytical procedures, which detract from their use as an indicator organism.
Enterococci	Two strains of fecal streptococci, S. *faecalis* and S. *faecium*, are the most human specific members of the fecal streptococcus group. By eliminating the other strains through the analytical procedures, the two strains known as enterocci can be isolated and enumerated. The enterocci are generally found in lower numbers than other indicator organisms, however, they exhibit better survival in seawater.
Clostridium perfringens	This organism is a spore-forming anaerobic persistent bacteria, and the characteristics make it a desirable indicator where disinfection is employed, where pollution may have occurred in the past, or where the interval before analysis is protracted.
P. aeruginosa and A. hydrophila	These organisms may be present in sewage in large numbers. Both can be considered aquatic organisms and can be recovered in water in the absence of immediate sources of fecal pollution.

Table 2–28

Indicator organisms used in establishing performance criteria for various water uses

Water use	Indicator organism
Drinking water	Total coliform Fecal coliform *E. coli*
Freshwater recreation	Fecal coliform *E. coli* Enterococci
Saltwater recreation	Fecal coliform Total coliform Enterococci
Shellfish growing areas	Total coliform Fecal coliform
Agricultural irrigation (For reclaimed water)	Total coliform
Wastewater effluent	Total coliform
Disinfection	Total coliform Fecal coliform *E. coli* MS2 coliphage

Use of Coliform Organisms as Indicators. The intestinal tract of humans contains a large population of rod-shaped bacteria known collectively as coliform bacteria. Each person discharges from 100 to 400 billion coliform bacteria per day, in addition to other kinds of bacteria. Thus, the presence of coliform bacteria in environmental samples has, over the years, been taken as an indication that pathogenic organisms associated with feces (e.g., viruses) may also be present. The absence of coliform bacteria is taken as an indication that the water is free from disease producing organisms.

The total coliform group includes four genera in the *Enterobacteriaceae* family: *Escherichia, Citrobactor, Enterobacter*, and *Klebisella*. The coliform bacteria have common biochemical and morphological attributes. Typically, these organisms are gram negative, non-spore forming, rod-shaped organisms (see Fig. 2–36) that ferment lactose in 24 to 48 hours at 35 ± 0.5°C (Standard Methods, 2012). The term *gram negative* refers to a staining procedure used to differentiate groups of organisms. Three groups of coliform organisms that have been used as bacterial indicators are total coliform, fecal coliform, and *E coli*.

Total Coliform. The coliform group of bacteria is commonly found in the environment in soil or vegetation and in the intestines and feces of humans and warm-blooded animals. In general, coliform bacteria are harmless. When total coliform are detected in drinking water, their presence is taken as an indication that disease-causing pathogens could also potentially be present. If total coliforms are detected in drinking water, repeat samples are taken to verify their presence, and an investigation is undertaken to determine whether the water treatment and distribution system has been breached and to locate the source of contamination, if one exists.

Fecal Coliform. Fecal coliform, sub-group of the total coliform group, are found in large quantities in the intestines and feces of humans and warm-blooded animals. The presence of fecal coliform in drinking water is taken as an indication that there is a greater risk,

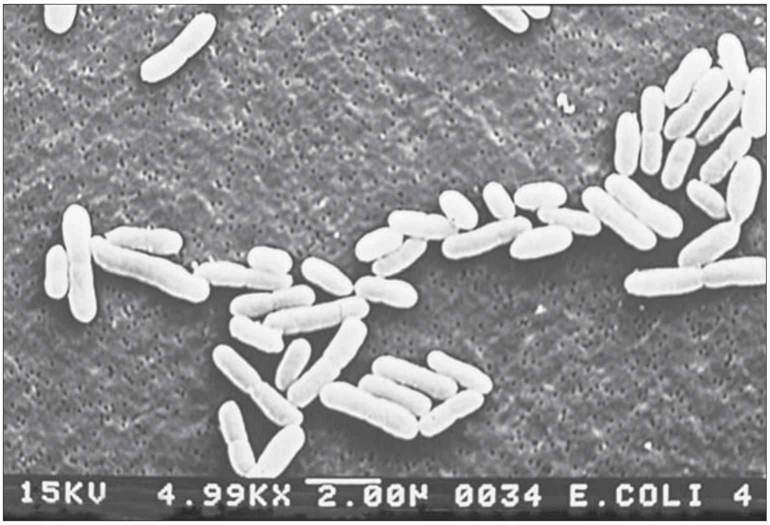

Figure 2–36

Micrograph of a pure culture of *E coli*.

as compared to the presence of total coliform, that disease-causing pathogens could also be present. If fecal coliform are detected, the same procedure as discussed for total coliform is followed to identify and eliminate the source of contamination, if one exists.

E. coli. The organism *Escherichia coli* (*E. coli*), specific to the intestines and feces of humans and warm blooded animals, has historically been the target organism tested for with the *total coliform test*. Although most *E. coli* strains are harmless to humans, serotype O157:H7 can cause food poisoning and, in some cases, become life threatening. Early on, it was found that the coliform test was not specific for fecal coliform or *E. coli* and that a variety of other coliform organisms were included in the test results. In recent years, tests have been developed that distinguish among total coliforms, fecal coliforms, and *E. coli*, and all three are currently being reported in the literature. The presence of *E. coli* in drinking water is taken as an indication that there is a greater risk, as compared to the presence of fecal or total coliform, that disease-causing pathogens could also be present. If *E. coli* are detected, the same procedure, as discussed above for total coliform, is followed to identify and eliminate the source of contamination, if one exists.

As a historical note, *Escherichia coli* (*E. coli*) is named after the German pediatrician Theodor Escherich (1857–1911), who first discovered this species in the feces of healthy infants and reported his findings in 1885. Initially, it was called *Bacterium coli commune* because it was found in the colon. Following a revision of the domain *Bacteria* in the late 1890s, it was reclassified in 1895 as *Bacillus coli*. In 1919, it was named *Escherichia coli* after its original discoverer (Castllani and Chalmers, 1919). The name *Escherichia coli* was adopted for use in Standard Methods in 1958. One of the most recent and important developments in the evolution of the coliform test is the ability to identify and quantify *E. coli* through the use of elevated temperatures and a specific growth medium 4-methylumbelliferyl-β-D-glucuronide (MUG). When *E. coli* are present, they are able to cleave the fluorogenic substrate MUG from the growth medium because they possess a specific enzyme (β-glucuronidase). The presence of a bright blue flourescnce is taken as a positive response for *E coli*.

Other Indicator Organisms. While total and fecal coliform organisms and *E. coli* may be present, it has not been demonstrated that they are indicators of the presence of enteric viruses and protozoa. Further, concerns for newly emerging pathogenic organisms which may arise from nonhuman reservoirs (e.g., pathogenic *E. coli, Cryptosporidium parvum,* and *Giardia lamblia*) have led to the questioning of the use of indicators that arise primarily from fecal inputs. In a recent study, it was concluded that coliform bacteria are adequate indicators for the potential presence of pathogenic bacteria and viruses but are inadequate as an indicator of the presence of waterborne protozoa. Waterborne disease outbreaks have also occurred in drinking water systems that have not violated their microbial water quality standards (Craun et al., 1997).

Given the limitations in using coliform organisms as indicators of potential contamination by wastewater, attention has now focused on the use of bacteriophages as an indicator organism and more specifically as indicators of enteric viruses. Bacteriophages are viruses that can infect prokaryotic cells. There are six major families of bacteriophages, five of which are DNA-based and one of which is RNA-based. Of the five DNA-based bacteriophages, three are double stranded and two are single stranded. Bacteriophages that infect *E. coli* are known as coliphages. Coliphages that attach directly to the cell wall are known as *somatic*. Coliphages that infect only male strains of *E. coli* (possess pilli) are known as male-specific (F^+) coliphages. The source of male-specific phages is thought only to be feces.

Within the male specific family there are four serotypes. Groups II and III are primarily of human origin whereas groups I and IV are of animal origin, with the exception of pigs, which may harbor groups II and III. Interest in using coliphages as an indicator of enterovirses is based on the fact that the phages are approximately the same size as most enteric viruses of interest (e.g., polio), are of fecal origin, and are always present in raw municipal wastewater. Coliphages have been used extensively in disinfection studies (see Sec. 12–9 in Chap. 12).

Evolving Pathogenic Microorganisms

In recent years there has been a disturbing increase in the number of disease outbreaks in the United States and in many other parts of the world, especially in light of the fact that it was thought that a number of endemic contagious diseases had been controlled or eliminated (only smallpox to date) (Levins et al., 1994). The bacteria *Legionella pneumophila,* the causative agent in Legionnaire's disease, is ubiquitous and is found in drinking water, wastewater, and reclaimed wastewater, is an example of a disease causing organism that has been identified relatively recently (Levins et al., 1994). The significance of the identification of new disease organisms, disease outbreaks, and the reemergence of old diseases is that the concern for public health must remain the primary objective of wastewater management.

2–10 TOXICITY

Wastewater can contain a variety of constituents, many of which can cause adverse impacts if discharged to the environment. *Toxicity* is a measure of the degree to which single or multiple constituents that may be present in untreated and treated wastewater can cause adverse impacts (damage) to human and animal health, sensitive aquatic biota, and ecosystems. To provide a general introduction to the subject of toxicity and toxicity testing, it will be useful to consider the following topics: (1) sources of toxicity in untreated and treated wastewater, (2) the evolution and application of toxicity testing, (3) toxicity testing procedures, (4) the analysis of toxicity test results, (5) the application of toxicity test results, and (6) methods that can be used to identify specific toxicity constituents.

Sources of Toxicity

The sources of toxicity in untreated and treated wastewater are derived from the constituents added during usage, treatment, and disinfection with chemical agents.

Constituents Added During Usage. Where a separate wastewater collection system is used, constituents added during usage can include (1) physical properties such as elevated temperature and TDS; (2) inorganic nonmetallic constituents such as ammonia and hydrogen sulfide; (3) metallic constituents such as chromium, mercury, and silver; (4) aggregate organic constituents such as cleaning and personal care products; and (5) individual organic compounds such as identified in Table 2–16. Where a combined wastewater collection system is used, an additional source of toxicity is from runoff. Constituents in runoff that can cause toxicity include pesticides and nutrients from yards, city landscaping, and agricultural lands, and heavy metals and organic and inorganic (e.g., salt) constituents from streets and highways.

Constituents Added During Treatment. Constituents added during treatment that can result in toxicity issues can include flocculent aids that contain contaminants, chemicals to precipitate phosphorus that contain contaminants, chemicals added to control foaming and frothing, and chemicals added to control algae growths.

Constituents Added During Disinfection. One of the most important sources of toxicity is from the disinfection byproducts formed during the disinfection of treated effluent with chemicals such as chlorine, chlorine dioxide, and ozone. The formation and control of chlorine, chlorine dioxide, and ozone disinfection byproducts is considered in Secs. 12–3, 12–4, and 12–6 in Chap. 12, respectively.

Evolution and Application of Toxicity Testing

Until the latter part of the twentieth century, pollution control measures were focused primarily on conventional pollutants (such as oxygen-demanding materials, suspended solids, etc.) which were identified as causing water quality degradation. During the past 30 y, increased attention has been focused on the control of toxic substances, especially those contained in wastewater treatment plant discharges. The national policy prohibiting the discharge of toxic pollutants in toxic amounts is documented in Section 101(a) (3) of the federal Clean Water Act. Because it is not economically feasible to determine the specific toxicity of each of the thousands of potentially toxic substances in complex effluents, whole effluent toxicity testing using aquatic organisms is a direct, cost-effective means of determining effluent toxicity. Whole effluent toxicity testing involves the introduction of appropriate bioassay organisms into test aquariums (see Fig. 2–37) containing various concentrations of the effluent in question and observing their responses. The whole effluent test procedure is used to determine the aggregate toxicity of unaltered effluent discharged into receiving waters. Toxicity is the only parameter measured.

Even though the focus of this section is on effluent toxicity, it should be noted that toxicity testing has number of other applications, including

1. Assess the suitability of environmental conditions for aquatic life.
2. Establish acceptable receiving water concentrations for conventional parameters (such as dissolved oxygen, pH, temperature, salinity, or turbidity).
3. Study the effects of water quality parameters on wastewater toxicity.
4. Assess the toxicity of wastewater to one or more freshwater, estuarine, or marine test organisms.
5. Establish relative sensitivity of a group of standard aquatic organisms to effluent as well as standard toxicants.
6. Assess the degree of wastewater treatment needed to meet water quality requirements.

Figure 2–37

Typical setup used to conduct of whole effluent toxicity tests where mortality is the test end point.

7. Determine the effectiveness of wastewater treatment methods.
8. Establish permissible effluent discharge rates.
9. Determine compliance with federal and state water quality standards and water quality criteria associated with NPDES permits (Standard Methods, 2012).

Such tests provide results that are useful in protecting human health, aquatic biota, and the environment from impacts caused by the release of constituents found in wastewater into surface waters. Toxicity identification, in which the constituents or compounds responsible for the observed toxicity are delineated, is another important aspect of toxicity assessment.

Toxicity Testing

Terms commonly encountered when considering the conduct of toxicity tests and the analysis, interpretation, and application of test results are summarized in Table 2–29. Because the terms reported in Table 2–29 are subject to change as new and improved methods of toxicity testing are developed, it is imperative that the latest version of Standard Methods and related U.S. EPA protocols be reviewed before undertaking any toxicity testing.

Toxicity tests are classified according to (1) duration (short-term, intermediate-term, or long-term); (2) method of adding test solutions (static, recirculation, renewal, or flow-through); (3) type of test (*in vitro,* tests in petri dishes or test tubes, or *in vivo*, toxicity tests using the whole organism); and (4) purpose (NPDES permit requirements, mixing zone determinations, etc). In vitro toxicity testing has been validated widely in recent years.

Even though organisms vary in sensitivity to effluent toxicity, the U.S. EPA has documented that (1) toxicity of effluents correlate well with toxicity measurements in the receiving waters when effluent dilution was measured, and that (2) predictions of impacts from both effluent and receiving water toxicity tests compare favorably with ecological community responses in the receiving waters. The U.S. EPA has conducted nationwide tests with freshwater, estuarine and marine ecosystems. Methods include both acute as

Table 2–29

Terms used in evaluating the effects of contaminants on living organisms[a, b]

Term	Description
Acute toxicity	Exposure that will result in significant response shortly after exposure (typically a response is observed within 48 or 96 h)
Chronic toxicity	Exposure that will result in sublethal response over a long-term, often 1/10 of the life span or more
Chronic value (ChV)	Geometric mean of the NOEC and LOEC from partial and full cycle tests and early-life-stages tests
Cumulative toxicity	Effects on an organism caused by successive exposures
Dose	Amount of a constituent that enters the test organism
Effective concentration (EC)	Constituent concentration estimated to cause a specified effect in a specified time period (e.g., 96-h EC_{50})
Exposure time	Time period during which a test organism is exposed to a test constituent
Inhibiting concentration (IC)	Constituent concentration estimated to cause a specified percentage inhibition or impairment in a qualitative function
In vitro	Tests conducted in glass petri dishes or test tubes
In vivo (in life)	Toxicity tests conducted using the whole organism
Lethal concentration (LC)	Constituent concentration estimated to produce death in a specified number of test organisms in a specified time period (e.g., 96-h LC_{50})
Lowest-observed-effect concentration (LOEC)	Lowest constituent concentration in which the measured values are statistically different than the control
Maximum allowable toxicant concentration (MATC)	Constituent concentration that may be present in receiving water without causing significant harm to productivity or other uses
Median tolerance limit (TLm)	An older term used to denote the constituent concentration at which at least 50 percent of the test organisms survive for a specified period of time. Use of the term "median tolerance limit" has been superseded by the terms median lethal concentration (LC_{50}) and median effective concentration (EC_{50})
No observed-effect concentration (NOEC)	Highest constituent concentration at which the measured effects are no different from the control
Sublethal toxicity	Exposure that will damage organism, but not cause death
Toxicity	Potential for a test constituent to cause adverse effects on living organisms
Whole effluent toxicity (WET)	The total (or aggregate) toxicity effect of treated effluent measured directly in a toxicity test

[a] Adapted from Hughes (1996) and Standard Methods (2012).

[b] It should be noted that the terms given in this table apply only to aquatic organisms and are, for the most part, distinct from the terms used for animals and humans.

Table 2–30

Typical examples of short-term chronic toxicity test methods using various freshwater and marine/estuarine aquatic species[a]

Species/common name	Test duration	Test endpoints
Freshwater species		
Cladoceran *Ceriodaphnia dubia*	Approximately 7 d (until 60 percent of control have 3 broods)	Survival, reproduction
Fathead minnow *Pimephales promelas*	7 d 9 d	Larval growth, survival Embryo-larval survival, percent hatch, percent abnormality
Freshwater algae *Selenastrum capricomutum*	4 d	Growth
Marine/estuarine species		
Sea urchin *Arbacia punctulata*	1.5 h	Fertilization
Red macroalgae *Champia parvula*	7–9 d	Cystocarp production (fertilization)
Mysid *Mysidopsis bahia*	7 d	Growth, survival, fecundity
Sheepshead minnow *Caprinodon variegatus*	7 d 7–9 d	Larval growth, survival Embryo-larval survival, percent hatch, percent abnormality
Inland silverside *Menidia beryijina*	7 d	Larval growth, survival

[a] Adapted from U.S. EPA (1988, 1989).

well as chronic exposures. Typical short-term chronic toxicity test methods are reported in Table 2–30. Detailed contemporary testing and analysis protocols are summarized in Standard Methods (2012) and in U.S. EPA publications (U.S. EPA, 1985b, c, d, e).

Analysis of Toxicity Test Results

Methods used to analyze both short-term (acute) and long-term (chronic) toxicity data are considered in the following discussion.

Acute Toxicity Data. The median lethal concentration (LC_{50}) when mortality is the test end point, or median effective concentration (EC_{50}) when a sublethal effect (e.g., immobilization, fatigue in swimming, "avoidance") is the end point, is typically used to define acute toxicity (Stephen, 1982). A typical bioassay setup using fish where mortality is the test endpoint is shown on Fig. 2–37. A fish swimming chamber is used to assess sublethal effects. A fish is placed in a chamber where the flow-through velocity can be increased until the fish is swept out of the chamber. The washout velocity for fish exposed to a specific compound can be compared to the washout velocity for the control fish.

Because the LC_{50} value is the median value, it is important to provide some information on the variability of the test population. The LC_{50} values can be determined graphically or analytically using the Spearman Karber, moving average, binomial, and probit methods. The 95 percent confidence limits are usually specified. Most standard statistical packages available for desktop computers include a probit analysis program. Determination of LC_{50} values, both graphically and by means of probit analysis, is illustrated in Example 2–13. Typically, LC_{50} values are computed based on survival at both 48-and 96-hour exposures.

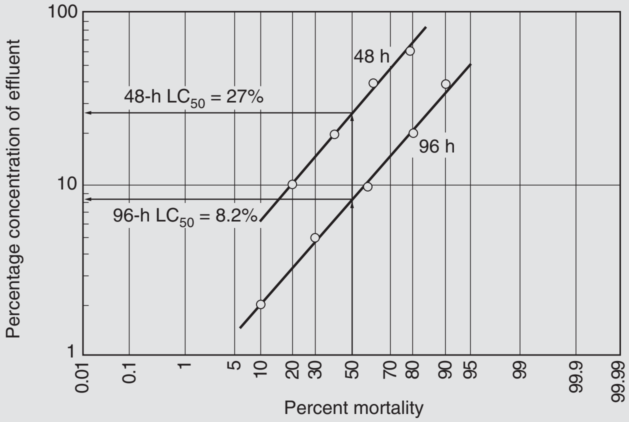
EXAMPLE 2–13 **Analysis of Acute Toxicity Data** Determine graphically and by probit analysis the 48-and 96-h LC_{50} values in percent by volume for the following toxicity test data obtained using flathead minnows.

Concentration of waste, % by volume	No. of test animals	No of test animals dead after[a] 48 h	96 h
60	20	16 (80)	20 (100)
40	20	12 (60)	18 (90)
20	20	8 (40)	16 (80)
10	20	4(20)	12(60)
5	20	0 (0)	6 (30)
2	20	0(0)	2 (10)

[a] Percentage values are given in parentheses.

Solution

1. Plot the concentration of wastewater in percent by volume (log scale) against the test animals that have died in percent (probability scale). The required plot is given below.



2. Fit a line to the data points by eye giving most consideration to the points lying between 16 and 84 percent mortality, which corresponds to approximately one standard deviation.
3. Find the wastewater concentration causing 50 percent mortality. The estimated LC_{50} values are
   a. 48-h $LC_{50} = 27.0\%$
   b. 96-h $LC_{50} = 8.2\%$

4. Compare the results obtained with a probit analysis to the values determined in Step 3. The probit analysis is conducted using a standard statistical analysis. The results of the probit analysis are as follows:
   a. 48-h $LC_{50} = 27.6\%$, 95% confidence limits 21.0 and 37.8%
   b. 96-h $LC_{50} = 8.1\%$, 95% confidence limits 5.8 and 10.9%

Comment Although the LC_{50} values obtained using the graphical analysis approach are approximate, they are quite close to the values obtained using the probit analysis approach and serve as a good check. To obtain confidence limits, a probit or similar analysis must be performed.

Chronic Toxicity Data. Results of chronic toxicity tests often are analyzed statistically to determine the lowest observed effect concentration (LOEC), the no observed effect concentration (NOEC), and the chronic value (ChV). Generally statistical significance is assumed to be at the $p = 0.05$ level. The chronic value (ChV) is calculated as the geometric mean of the LOEC and the NOEC.

Chronic toxicity limits may be specified with either NOEC or ChV as the end point. The term maximum acceptable toxicant concentration (MATC) often is used interchangeably with the chronic value. Similar to acute toxicity data, lethal concentration (LC) or effective concentration (EC) values can be used with chronic toxicity data to describe chronic toxicity tolerance levels. Recently, the concept of the inhibiting concentration (IC) has been introduced to characterize effects in chronic tests. A variety of nonparametric and parametric statistical methods are available to determine NOECs and LOECs and LCs, ECs, and ICs (Standard Methods, 2012).

Application of Toxicity Test Results

In applying acute and chronic toxicity test results, the toxic units (TU) approach has been adopted by a number of federal and state agencies. In the toxic units approach (U.S. EPA, 1985b), a TU concentration is established for the protection of aquatic life.

Toxic Unit Acute (TU_a). TU_a is defined as the reciprocal of the wastewater concentration that caused the acute effect by the end of the exposure period.

$$TU_a = 100/LC_{50} \tag{2–67}$$

Toxic Unit Chronic (TU_c). The TU_c is defined as the reciprocal of the effluent concentration at which the measured effects, by the end of the chronic exposure period, are no different from the control.

$$TU_c = 100/NOEC \tag{2–68}$$

where NOEC = no observed effect concentration.

Depending on the use to be made of the toxicity test results, a variety of different numerical values have been used for TU_a and TU_c as a basis for assessing the suitability of a given effluent for discharge to the environment. For example, to protect against acute toxicity it has been suggested that the MATC should be less than 0.3 × TU_c. Because the limiting values vary from location to location, current regulatory standards must reviewed in applying toxicity results. The application of toxicity test results is illustrated in Example 2–14.

EXAMPLE 2–14 **Application of Toxicity Test Results** A critical initial dilution of 100:1 is achieved for a treated effluent discharged to marine receiving waters. Toxicity tests were conducted with the wastewater treatment plant effluent using three marine species. Based on the toxicity test results, it was found that *Champia parvula* was the most sensitive species acute end point (2.59 percent effluent) as measured by the EC_{50}, and also the most sensitive species chronic end point (1.0 percent) as measured by the NOEC. For protection of the aquatic environment, the acute and chronic toxicity requirements have been set at 10 TU_a and 1.0 Tu_c, respectively.

Results of Acute Toxicity Tests

Species	Control exposure, h	Survival, %	Percent effluent	
			LC_{50} or EC_{50}[a]	NOael
Mysidopis bahia	96	100	18.66	10.00
Cyprinodon variegatus	96	100	>100	50.00
Champia parvula	48/168	100	2.59	12.25

[a] EC_{50} results based on reduction of cystocarp production.

Results of Chronic Toxicity Tests

Species	Control exposure, d	Survival, %	Percent effluent	
			NOEC	LOEC
Mysidopis bahia	7	82.0	6.0	10.00
Cyprinodon variegatus	7	98.8	15.0	15.00>
Champia parvula	7	100.0	1.0	2.25

Solution

1. Check compliance with acute toxicity requirements.
   a. Based on data for the most sensitive species tested, the number of acute toxic units (TU_a), based on Eq. (2–67), is

   $$TU_a = 100/LC_{50} = 100/2.59 = 38.6$$

   b. Following an initial dilution of 100, the TU_a value is

   $$TU_a /100 = 38.6/100 = 3.86\ TU_{ad} \text{ (after dilution)}$$

   Because the TU_a value after dilution (3.86 TU_{ad}) is less than 10 TU_a the acute toxicity requirement has been met.

2. Check compliance chronic toxicity requirements.
   a. Based on data for the most sensitive species tested, the number of chronic toxic units (TU_c), based on Eq. (2–68), is

      $TU_c = 100/\text{NOEC} = 100/1.0 = 100$

   b. Following an initial dilution of 100, the TU_c value is

      $TU_c = 100/100 = 1.0\ Tu_{cd}$ (after dilution)

      Because the TU_c value after dilution (1.0 TU_{cd}) is equal to 1.0 TU_c, the chronic toxicity requirement has been met.

In summary, there are a number of advantages to the use of whole effluent toxicity testing. In this approach, the bioavailability of the toxics is measured, and the effects of any synergistic interactions are also considered. Because the aggregate toxicity of all components of the wastewater effluent is determined, the toxic effect can be limited by limiting only one parameter, the effluent toxicity. Because contemporary receiving water management strategies are based on site-specific water quality criteria, toxicity testing facilitates comparison of effluent toxicity with site-specific water quality criteria designed to protect representative, sensitive species and yet allow for establishment of discharge limitations that will protect aquatic environments.

Identification of Toxicity Components

Toxicity testing can also be used to determine the source of toxicity, an especially important test for industrial discharges. For example, is the toxicity caused by the suspended solids, the colloidal solids, the long- or short-chain dissolved organic constituents, or the dissolved inorganic constituents? To determine the source(s) of the toxicity, each of the potential sources must be isolated from the other constituents in the sample and tested for toxicity. The various methods that can be used to fractionate a wastewater sample are illustrated graphically on Fig. 2–38 and described in Table 2–31.

Figure 2–38

Separation techniques that can be used to fractionate a wastewater sample. (Adapted from Eckenfelder, 1999.)

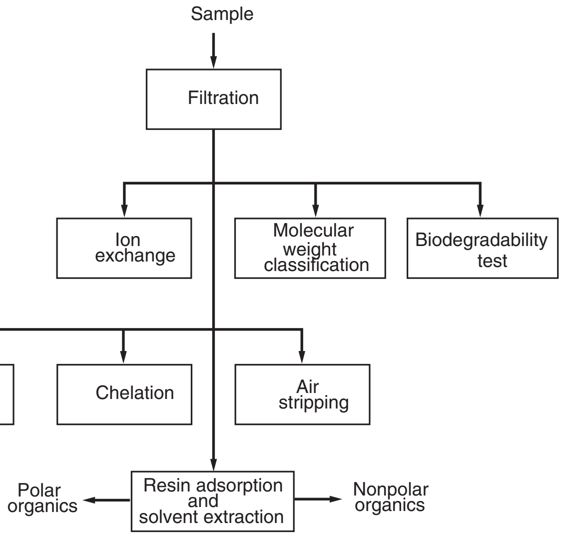


Table 2–31

Description of separation techniques that can be used to fractionate a wastewater sample[a]

Separation technique	Description
Filtration for suspended solids	Filtration is generally performed first to determine whether the toxicity is related to the soluble or insoluble phase of the sample. Typically, 1 μm glass fiber filters that have been prewashed with ultrapure water are used. The insoluble phase should be resuspended in control water to insure that filtration, not adsorption on the filter medium, removed the toxicity.
Filtration for colloidal solids	A 0.1-μm filter should be used to determine if the colloidal fraction is responsible for the toxicity.
Ion exchange	Inorganic toxicity can be studied by using cationic and anionic exchange resins to remove potentially toxic inorganic compounds or ions.
Molecular weight classification	Evaluating the molecular weight distribution of the influent, and the toxicity of each molecular weight range, can often narrow the list of suspected contaminants.
Biodegradability test	Controlled biological treatment of effluent samples in the lab can result in almost compete oxidation of the biodegradable portion of organics. Bioassay analysis can then quantify the toxicity associated with the nonbiodegradable components, as well as the reduction in toxicity attainable by biological treatment.
Oxidant reduction	Residual chemical oxidants carried over from a process (e.g., chlorine and chloramines used for disinfection, or ozone and hydrogen peroxide used in sludge conditioning) can be toxic to most organisms. A simple batch reduction of these oxidants at various concentrations, using an agent such as sodium thiosulfate, can be used to assess the toxicity of any remaining oxidants.
Metal chelation	The toxicity of the sum of all cationic metals (with the exception of mercury) can be determined by chelation of samples, using varying concentrations of ethylenediaminetetraacetic acid (EDTA) and evaluating the change in toxicity.
Air stripping	Batch air stripping at acid, neutral, and basic pH can remove essentially all volatile organics. At a basic pH, ammonia is removed as well. Thus, if both volatile organics and ammonia are suspected toxicants, an alternative ammonia removal technique, such as a zeolite exchange, should be used. (Note that ammonia is toxic in the nonionized form, so ammonia toxicity is very pH dependent.)
Resin adsorption and solvent extraction	Specific nonpolar organics can sometimes be identified as toxics, using a resin-adsorption/solvent-extraction process. A sample is adsorbed on a long-chain organic resin, the organics are reextracted from the resin with a solvent (e.g., methanol), and the toxicity of the sample is determined using a bioassay test procedure.

[a] Adapter from Eckenfelder (2000).

PROBLEMS AND DISCUSSION TOPICS

2–1 The following test results were obtained for three treated wastewater effluent samples. Check the accuracy of the analytical measurements for one of the waters (to be selected by instructor). Do you suspect that a constituent of significance has been neglected? If so, is it a cation or anion?

	Concentration, mg/L				Concentration, mg/L		
	Wastewater sample no.				Wastewater sample no.		
Cation	1	2	3	Anion	1	2	3
Ca^{2+}	121.3	76.0	190.2	HCO_3^-	280.0	128.2	260.0
Mg^{2+}	36.2	27.2	84.1	SO_4^{2-}	116.0	240.0	64.0
Na^+	8.1	22.9	75.2	Cl^-	61.0	37.2	440.4
K^+	12.0	18.7	5.1	NO_3^-	15.6	2.0	35.1
Fe^{2+}	—	2.1	0.2	CO_3^{2-}	—	—	30.0

2–2 Determine the mole fraction of Ca^{2+}, Mg^{2+}, and SO_4^{2-} for one of the following treated wastewater effluents (to be selected by instructor).

	Concentration, mg/L				Concentration, mg/L		
	Wastewater sample no.				Wastewater sample no.		
Cation	1	2	3	Anion	1	2	3
Ca^{2+}	206.6	161.4	226.1	HCO_3^-	525.4	438.7	476.6
Mg^{2+}	95.3	47.5	62.1	SO_4^{2-}	219.0	153.2	483.2
Na^+	82.3	71.4	46.2	Cl^-	303.8	163.8	20.6
K^+	5.9	2.2	3.5	NO_3^-	19.2	8.1	9.3
Fe^{2+}			3.1	CO_3^{2-}			

2–3 Determine the ionic strength and activity coefficients and activity for the constituents for one of the wastewater effluents in Problem 2–1 or 2–2 (to be selected by instructor).

2–4 Estimate the TDS for one of the water samples in Problem 2–1 or 2–2 (to be selected by instructor) using Eq. (2–11) and by summing the mass of the individual ionic species. How do the computed values compare?

2–5 Using the following formula, modified appropriately, determine the concentration of total and volatile solids, expressed as mg/L, for one of the wastewater samples (to be selected by instructor).

$$\mathrm{TS} = \frac{\left[\begin{pmatrix}\text{mass of evaporating}\\ \text{dish plus residue, g}\end{pmatrix} - \begin{pmatrix}\text{mass of evaporating}\\ \text{dish, g}\end{pmatrix}\right]\left(\dfrac{10^3\ \text{mg}}{\text{g}}\right)}{\text{sample size, L}}$$

		Weight, g			
		Sample number			
Item	Unit	1	2	3	4
Sample size	mL	90	100	120	200
Tare mass of evaporating dish	g	22.6435	22.6445	22.6550	22.6445
Mass of evaporating dish plus residue after evaporation at 105°C	g	22.6783	22.6832	22.6995	22.6667
Mass of evaporating dish plus residue after ignition at 550°C	g	22.6768	22.6795	22.6832	22.6433

2–6 The following test results were obtained for a wastewater sample taken at the headworks to a wastewater treatment plant. All of the tests were performed using a sample size of 50 mL. Determine the concentration of total solids, total volatile solids, total suspended solids, volatile suspended solids, and dissolved solids for one of the samples (to be selected by instructor) (refer to the formula given in Problem 2–5).

	Weight, g			
	Sample number			
Item	1	2	3	4
Tare mass of evaporating dish	53.5435	53.5434	53.5436	53.5433
Mass of evaporating dish plus residue after evaporation at 105°C	53.5765	53.5693	53.5725	53.5793
Mass of evaporating dish plus residue after ignition at 550°C	53.5515	53.5489	53.5495	53.5523
Tare mass of Whatman GF/C filter	1.5433	1.5435	1.5436	1.5434
Mass of Whatman GF/C filter plus residue after drying at 105°C	1.5533	1.5521	1.5635	1.5541
Mass of Whatman GF/C filter plus residue after ignition at 550°C	1.5457	1.5455	1.5456	1.5457

2–7 The following data were obtained from a serial filtration test of a settled effluent after biological treatment. Prepare a plot of one of the samples (to be selected by instructor). How great an error in the measurement of the total suspended and colloidal solids would occur if a filter paper with a nominal pore size of 1.2 μm was used to determine the total suspended solids, as compared to using a filter with a nominal pore size of 0.1 μm filter?

Nominal pore size, μm	Suspended solids, mg/L			
	Sample number			
	1	2	3	4
12	20.2	29.4	22.5	25.1
8	8.8	11.5	8.0	15.1
5	4.1	3.5	4.9	2.2
3	7.5	5.1	11.6	8.9
1	15.1	13.5	21.2	25.0
0.1	9.9	15.1	24.9	17.5

2–8 Determine the coefficients A and β in Eq. (2–16) for the following particle size data obtained using a particle counter with arithmetic channel settings.

	Number of particles			
	Sample number			
Channel size, μm	1	2	3	4
1–2	27,000	3980	25,119	1000
2–5	9029	1690	4979	599
5–10	4050	450	561	199
10–15	1418	100	123	100
15–20	405	60	45	45
20–30	203	40	26	40
30–40	36	20	8	20
40–60	16	9		20
60–80	8	5		10
80–100	5	3		6
100–140	4	2		

2–9 If the average intensity of the UV irradiation to which a sample was exposed is 5, 10, 15 mW/cm^2 (to be selected by instructor), determine the UV intensity measured at the water surface in a Petri dish. The depth of water in the Petri dish is 8, 10 or 12 mm (to be selected by instructor). Assume the absorptivity, $k(\lambda = 254\ \text{nm})$, is equal to 1.25 cm^{-1}.

2–10 Estimate the alkalinity, expressed as mg/L as $CaCO_3$, for one of the water samples in Problem 2–1 (to be selected by instructor).

2–11 What is the molar mass of a gas at 20°C assuming the gas has a density of 0.68 g/L at standard temperature and pressure (STP)?

2–12 At what pH would 95 percent of the ammonia be present as gas? Apply Eq. (2–40) and give the acid ionization (dissociation) constant at 25°C?

2–13 Compare the saturation concentrations of O_2, N_2, and CO_2 between San Francisco (sea level) and Taos, NM (elevation 2150 m), Denver, CO (elevation 1600 m) or La Paz, Bolivia (elevation 4270 m) (city to be selected by instructor).

2–14 Using Henry's law, determine the saturation concentration of O_2, N_2, or CO_2 (gas to be selected by instructor) in water at 0, 10, 20, 30, 40, and 50°C. Construct a plot of O_2, N_2, or CO_2 saturation concentration as a function of temperature.

2–15 Determine the concentration of oxygen in the liquid phase of a covered pure-oxygen-activated sludge plant subject to 2, 2.5, or 3 atm of pressure (pressure to be selected by instructor). For the purposes of this problem, neglect any reactions occurring in the system. The composition of the gas in the head space above the wastewater is 80 percent oxygen, 15 percent nitrogen, and 5 percent carbon dioxide by volume.

2–16 Bottled soda water is produced by increasing the gas pressure and carbon dioxide content. For a bottle having a total gas pressure of 2 atm, determine the pH of the soda water at 25°C. The composition of the gas in the head space above the soda water is 95 percent carbon dioxide by volume.

2–17 Intensity measurements were made at different dilutions for three odor samples. Using the data provided, determine which of the three odors is more persistent.

n-butanol odor intensity, ppm$_v$	Dilution-to-threshold, D/T Sample 1	 2	 3
10,000	0	0.0	0
100	25	3.2	11
10	316	10.0	56
0	3160	32.0	265

2–18 A 175, 200, 225 mL volume (volume to be selected by instructor) of distilled odor-free water was required to reduce the odor of a 25 mL sample of treated wastewater to a level that is just perceptible. What is the threshold odor number (TON)? What is the corresponding value expressed in D/T (dilutions-to–threshold)? Assuming the odorous compound is hydrogen sulfide, find the concentration of hydrogen sulfide in the original sample of treated wastewater. Assume the sample is at equilibrium with the atmosphere. Assume the data in Table 2–8 apply.

2–19 The local Air Pollution Control District has threatened to fine and penalize the local wastewater management agency, your client, because of frequently recurring odor complaints from residents who live downwind of the plant. The plant manager, a full-time employee at the treatment plant, claims that no problem exists. He proves his point by consistently finding less than 5 dilutions to MDTOC at the plant boundary using a hand-held sniff dilution olfactometer as employed by the local Air Pollution Control District. You, however, live downwind of the plant and have frequently detected odors from it. Why do these differences exist? How would you resolve them objectively?

2–20 You have been asked to review an odor-control system that has apparently failed to control odors from a sludge-dewatering building adequately. The wastewater management agency, your client, claims the system has failed to perform according to specifications. The engineering contractor who installed the system claims that the specifications were not adequate.

In your investigation you find that the agency employed a reputable odor consultant to develop the odor-control-system specifications. The consultant used the ASTM Panel Method for odor measurement, using evacuated glass cylinders for sample collection. Several measurements were made, and the maximum observed value was doubled to develop the control-system specifications. In this way a 90 percent odor-removal requirement was established to meet the desired final odor-emission limit of 2.8×10^4 odor units per minute (the product of airflow in m^3/min and number of dilutions to MDTOC).

Using a direct-reading olfactometer, you find that the control system removes 99 percent of the odor, and that at a rate of 10^6 odor units per minute the final odor emission is 10^6 odor units per minute. What reasons might explain your findings? How would you resolve the problem?

2–21 In a BOD determination, 6 mL of wastewater are mixed with 294 mL (total volume of BOD bottle is 300 mL) of diluting water containing 9.1 mg/L of dissolved oxygen. After a 5-d incubation at 20°C, the dissolved oxygen content of the mixture is 2.8 mg/L. Calculate the BOD of the wastewater. Assume that the initial dissolved oxygen concentration in the wastewater is zero and that the following equation applies:

$$\text{BOD, mg/L} = \frac{D_1 - D_2}{P}$$

where D_1 = dissolved oxygen of diluted sample immediately after preparation, mg/L
D_2 = dissolved oxygen of diluted sample after 5-d incubation at 20°C, mg/L
P = fraction of wastewater sample volume to total combined volume

2–22 Solve Problem 2–21 for one of the following conditions (to be selected by instructor). In all cases, the total volume of the BOD bottle is 300 mL.

a. sample size = 8 mL, oxygen in dilution water = 9.0 mg/L, oxygen in mixture after 7-d incubation at 20°C = 1.8 mg/L
b. sample size = 6 mL, oxygen in dilution water = 9.2 mg/L, oxygen in mixture after 6-d incubation at 20°C = 1.65 mg/L
c. sample size = 6 mL, oxygen in dilution water = 8.9 mg/L, oxygen in mixture after 4-d incubation at 20°C = 1.5 mg/L
d. sample size = 10 mL, oxygen in dilution water = 9.15 mg/L, oxygen in mixture after 5-d incubation at 20°C = 1.42 mg/L

2–23 Determine the UBOD and BOD_5 (in mg/L) of a mixture of 150 mg/L glucose ($C_6H_{12}O_6$) and 150 mg/L glutamic acid ($C_5H_{10}N_2O_3$). Assume the value of the BOD_5 first-order reaction rate constant is $0.23\ d^{-1}$ (base e), at 20°C.

2–24 If the 5-d 20°C BOD of a wastewater is 185, 200, or 220 mg/L (to be selected by instructor), what will be the ultimate BOD (UBOD)? What will be the 10-d demand? If the bottle had been incubated at 15°C and the first order reaction rate constant, k_1, is $0.23\ d^{-1}$ (base e), what would the 5-d BOD have been?

2–25 If the BOD value at 20°C of a wastewater measured at 2 and 8 d, 1 and 9 d, 2 and 7 d, and 3 and 10 d (day to be selected by instructor) was found to be 125 and 225 mg/L, respectively, determine the 5-d value using the first-order rate model.

2–26 The following results for a wastewater sample were determined at 20°C. For a sample (to be selected by instructor) determine the ultimate carbonaceous oxygen demand, the ultimate nitrogenous oxygen demand (NOD), the carbonaceous BOD reaction-rate constant (k), and the nitrogenous NOD reaction-rate constant (k_n). Determine $k(\theta = 1.05)$ and $k_n(\theta = 1.08)$ at 25°C.

	BOD, mg/L			
	Sample number			
Time, d	1	2	3	4
0	0	0	0	0
2	18	30	45	36
4	26	43	75	58
6	30	52	95	70
8	33	58	114	80
10	56	60	135	90
12	69	90	144	98
14	77	104	149	102
16	82	114	151	145
18	84	120	152	170
20	87	125	152	182
25	90	135	170	210
30	91.5	142	239	222
35	92.5	147	260	233
40	93	148	268	239
45	94	149	271	240
50	94.5	150	272	241

2–27 If the observed first-order carbonaceous BOD reaction rate coefficients are 0.23 and 0.28 d^{-1} at 20 and 30°C, 0.22 and 0.15 d^{-1} at 20 and 12°C, or 0.15 and 0.30 d^{-1} at 10 and 20°C (to be selected by instructor), estimate the activation energy for the reaction. Hint: see Example 1–1.

2–28 Compute the carbonaceous and nitrogenous oxygen demand of a wastewater represented by the formula $C_6N_2H_4O$, $C_9N_2H_6O_2$, $C_{10}N_2H_8O_2$ or $C_{12}N_4H_6O_2$, (formula to be selected by instructor). Assume N is converted to NH_3 in the first step.

2–29 The following data have been obtained for five different wastewater samples. Estimate the total quantity of oxygen in mg/L that must be furnished to stabilize completely one of the wastewaters (to be selected by instructor). What are the corresponding COD and the ThOD for the wastewater?

		Wastewater sample				
Item	Unit	1	2	3	4	5
BOD	mg/L	400	375	225	185	325
k (base *e*)	d^{-1}	0.29	0.23	0.027	0.025	0.023
NH_3	mg/L	80	65	75	67	83

2–30 An industrial wastewater is known to contain only glycine ($C_2H_5O_2N$), glucose ($C_6H_{12}O_6$), and stearic acid ($C_{18}H_{36}O_2$). The results of a laboratory analysis for four different samples are as follows. For one of these samples (to be selected by instructor), determine the concentration of each of the three constituents in mg/L. Base your answer on 10^5 L so that the mole numbers are greater than one.

a. organic nitrogen = 11 mg/L, organic carbon = 130 mg/L, and COD = 425 mg/L. Determine the concentration of each of the three constituents in mg/L.

b. organic nitrogen = 13 mg/L, organic carbon = 109 mg/L, and COD = 440 mg/L. Determine the concentration of each of the three constituents in mg/L.

c. organic nitrogen = 9 mg/L, organic carbon = 123 mg/L, and COD = 625 mg/L. Determine the concentration of each of the three constituents in mg/L.

d. organic nitrogen = 12 mg/L, organic carbon = 143 mg/L, and COD = 425 mg/L. Determine the concentration of each of the three constituents in mg/L.

2–31 How many mg/L of $Cr_2O_7^{-2}$ are consumed if the COD of a wastewater sample is found to be 300, 375, 450, or 525 mg/L (value to be selected by instructor)?

2–32 If the chemical composition of food waste is $C_{21.53}H_{34.21}O_{12.66}N_{1.00}S_{0.07}$, estimate the chemical energy content on a COD basis. Express results on the basis of MJ/kg COD computed as HHV on dry weight basis. How does the computed energy content for food waste compare to that of wastewater as determined in Example 2–12? How much energy has been removed from the food waste?

2–33 Bacteria have equivalent diameters of 2×10^{-6} μm and densities of approximately 1 kg/L. Under optimal conditions, bacteria can divide every 30 min. Determine the mass of bacteria that would accumulate in 72 h under continuing optimal growth conditions. Can this occur? Explain.

2–34 If the bacteria found in feces have an average volume of 2.0 μm^3, determine the concentration of suspended solids that would be represented by a bacterial density equal to 10^8 organisms/mL. Assume the density of the bacteria is 1.005 kg/L.

2–35 Using the following joint probability equation, based on the Poisson distribution, derive an expression that can be used to compute the MPN based on a single sample comprised of 5 fermentation tubes. What is the MPN if the sample size is 0.1 mL and 3 of 5 fermentation tubes are positive?

$$y = 1/a[(1 - e^{-n\lambda})^p(e^{-n\lambda})^q]$$

where y = probability of occurrence of a given result
a = constant for a given set of conditions
n = sample size, mL
λ = coliform density, number/mL
p = number of positive tubes
q = number of negative tubes

2–36 Seven effluent samples have been analyzed for total coliform using the standard confirmed test. Using the standard MPN tables, determine the coliform density, expressed as MPN, for three of the seven samples (to be selected by instructor). Refer to the most recent edition of Standard Methods for MPN tables.

Size of portion, mL	Positive tubes/total tubes						
	Sample number						
	1	2	3	4	5	6	7
100.0			5/5	5/5	5/5	5/5	5/5
10.0		4/5	4/5	5/5	5/5	5/5	5/5
1.0	4/5	5/5	5/5	5/5	5/5	5/5	5/5
0.1	3/5	3/5	3/5	2/5	1/5	2/5	5/5
0.01	1/5	2/5	2/5	3/5	2/5	2/5	5/5
0.001					0/5	1/5	1/5

2–37 Discuss the advantages and disadvantages of using the fecal coliform and fecal streptococci tests to indicate bacteriological contamination. Cite a minimum of three references from the literature.

2–38 A coliphage virus test using MS-2 was performed to determine the titer of the undiluted sample. During the test, one milliliter of each dilution was added to each plate. The results of the plaque counting are shown in the table given below. Based on the results, calculate the titer of the culture in the undiluted sample.

	Count/plate				
	Sample				
Dilution	Original	Dup. 1	Dup. 2	Dup. 3	Dup. 4
10^{-7}	FP[a]	FP	FP	FP	FP
10^{-8}	TNTC[b]	TNTC	TNTC	TNTC	TNTC
10^{-9}	120	110	116	TNTC	123
10^{-10}	60	51	38	43	56
10^{-11}	1	2	0	1	1

[a] FP = full plaque on plate.
[b] TNTC = too numerous to count.

2–39 Using the following toxicity test data, determine the 48 and 96 h LC_{50} values in percent by volume.

Concentration of waste, % by volume	Number of test animals	Number of test animals dead after	
		48 h	96 h
80	20	17	20
60	20	13	20
40	20	10	15
20	20	6	13
10	20	3	9
5	20	1	4
2	20	0	2

2–40 Using the following toxicity test data, determine the 48 and 96 h LC_{50} values in percent by volume.

Concentration of waste, % by volume	Number of test animals	Number of test animals surviving after		
		24 h	48 h	96 h
12	20	0	2	8
10	20	0	5	10
8	20	1	8	13
6	20	3	11	16
4	20	6	16	20
2	20	14	20	20

3

Wastewater Flowrates and Constituent Loadings

WORKING TERMINOLOGY

Term	Definition
Combined sewer overflow (CSO)	A hydraulic relief structure within a combined collection system to allow excess wet-weather flow to be discharged ahead of the interceptor, pumping station or wastewater treatment plant.
Combined sewer system	A collection system which conveys both sanitary wastewater at all times and stormwater runoff during wet weather, as well as snowmelt.
Delayed inflow	Stormwater that may require several hours or days or more to drain through the collection system.
Direct inflow	Those types of inflow that have a direct stormwater runoff connection to the sanitary collection system and cause an almost immediate increase in wastewater flowrates.
Domestic wastewater	Wastewater discharged from residences and from commercial, institutional, and similar facilities including infiltration.
Exfiltration	Flow out of a collection system through breaks in the pipe wall, defective pipe joints or connections, or breaks in access port (manhole) walls.
Flow equalization	The dampening of flowrate variations to obtain a constant or nearly constant flowrate, usually by means of a storage (equalization) basin.
Industrial wastewater	Wastewater from nondomestic sources in which industrial wastes predominate.
Infiltration	Water entering a collection system from a variety of entry points including service connections and from the ground through defective pipe joints, connections, or breaks in access port (manhole) walls.
Inflow	Extraneous water that is discharged to the collection system such as from roof leaders, area drains, access port covers, cross connections from storm drains and catch basins, and combined systems.
Instantaneous peak flowrate	Highest recorded flowrate occurring for a period consistent with the recording equipment. In many situations the recorded peak flow may be considerably below the actual peak flow because of metering and recording equipment limitations.
Mass loading rate	The product of flowrate times constituent concentration.
Peaking factor	The ratio of the peak flowrate to the average flowrate.
Sanitary sewer overflow (SSO)	The release of wastewater from the sanitary sewer system caused by backups, clogging or hydraulic overloading.
Sanitary sewer system	A collection system in which primarily domestic wastewater is conveyed.
Steady inflow	Water discharged from cellar and foundation drains, cooling water discharges, and drains from springs and swampy areas.
Stormwater	Runoff resulting from rainfall and snowmelt.
Sustained flowrates	Flowrates that are equalled or exceeded for a specified number of consecutive days based on annual operating data.
Sustained mass loadings	The mass loading rate value sustained or exceeded for a given period of time (e.g., 1 h, 1 d, or 1 mo).

Determining wastewater flowrates and constituent mass loadings is a fundamental step in initiating the conceptual process design for upgrading existing and developing new wastewater treatment facilities. Reliable data for existing and projected flowrates are essential for determining the hydraulic characteristics, sizing, and operational considerations of the treatment system components. Constituent mass loading rate, the product of constituent concentration and flowrate, is necessary to determine the capacity and operational characteristics of the treatment facilities and ancillary equipment to ensure that treatment objectives are met.

Important factors and issues, typical to most planning and design projects, addressed in this chapter include (1) wastewater sources and flowrates, (2) impact of the collection system on wastewater flowrates, (3) analysis of wastewater flowrate data, (4) analysis of wastewater constituents, (5) analysis of constituent concentrations and mass loading rate data, (6) selection of design flowrates and mass loading rates, and (7) flow equalization.

3–1 WASTEWATER SOURCES AND FLOWRATES

The components that make up the wastewater flow from a community, identified previously in Chap. 1, and repeated here for convenience, are

Domestic (also called sanitary) wastewater. Wastewater discharged from residences and from commercial, institutional, and public facilities.

Industrial wastewater. Wastewater in which industrial process wastes predominate.

Infiltration/inflow (I/I). Water that enters the collection system through indirect and direct means. Infiltration is extraneous water that enters the collection system through leaking joints, cracks and breaks, or porous walls. Inflow is stormwater that enters the collection system from storm drain connections (catch basins), roof leaders, foundation and basement drains, or through access port (manhole) covers or breaks in the access port the walls.

Stormwater. Runoff resulting from rainfall and snowmelt.

Data that can be used to estimate average wastewater flowrates from various domestic, commercial, institutional, and industrial sources are presented in this section. The contributions associated with the collection system are considered in the following section.

Municipal Uses of Water

To understand the sources of wastewater it is helpful to review briefly the municipal use of water. Municipal uses of water may be divided into various categories as reported in Table 3–1. Domestic use includes water used indoors in private residences, apartment houses, etc., for drinking, cooking, hand washing, bathing, laundry, toilet flushing, and other uses, and outdoors for landscape irrigation, car washing, and other outdoor purposes.

Commercial and industrial use includes water used by commercial establishments and industries. In small residential communities the commercial and industrial use may be as low as 40 L/capita·d (10 gal/capita·d), but in industrial cities it may as high as 400 L/capita·d (100 gal/capita·d). Public use includes the water required for use in parks, civic buildings, schools, hospitals, churches, street washing, etc. Water that leaks from the system, meter slippage, unauthorized connections, and all other unaccounted-for water is classified as loss and waste. The loss and waste category is often estimated at about 75 L/capita·d (20 gal/capita·d), but with proper construction and careful maintenance it can be reduced to less than 20 L/capita·d (5 gal/capita·d).

Table 3–1

Municipal uses of water and typical quantities in the United States[a]

Use	Flowrate, gal/capita·d		Flowrate, L/capita·d	
	Range	Typical	Range	Typical
Domestic				
Indoor use	40–80	65[b]	150–300	250
Outdoor use	16–90	35[c]	60–340	132
Commercial	10–75	40	40–300	150
Public	15–25	20	60–100	75
Loss and waste	15–25	20	60–100	75
Total	96–255	170	370–990	682

[a] Data developed from numerous sources and the authors experience.

[b] Based on current (mid-2013) level of water conservation.

[c] In some parts of the country, outdoor water use is significantly higher than indoor use, depending on the season of the year.

Domestic Wastewater Sources and Flowrates

The principal sources of domestic wastewater in a community are the residential areas and commercial districts. Other important sources include public and private institutional facilities and public recreational facilities. Knowledge of the wastewater flowrates is of fundamental importance in the design and operation of wastewater treatment systems. Flowrates are measured both within the collection system and wastewater treatment plants.

Flowrate Measurements in the Collection System. For areas served with collection systems, wastewater flowrates are determined commonly from existing records or by direct field measurements. Flowrate measurements can be made within gravity sewers by installing flow meters in access ports. In the past, measuring flumes (e.g., Palmer Bowlus) or weirs were installed with level measuring equipment calibrated to output direct flowrate readings. Although flumes and weirs are still used occasionally, most collection system flowrate measurements are now made using area-velocity meters. Area-velocity devices are used to measure simultaneously the depth of flow and the velocity in the collection system without restricting the flow path. Both ultrasonic and radar based devices are used [see Figs. 3–1(a) and (b)]. Unmetered pump stations in the collection system can also be used for gathering flowrate information by measuring the wet well volume and determining the time between pump starting and stopping.

Flowrate Measurements at Treatment Plants. Flowrate measurements at wastewater treatment plants are made with a variety of flowmeters. In the past, influent flowrate measurements were made with Venturi meters for measurements in force mains and Parshall flumes for open channel measurements. Today, the preference is for magnetic meters for force mains because they have a shorter laying length, no flow constrictions, and minimal headloss [see Figs. 3–1(c), (d) and (e)]. Ultrasonic meters are also used. Parshall flumes are the least complicated and flow can be measured manually in case the metering equipment is out of calibration or inoperative [see Figs. 3–1(f) and (g)]. The only problem with the Parshall flume is that to operate properly it requires a free discharge, and thus, the headloss is higher than other measuring devices.

Flowrate Estimates from Available Data. For new developments or newly sewered areas, wastewater flowrates are derived from an analysis of population data and estimates of per capita wastewater flowrates from similar communities. These records are

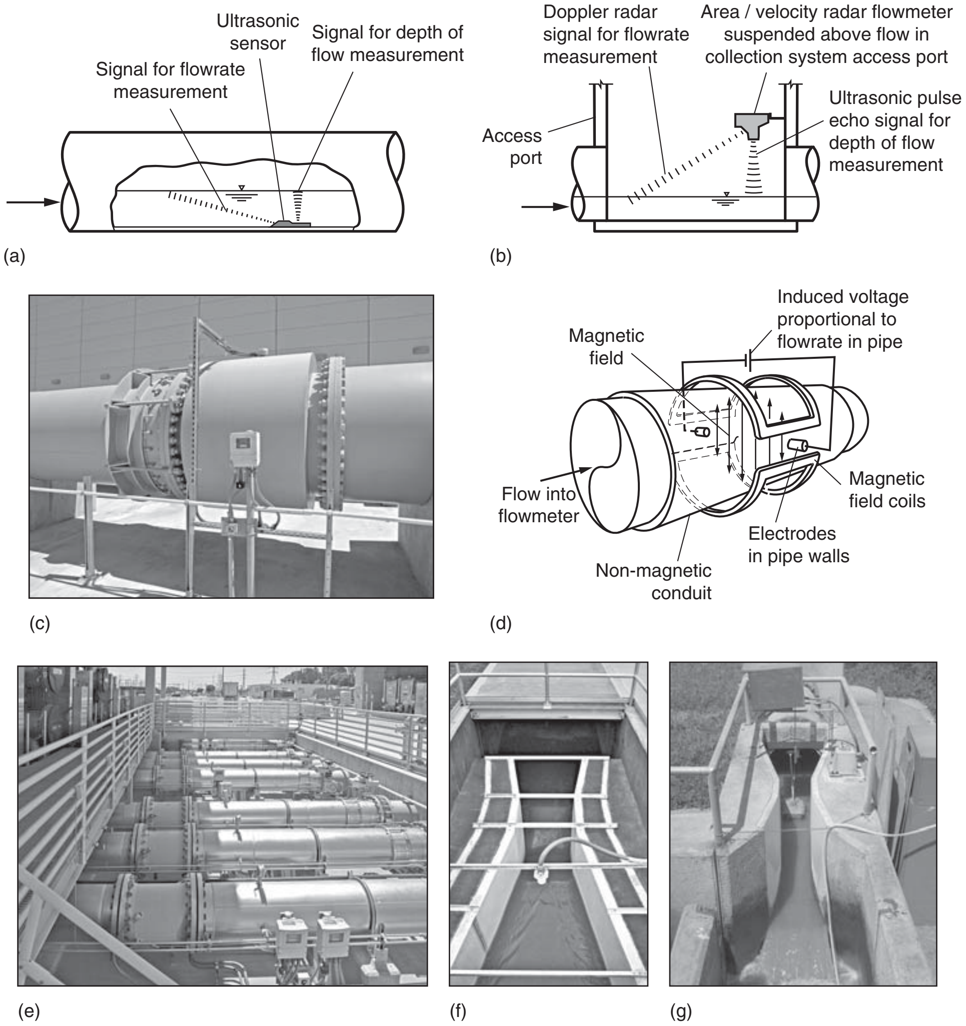

Figure 3–1

Examples of devices used for measurement of wastewater flowrates: (a) schematic of area/velocity ultrasonic flowrate meter sensor, (b) schematic of area/velocity radar flow meter sensor. Velocity is measured using Doppler Radar and ultrasonic echo plus is used to sense depth of flow, (c) view of magnetic flow meter and (d) schematic of magnetic flow meter. When a conductive fluid moves through a magnetic field a voltage is generated; the magnitude of the voltage is proportional to the flowrate, (e) view of multiple magnetic flow meters used to monitor flowrates to advanced oxidation facilities, and (f) Parshall flume equipped with a sonic water level indicator to determine the depth of flow that is correlated to the flowrate and (g) Parshall flume equipped with a float can also be used to determine depth. (Note: Parshall flumes are used commonly at smaller wastewater treatment plants.)

especially useful in other parts of the world where water use for landscape irrigation is limited and 90 percent or more of the water used becomes wastewater. In the United States, on average about 50 to as high as 90 percent (e.g., from high-rise apartments) of the per capita water consumption becomes wastewater. The higher percentages apply to the northern states during cold weather; the lower percentages are applicable to the semi-arid region of southwestern United States where landscape irrigation is used extensively. When water consumption records are used for estimating wastewater flowrates, the amount of water consumed for purposes such as landscape irrigation (that is not discharged to the collection system), leakage from water mains and service pipes, or product water that is used by manufacturing establishments must be evaluated carefully.

Residential Areas. For many residential areas, wastewater flowrates are commonly determined based on population and the average per capita contribution of wastewater. For residential areas where large residential development is planned, it is often advisable to develop flowrates on the basis of land-use areas and anticipated population densities. Where possible, these rates should be based on actual flow data from selected similar communities, preferably in the same locale. In the past, the preparation of population projections for use in estimating wastewater flowrates was often the responsibility of the engineer, but today population projection data are usually available from local, regional, and state planning agencies.

Wastewater flowrates can vary depending on the quantity and quality of the water supply, the potable water billing rate structure, the extent of conservation measures, geographic location, rates of infiltration/inflow, and other economic and social characteristics of the community. In a report published by the U.S. Geological Survey (Kenny et al., 2009), the average domestic water use per capita by state varied from a high of 715 L/capita·d (189 gal/capita·d) to a low of 193 L/capita·d (51 gal/capita·d). The average for the country was 375 L/capita·d (99 gal/capita·d), which is consistent with the data reported in Table 3–1. If it is assumed that 50 to 90 percent of the water supply becomes wastewater, the average wastewater flowrates would vary from 188 to 338 L/capita·d (50 to 89 gal/capita·d). The reason that an average range is given is that no one has an accurate estimate of the extent of water conservation measures that have been implemented, which varies from community to community. The typical average range reflects an estimate of the current (2013) extent to which conservation measures have been implemented in different parts of the country.

Data on the typical flowrate values for residential sources in the United States as a function of the number of residents with the current (2013) level of conservation and with significant water conservation are given in Table 3–2. The data from Table 3–2 are plotted on Fig. 3–2. As shown on Fig. 3–2, as the number of persons per residence increases, the average wastewater flowrate per capita decreases. In the case with significant conservation measures, the per capita value approaches a value of about 150 L/capita·d (39.6 gal/capita·d). At the present time this asymptotic value represents a reasonable estimate of what can be achieved with extensive water conservation measures and fixtures and appliances. Assuming an occupancy rate of 3.3 persons per residence, the range of anticipated wastewater flowrates will vary from about 250 to 175 L/capita·d (66 to 46 gal/capita·d). The value of 250 L/capita·d (66 gal/capita·d) is within the range of typical per capita values reported above. With the passage of time, it is anticipated that the right-hand curve on Fig. 3–2 will move to the left. It is estimated that reaching significant conservation may take more than 20 y. Reduced household water use not only changes the quantity of wastewater generated, but, as discussed later in this chapter, the characteristics of wastewater as well.

Commercial Districts. Depending on the function and activity, unit flowrates for commercial facilities can vary widely. Because of the wide variations that have been observed,

Table 3–2

Typical wastewater flowrates from urban residential sources in the United States

Household size, no. of persons	Flowrate, gal/capita·d: With current level of conservation	Flowrate, gal/capita·d: With extensive conservation	Flowrate, L/capita·d: With current level of conservation	Flowrate, L/capita·d: With extensive conservation
1	103	74	390	280
2	77	54	290	205
3	68	48	257	180

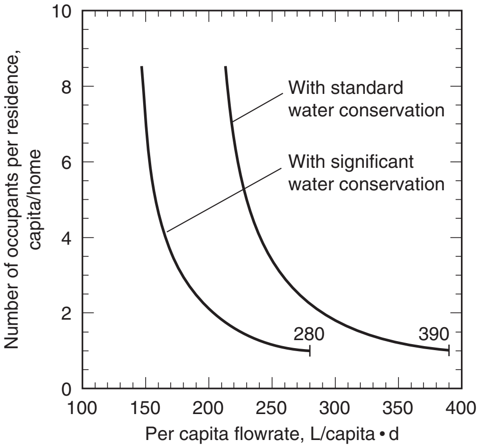
5	61	42	230	160
6	59	41	223	155
7	58	40	218	151
8	57	39	215	149

Figure 3–2

Per capita flowrate from individual residences as a function of the number of residents.



every effort should be made to obtain records from actual or similar facilities. If no other records are available, estimates for selected commercial sources, based on function or persons served, may be made using the data presented in Table 3–3. In the past, commercial wastewater flowrates were often based on existing or anticipated future development or comparative data. Flowrates were generally expressed in terms of quantity of flow per unit area [i.e., m^3/ha·d (gal/ac·d)]. Typical unit area flowrate allowances for commercial developments normally range from 7.5 to 14 m^3/ha·d (800 to 1500 gal/ac·d). The latter approach can be used to check the values obtained from existing records or estimates made using Table 3–3.

Institutional Facilities. Typical flowrates from some institutional facilities are shown in Table 3–4. Again, it is stressed that flowrates vary with the region, climate, and type of facility. The actual records of institutions are the best sources of flow data for design purposes.

Recreational Facilities. Wastewater flowrates from many recreational facilities are subject to seasonal variations. Typical data on wastewater flowrates from recreational facilities are presented in Table 3–5.

Strategies for Reducing Interior Water Use and Wastewater Flowrates

Because of the importance of conserving both resources and energy, various means for reducing wastewater flowrates are available. The reduction of wastewater flowrates from domestic sources results directly from the reduction in interior water use. Therefore, the terms *interior water use* and *domestic wastewater flowrates* are sometimes used interchangeably. Representative water use rates for various devices and appliances are reported in Table 3–6. Information on the relative distribution of water use within a residence is reported in Table 3–7. Devices and appliances that can be used to reduce interior domestic water use and wastewater flows are described in Table 3–8.

Another method of achieving flow reduction that has been adopted by a number of communities is to restrict the water usage of certain appliances, such as automatic dishwashers and kitchen food-waste grinders (i.e., garbage disposal units), that tend to increase water consumption. The use of one or more of the flow-reduction devices is specified for all new residential dwellings in many communities; in others, the use of waste-food grinders has been limited in new housing developments. Further, many individuals concerned

about conservation have installed such devices on their own as a means of reducing water consumption. New designs in front-loading clothes washers also offer significant reductions in water use, on the order of 50 to 75 percent of older models. A comparison of residential interior water use (and resulting per capita wastewater flows) is given in Table 3–9 for homes with the current levels of conservation and with extensive water conserving appliances and fixtures. The potential savings of employing selected water-efficient devices is illustrated in Example 3–1.

Table 3–4

Other domestic[c]	2–3	2.2	1.4	5.4
Leakage	8–12	9.6	6.2	23.6
Total		100	65.0	246.0

[a] Typical range of indoor water use in the United States ranges from 150 to 300 L/capita·d (40 to 80 gal/capita·d).

[b] Based on an indoor water usage rate of 246 L/capita·d (65 gal/capita·d).

[c] Houseplant watering, water for pets, etc.

Table 3–8

Flow reduction devices and appliances

Device/appliance	Description and/or application
Faucet aerators	Increases the rinsing power of water by adding air and concentrating flow, thus reducing the amount of washwater used
Flow-limiting shower heads	Restricts and concentrates water passage by means of orifices that limit and divert shower flow for optimum use by the bather
Low-flush toilets	Reduces the amount of water per flush
Pressure reducing valve	Reduces home water pressure below that of the water distribution system, decreases the probability of leaks and dripping faucets
Pressurized shower	Water and compressed air are mixed together. Impact provides the sensation of conventional shower
Retrofit kits for bathroom	Kits may consist of shower flow restrictors, toilet dams or fixture displacement bags, and toilet leak detector tablets
Toilet dam	A partition in the toilet tank that reduces the amount of water per flush
Toilet leak detectors	Tablets that dissolve in the toilet tank and release dye to indicate leakage of the flush valve
Vacuum toilet	A vacuum along with a small amount of water is used to remove solids from toilet
Water efficient dishwasher	Reduces the amount of water used to wash dishes
Water efficient clothes washer	Reduces the amount of water used to wash clothes. New front-loading machines have been developed that not only use less water but are more energy efficient

EXAMPLE 3–1 **Determine Water Savings by Employing Water Efficient Appliances** A new subdivision of 2000 homes is planned, and a condition of the building permit is to determine the potential savings in water consumption (and wastewater flows) if the following water-efficient appliances are used: front-loading washing machines, ultra-low flush toilets, and ultra-low flow shower heads. Use 3.5 residents per home and values for devices and appliances from Table 3–9 to determine the potential savings.

The estimated water use and percentage savings are illustrated in the following table.

		Unit water use, L/capita·d		Water Use, L/d	
Appliance/device	No. of Residents	With current level of conservation	With extensive conservation	With current level of conservation	With extensive conservation
Clothes washing	7000	56.6	36.0	396,200	252,000
Toilets	7000	68.9	31.0	482,300	217,000
Showers	7000	44.3	26.1	310,100	182,700
Total				1,188,600	651,700
Savings, %					45

Comment Three of the largest water using appliances and devices utilized in the home are those described in this example. Interior water use and the generation of wastewater can be reduced significantly with the community-wide installation of water-efficient appliances and devices, thus reducing the flows that will have to be handled by the collection system and treatment plant. Where high infiltration rates occur within the collection system, it is difficult or impossible to assess the beneficial effects of using water conservation devices.

Water Use in Other Parts of the World

The typical flowrates and use patterns presented in Tables 3–1 through 3–7 and Table 3–9 are based on water use and wastewater flowrate data from communities and facilities in the United States. Many developed countries (e.g., Canada) have flowrates in similar ranges. Water use, and consequently the per capita wastewater generation rate in less developed countries, is significantly lower. In some cases, the water supply is only available for limited periods of the day. Water use data from other parts of the world are given in Table 3–10. The striking aspect of the data presented in Table 3–10 is the variability that exists between countries. In general, information such as presented in Table 3–10 is not very useful, other than for gross comparisons, as it is not presented in the context of the country dynamics and the basis for the collection and reporting of data is not uniform.

Sources and Rates of Industrial (Nondomestic) Wastewater Flows

Nondomestic wastewater flowrates from industrial sources vary with the type and size of the facility, the degree of water recycling within the facility, and the presence of any onsite wastewater pretreatment or final treatment methods. Extremely high peak flowrates may be reduced by the use of onsite detention tanks and equalization basins. Typical design values for estimating the flows from industrial areas that have no or little

Table 3–9

Typical comparisons of indoor water use with current level of conservation and with extensive conservation practices and devices in the United States

	Flow, gal/capita·d		Flow, L/capita·d	
Use	**With current level of conservation[a,b,c]**	**With extensive conservation[d]**	**With current level of conservation**	**With extensive conservation**
Bath	1.2 (30)	1.2 (30)	4.4	4.5
Clothes washing (Laundry)	15.0 (30)	9.5 (20)	56.6	36.0
Dishwashing	0.9 (10)	0.7 (8)	3.4	2.6
Faucet	10.4 (3)	6.9 (2)	39.4	26.1
Shower	11.7 (4)	6.9 (2.5)	44.3	26.1

Other domestic	1.4 (3)	1.4 (3)	5.4	5.3
Leakage	6.2	6.0	23.6	22.7
Total	65.0	40.8	246.0	154.4

[a] Rates of indoor water use based on values given in Table 3–7.

[b] Current level of conservation assumed to reflect mid-2013 values.

[c] Number in parenthesis is the assumed current water usage rate per use for various uses and devices as given in Table 3–6. For example, the number in parenthesis for the bath is 30 gal/use.

[d] Number in parenthesis is assumed to correspond to the water usage rate with extensive conservation based on the values given in Table 3–6.

[e] Estimated average of currently installed toilets.

wet-process type industries are 7.5 to 14 m^3/ha·d (1000 to 1500 gal/ac·d) for light industrial developments and 14 to 28 m^3/ha·d (1500 to 3000 gal/ac·d) for medium industrial developments. For industries without internal water recycling or reuse programs, it can be assumed that about 85 to 95 percent of the water used in the various operations and processes will become wastewater. For large industries with internal water-recycling programs, separate estimates based on actual water consumption records must be made. Average domestic (sanitary) wastewater contributed from industrial facilities per employee may vary from 30 to 95 L/capita·d (8 to 25 gal/capita·d).

Variations in Wastewater Flowrates

Wastewater flowrates vary during the time of day, day of the week, season of the year, and year to year depending upon the nature of the discharges to the collection system and sources and rates of infiltration/inflow. Short-term, seasonal, multiyear, and industrial variations in wastewater flowrates are briefly discussed here.

Short-Term Variations. The typical current diurnal pattern of wastewater flows observed at treatment plants, such as shown on Fig. 3–3(a) for an intermediate size community, began in the latter half of the 20th century. In the early part of the twentieth century, the daily variation in wastewater flowrates was characterized by a single peak in the morning as illustrated on Fig. 3–3(a). The shift from a single to a dual peak reflects the changes that have occurred in the workplace, perhaps the most notable event being the employment of women in factories during the early 1940s as part of the war effort.

Table 3–10

Water consumption in various countries and the United States in 2000[a]

Country	Per capita water consumption gal/d	 L/d
Argentina	93	350
Austria	113	430
Canada	196	742
Chile	63	238
Germany	41	156
Greece	93	350
Hungary	139	526
India	34	129
Kuwait	53	200

Nepal	8	30
Mexico	92	348
Mozambique	3	11
Norway	29	110
Russian Federation	72	274
Saudi Arabia	50	189
South Africa	59	224
United States	100	380

[a] Adapted from United Nations (2005).

Referring to Fig. 3–3(a), minimum flows occur during the early morning hours when water consumption is lowest and when the base flow consists of infiltration and small quantities of sanitary wastewater. The first flowrate peak generally occurs in the late morning when wastewater from the peak morning water use reaches the treatment plant. A second flowrate peak generally occurs in the early evening between 7 and 9 p.m. In some bedroom communities, the amplitude of the second peak will exceed the morning peak. It should also be noted that a shift occurs on the weekends with respect to the morning peak [see Fig. 3–3(a)] as people tend to get up a bit later.

The time of occurrence and the amplitude of the flowrate peaks vary with the size of the community and the length and storage capacity of the collection system [see Fig. 3–3(b)]. In the curves shown on Fig, 3–3(b), there is essentially no late afternoon peak. The reason for this occurrence is that the collection system has excess storage capacity and there is a significant travel time to reach the treatment plant. The same phenomena will be observed where a centralized treatment plant for a larger community also serves a number of smaller communities located some distance from the plant. Because of the travel time, the flows from the outlying communities will arrive later than the peak flow from the main community. Arriving later, these flows tend to dampen the second peak that would have been observed had the treatment plant only received wastewater from the single community. Further, as a community increases in size, the diurnal variations tend to be reduced as shown on Fig. 3–3(c). The masking effect caused by high infiltration rates during a storm event is illustrated on Fig. 3–3(d), in

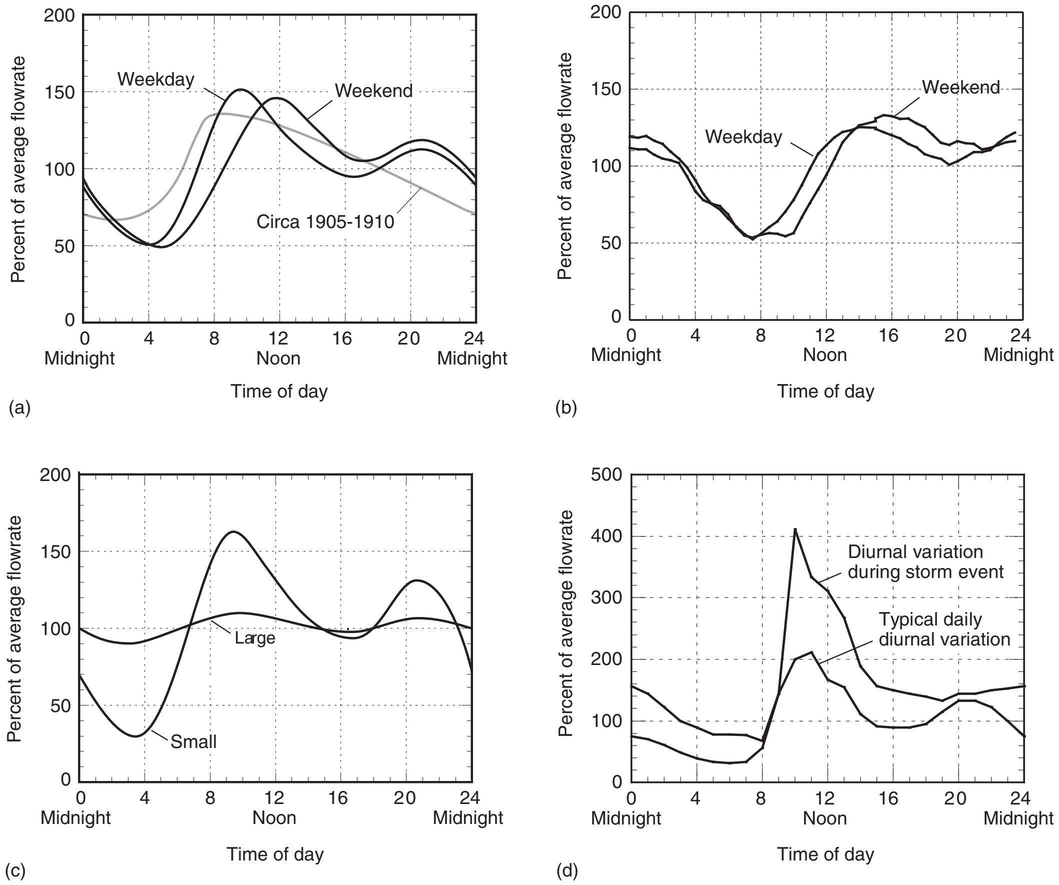

Figure 3–3

Typical variations in normalized influent flowrate data for domestic wastewater systems: (a) generalized diurnal pattern for weekdays and weekends in the latter part of the 20th century for an intermediate sized community (40,000–400,000 m^3/d), and the corresponding curve observed in the early part of the 20th century (ca. 1905–1910); (b) observed flowrate variations for the City of Davis (population 65,000), based on half hour flowrate measurements (courtesy of West Yost and Associates); (c) generalized flowrate variations for small (4000–40,000 m^3/d) and large (>400,000 m^3/d) communities; and (d) masking effect of excess stormwater infiltration, based on hourly flowrate measurements (note change in vertical scale).

which the late afternoon peak is masked by the continued flow resulting from the storm event.

When extraneous flows are minimal, wastewater discharge curves resemble water consumption curves, but with a lag of several hours. As the community size increases, the variations between the high and low flows decrease due to (1) the increased storage in the collection system of large communities that tends to equalize flowrates and (2) changes in the economic and social makeup of the community.

Industrial Variations. Industrial wastewater discharges are difficult to predict. Many manufacturing facilities generate relatively constant flowrates during production, but the flowrates change markedly during cleanup and shutdown. While internal process changes may lead to reduced discharge rates, plant expansion and increased production may lead to increased wastewater generation. Where joint treatment facilities are to be constructed, special attention should be given to industrial flowrate projections, whether they are prepared by the industry or jointly with the city's staff or engineering consultant. Industrial discharges are most troublesome in smaller wastewater treatment plants where there is limited capacity to absorb shock loadings.

Seasonal Variations. Seasonal variations depend on location and the nature of the community. In the eastern part of the United States, where it tends to rain throughout the year, there is less seasonal variation in observed flowrates as compared to the western United States where there are distinct wet (November through April) and dry (May through October) periods. Snowmelt is a significant factor in the areas with high rates of infiltration observed each spring, due to seasonably high groundwater levels in the Northeast and other snow-belt states. The difference in observed flowrates is illustrated on Fig. 3–4. It is important to note that the general patterns and the magnitude of the flowrates shown on Fig. 3–4 will vary considerably with increased or decreased rainfall patterns resulting from global climate change.

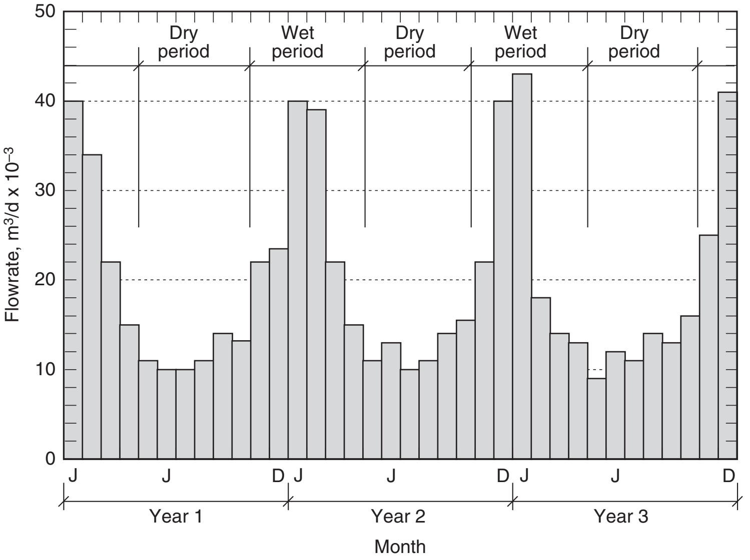
Seasonal variations in domestic wastewater flows are commonly observed at resort areas, in small communities with college campuses, and in communities that have seasonal commercial and industrial activities. The magnitude of the variations to be expected depends on both the size of the community and the seasonal activity.

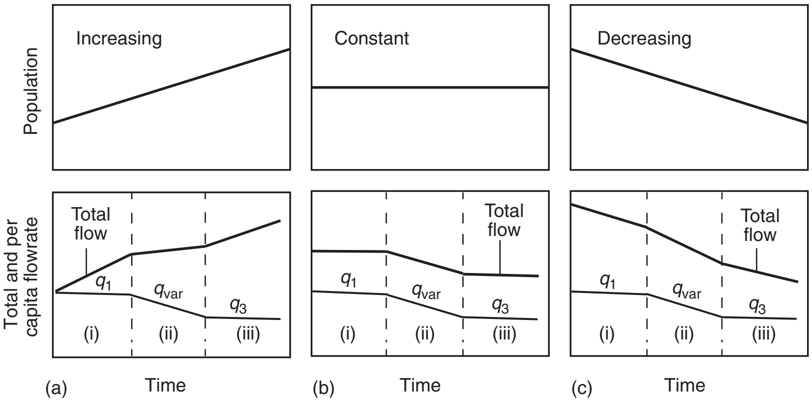
Long-Term Multiyear Variations Due to Conservation

In addition to the daily and seasonal changes described above, some significant trends have been observed in the long-term flowrates measured at wastewater treatment plants at many large cities in the United States. In general, three major trends in flowrates are observed based on cities with (1) increasing population, (2) relatively constant population, and (3) decreasing population as illustrated on Fig. 3–5. In all cases, the recent and ongoing implementation of low-flow appliances and fixtures and practices that result in water conservation will result in an increase in wastewater constituent concentrations.

Figure 3–4

Seasonal flowrate variations observed in the Western United States in the dry period (May through October) and wet period (November through April). In some locations, the distinction between dry and wet periods is becoming blurred due to global climate change.





q = per capita wastewater flowrate

(i) Pre-1992

(ii) Improved water conservation, period end point unknown

(iii) Maximum water conservation

Figure 3–5

Flowrate variations observed in cities in the United States with (a) increasing population, (b) constant population, and (c) decreasing population. The three time periods depicted in these plots are as follows: (i) time period up to about 1990 with relatively limited implementation of water conservation measures, (ii) period following 1990 when the per capita flowrate is decreasing as a result of greater implementation of conservation devices and public awareness, and (iii) period after the time that maximum water conservation has been implemented. The time when maximum conservation has been implemented will vary with each community.

Increasing Population. In cities where the population is increasing, the per capita wastewater flowrates were relatively constant up to the early nineties and the total wastewater flowrate increased in proportion to the population [see Fig. 3–5(a), period (i)]. After the early nineties, the per capita flowrate started to decrease reflecting changes in the plumbing code and the installation of water conserving appliances (e.g., low flush toilets). As more water conservation measures are adopted and water conservation devices and appliances become the norm [Note: the per capita flowrate, q_{var}, is variable in period (ii)], the total flowrate will continue to increase, but at a slower rate of increase [see Fig. 3–5(a), period (ii)]. At some point in the future, water conservation practices and low-flow devices and appliances will be installed in essentially all homes. At that point, the total flow will continue to increase with population, but at a stable and reduced per capita flowrate [see Fig. 3–5(a), period (iii)]. The result of these practices will be that while the constituent mass loading to the wastewater treatment plant will be expected to increase in proportion to the population increase, the concentration of the constituents will be higher than before.

Relatively Constant Population. In cities where the population has been relatively constant, the per capita flowrate was also more or less constant up to the early nineties [see Fig. 3–5(b), period (i)]. After the nineties, the total per capita flowrate started to decrease reflecting the installation of water conserving appliances (e.g., low flush toilets) [see Fig. 3–5(b), period (ii)]. The total flowrate will continue to decrease as more water conservation measures are adopted and low-flow devices and appliances are installed. As discussed above, at some point in the future water conservation devices and appliances will be installed in essentially all of the homes. At that point, the total per capita flowrate will again become more-or-less constant, but at a reduced per capita flowrate [see Fig. 3–5(b), period (iii)]. The constituent mass loading to the wastewater treatment plant is expected to remain relatively constant, but, as above, the concentration of the constituents will increase to reflect the reduced per capita flowrate.

Decreasing Population. In cities with a decreasing population, the per capita wastewater flowrate was relatively constant up to the nineties and the total flowrate decreased in proportion to the population [see Fig. 3–5(c), period (i)]. With the adoption of water conservation measures, total flowrate has decreased along with the the per capita wastewater flowrate [see Fig. 3–5(c), period (ii)]. When water conservation devices and appliances will be installed in essentially all of the homes, the total flow will again decrease with decreasing population, but at a reduced per capita flowrate [see Fig. 3–5(c), period (iii)]. The constituent mass loadings to the wastewater treatment plant are expected to decrease in proportion to the population decrease, while the concentration of the constituents will increase to reflect the reduced per capita flowrate.

Impact of Water Conservation on Future Planning

Because of the variations in flowrates now observed, great care must be taken in the selection of future flowrates for planning purposes. An important aspect in the selection of future flowrates will be to try to estimate the degree to which conservation measures will have already been implemented, the projected maximum level of water conservation that is expected, and the possible future use of satellite water reuse systems. Satellite water reuse systems, including onsite greywater systems, divert wastewater flow to onsite or local reuse applications and effectively reduce the flow of wastewater to the centralized wastewater treatment plant (Tchobanoglous and Leverenz, 2013).

3–2 IMPACT OF COLLECTION SYSTEM ON WASTEWATER FLOWRATES

In addition to the domestic and industrial sources of wastewater, as discussed above, other significant variables in estimating wastewater flowrates are the contributions from infiltration/inflow and from stormwater runoff and snowmelt, where combined collection systems are used. Exfiltration from collection systems can also affect the total quantity of wastewater. The flowrate contributions from these sources are considered in this section.

Infiltration/Inflow

Extraneous flows in collection systems, described as infiltration and inflow, are illustrated on Fig. 3–6 and are defined as follows:

Infiltration. Water entering a collection system from a variety of entry points, including service connections and from the ground through such means as defective pipes, pipe joints, connections, or access port (manhole) walls and joints.

Steady inflow. Water discharged from cellar and foundation drains, cooling-water discharges, and direct connections from springs and swampy areas. This type of inflow is steady and is identified and measured along with infiltration.

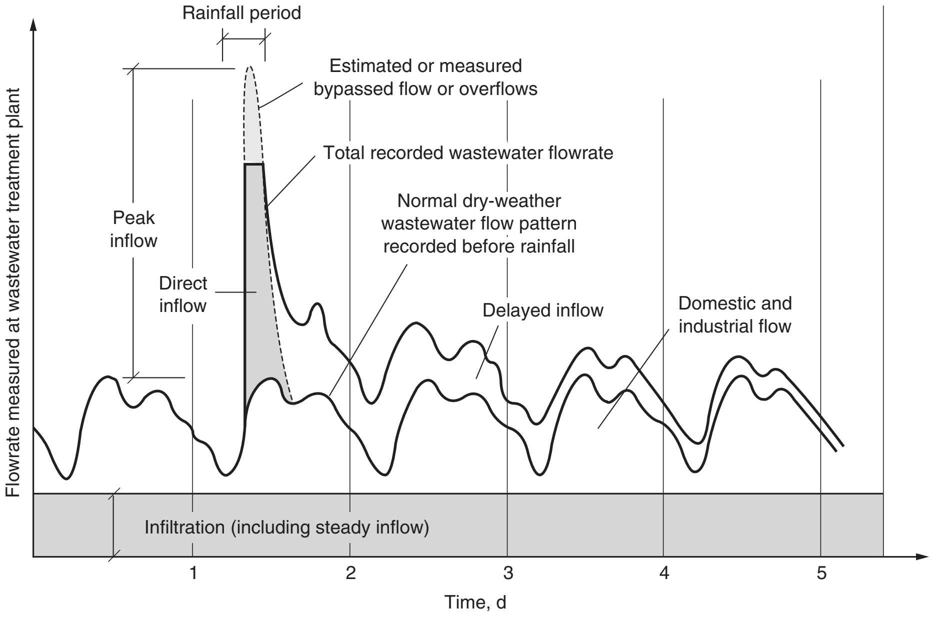
Direct inflow. Inflow sources that result from direct stormwater runoff connections to the sanitary or combined collection system and cause an almost immediate increase in wastewater flowrates. Possible sources are roof leaders, yard and areaway drains, access port covers, cross connections from storm drains and although typically confined to combined systems, catch basins. River or tidal intrusion from faulty tide or backwater gates is another source of direct inflow.

Total inflow. The sum of the direct inflow at any point in the system plus any flow leaving from the system upstream through sanitary sewer overflow (SSO) and combined sewer overflow (CSO) discharges, pumping station bypasses, and the like.

Delayed inflow. Delayed inflow, which is not caused by the direct connections listed above, can include foundation drains, the discharge of sump pumps from cellars, and the slowed entry of surface water through access ports (manholes) in ponded areas.

Figure 3–6

Graphic identification of infiltration/inflow.



The initial impetus in the United States for defining and identifying infiltration/inflow was the Federal Water Pollution Control Act Amendments of 1972. As a condition of receiving a federal grant for the design and construction of wastewater treatment facilities, grant applicants had to demonstrate that their wastewater collection systems were not subject to excessive infiltration/inflow. The several benefits to the community that are realized by "tightening" the collection system and reducing the rates of infiltration/inflow include (1) reducing wastewater backups and SSOs in separate sanitary collection systems and reducing CSOs in combined collection systems (see Fig. 1–2 in Chap. 1), (2) increasing the efficiency of operation of wastewater treatment plants, and (3) improving the utilization of collection system hydraulic capacity for wastewater requiring treatment instead of for infiltration/inflow. Because an understanding of the effects of infiltration/inflow is important in determining treatment plant flowrates, a discussion of excessive infiltration/inflow is included in this section.

Infiltration into Collection Systems. Rainfall runoff can be divided into three components for a given area: one portion runs quickly into the stormwater systems or other drainage channels, another portion evaporates or is absorbed by vegetation, and the remainder percolates into the ground, becoming groundwater. The proportion of the rainfall that percolates into the ground depends on the character of the surface and soil formation and on the rate and distribution of the precipitation. Any reduction in permeability, such as that due to buildings, pavements, or frost, decreases the opportunity for precipitation to become groundwater and increases the surface runoff correspondingly. The amount of groundwater flowing from a given area may vary from a negligible amount for a highly impervious district or a district with dense subsoil to 25 or 30 percent of the rainfall for a semi-pervious district with sandy subsoil permitting rapid passage of water. The percolation of water through the ground from rivers or other bodies of water sometimes has considerable effect on the groundwater table, which rises and falls continually.

Impact of High Groundwater. The presence of high groundwater levels results in leakage into the collection systems and in an increase in the quantity of wastewater and the expense of its conveyance and treatment. This occurrence is of particular importance in the Northeast when spring snowmelt occurs. The amount of flow that can enter a collection system from groundwater infiltration, may range from 0.01 to 1.0 m^3/d·mm-km (100 to 10,000 gal/d·in.-mi) or more. The number of millimeter-kilometers (inch-miles) in a wastewater collection system is the sum of the products of sewer diameters, in millimeters (inches), times the lengths, in kilometers (miles), of sewers of corresponding diameters.

Estimating Infiltration. Infiltration may also be estimated based on the area served by the collection system and may range from 0.2 to 28 m^3/ha·d (20 to 3000 gal/ac·d) (Metcalf & Eddy, 1981). The variation in the amount of infiltration encompasses a wide range of values because the lot sizes may vary in area, which in turn affects the length and extent of the collection system network. During heavy rains, when there may be leakage through access port covers, or inflow as well as infiltration, the rate may exceed 500 m^3/ha·d (50,000 gal/ac·d).

Factors Affecting Infiltration. Infiltration/inflow is a variable part of the wastewater flowrate and depends on the quality of the material and workmanship in constructing the collection systems and building connections, the collection system age, the collection system maintenance program, and the elevation of the groundwater compared with that of the collection system. The rate and quantity of infiltration depend on the length of the collection system, the area served, the soil and topographic conditions, and, to a certain extent, the population density (which affects the number and total length of house connections). Although the elevation of the water table varies with the quantity of rain and melting snow percolating into the ground, the leakage through defective joints, porous concrete, and cracks has been, in some cases, large enough to lower the groundwater table to the wastewater level in the collection system.

The pipe joints in most of the collection systems built during the first half of the twentieth century were constructed with cement mortar or hot-poured bituminous compounds. Access ports were almost always constructed of brick masonry. Deterioration of pipe joints, pipe-to-access port joints, and the waterproofing of brickwork has resulted in a high potential for infiltration into these old sewers. The use of high-quality pipe with dense walls, precast access port sections, and joints sealed with rubber or synthetic gaskets is standard practice in modern collection system design. The use of these improved materials has greatly reduced rates of both infiltration and exfiltration from newly constructed collection systems. However, as these newer systems age, infiltration rates will rise over time, though at a much lower rate than with older sewers.

As noted above, a key factor in the rate of infiltration of both older and newer collection systems is the quality of the actual installation. Even some newer systems, however, exhibit higher than expected rates of infiltration, and in some cases inflow as well, due to poor construction practices or lack of construction supervision and inspection.

Inflow into Collection Systems

As described previously, the type of inflow that causes a "steady flow" cannot be identified separately and so is included in the measured infiltration. The direct inflow can cause an almost immediate increase in flowrates in sanitary systems. The effects of inflow on peak flowrates that must be handled by a wastewater treatment plant are shown in Example 3–2.

EXAMPLE 3–2 **Determine Infiltration/Inflow from Wastewater Flow Records** A large city has measured high flowrates during the wet season of the year. The flow during the dry period of the year, when rainfall is rare and groundwater infiltration is negligible, averages 120,000 m^3/d (31.7 Mgal/d). During the wet period when groundwater levels are elevated, the flowrate averaged 230,000 m^3/d (60.8 Mgal/d) excluding those days during and following any significant rainfall events. During a recent storm, hourly flowrates were recorded during the peak flow period, as well as several days following the storm. The flow plots are shown on the accompanying figure. Compute the infiltration and inflow and determine if the infiltration is excessive. Excessive infiltration is defined by the local regulatory agency as rates over 0.75 $m^3/d\cdot mm\text{-}km$ (8000 gal/d·in.-mi) of collection system. The composite diameter-length of the collection system is 270,000 mm-km (6600 in.-mi).

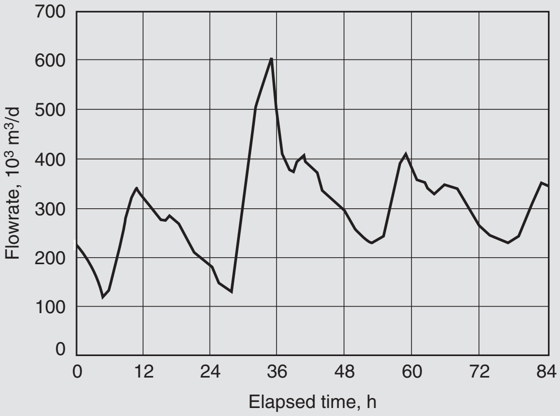
Solution

1. Determine the infiltration and inflow components during the wet season.
   a. Because infiltration is low during dry periods, high groundwater infiltration is

$$\begin{aligned}\text{Infiltration} &= (230{,}000 - 120{,}000)\ m^3/d \\ &= 110{,}000\ m^3/d\end{aligned}$$

   b. The maximum hourly inflow is determined graphically from the accompanying figure as the difference between the peak hourly wet-weather flow during the storm and the comparable flowrate on the preceding day. The maximum flowrate at hour 35 is 606,000 m^3/d, and the flow at hour 11 is 340,000 m^3/d. In this case, the maximum inflow is

$$\begin{aligned}\text{Inflow} &= (606{,}000 - 340{,}000)\ m^3/d \\ &= 266{,}000\ m^3/d\end{aligned}$$



2. Determine if the infiltration is excessive.
   a. Calculate the infiltration by dividing the calculated flowrate by the composite diameter-length of the collection system.

$$\frac{(110{,}000\ m^3\cdot d)}{(270{,}000\ mm\cdot km)} = 0.407\ m^3/d\cdot mm\text{-}km$$

   b. Using the regulatory agency criterion of 0.75 $m^3/d\cdot mm\text{-}km$, the infiltration is not excessive.

Comment In this example, the peak flow during the storm period was 4.7 times the average dry weather flow. As discussed later in this chapter, the peak flow factor is high for a system of this size. Because inflow represents over 50 percent of the peak flow and requires oversizing of the hydraulic capacity of the treatment plant, methods of inflow reduction should be investigated to decrease the hydraulic load on the collection system and treatment facilities.

Exfiltration from Collection Systems

Collection systems that exhibit high rates of infiltration may also exhibit high rates of exfiltration during low groundwater conditions. When exfiltration occurs, untreated wastewater leaks out of pipe joints and service connections. If the piping and joints are in poor condition, significant quantities of wastewater may seep into the ground, travel through the gravel bedding of the piping system, or even surface in extreme cases. Seepage of untreated wastewater into the ground near shallow wells can result in pollution of the water supply. Well contamination has occurred in urban areas such as Los Angeles, CA, where collection systems are within 300 m (1000 ft) of water wells. Exfiltration in collection systems near surface water bodies can also contribute to ongoing high coliform counts in those water bodies that may be difficult to correct. Reduction of inflow/filtration in collection systems may serve to limit exfiltration and remove potential threats to water supplies and public health. The potential adverse effects of exfiltration on surface water quality are illustrated in Example 3–3.

EXAMPLE 3–3 **Determine the Pollution Contributing Effects of Exfiltration on Nearby Water Body** Untreated wastewater from a damaged collection system pipeline leaked into a small nearby lake. The leakage is estimated to be 10,000 L/d. What increase in concentration of organisms can be expected in the lake if the initial coliform count in the wastewater is 10^7 organisms/100 mL, the wastewater is diluted by a ratio of 1000 to 1, and the leak lasted for one day? Assume the number of coliform organisms in the dilution water is zero.

Solution

1. To solve this problem, a concentration balance must be prepared (see Chap. 1 for additional details for mass and concentration balances). The required concentration mass balance is:

Total number of organisms in mixture	=	total number of organisms in leakage	+	total number of organisms in dilution water
$Q_M C_M$	=	$Q_L C_L$	+	$Q_{DW} C_{DW}$

Where Q_M = the volume of the mixture $(Q_L + Q_{DW})$
C_M = number of organisms/100 mL in the mixture
Q_L = volume of leakage
C_L = number of organisms/100 mL in the leakage
Q_{DW} = volume of the dilution water
C_{DW} = number of organisms/100 mL in the dilution water

2. Substitute for the various quantities and solve for the number of organisms in the mixture.

$$[(10^4\text{ L/d})(1\text{ d}) + (10^3)(10^4\text{ L})]\left(\frac{C_M}{100\text{ mL}}\right)$$

$$= (10^4\text{ L/d})(1\text{ d})\left(\frac{10^7}{100\text{ mL}}\right) + (10^3)(10^4\text{ L})\left(\frac{0}{100\text{ mL}}\right)$$

$$(10^4\text{ L} + 10^7\text{ L})\left(\frac{C_M}{100\text{ mL}}\right) = (10^4\text{ L})\left(\frac{10^7}{100\text{ mL}}\right)$$

$$C_M \approx \frac{10^4}{100\text{ mL}}$$

Comment Because untreated wastewater contains a high concentration of coliform organisms, the receiving water, even under the assumed condition that the exfiltration is well mixed, can contain high concentration levels. Such high coliform counts would be taken as indicators that a potential health hazard may exist. Therefore, in this example, because the exfiltration from the collection system into the lake is significant, receiving water quality objectives will be difficult to maintain.

Combined Collection System Flowrates

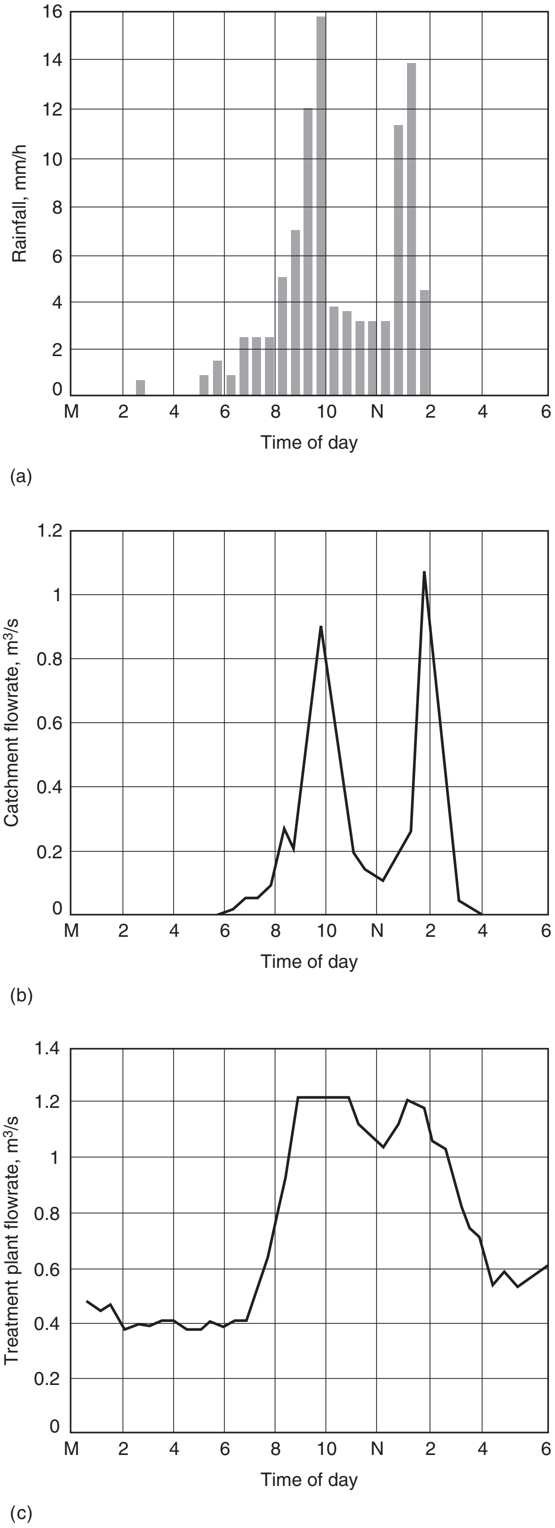
Flow in a combined collection system is composed of the same flow components found in a sanitary sewer system, but with the addition of two major sources of inflow: stormwater runoff during wet-weather periods and snowmelt, typically during late winter and early spring (see Fig. 1–1 in Chap. 1). The dry-weather flow may include domestic, commercial, and industrial wastewater plus infiltration and inflow. During a rainfall event, the amount of flow directly attributable to the storm—the inflow—is significantly larger than the dry-weather wastewater flow and can completely mask the typically observed dry-weather flow patterns. Further, some recent short-duration, high-intensity rainfall events, attributed to global climate change, have resulted in flowrates in combined collection system far in excess of the wet-weather flowrates observed normally.

Past Design Constraints. While combined systems were designed to convey both sanitary and stormwater flows, the downstream interceptors, pumping stations, and wastewater treatment plants were typically designed, at a much later date, to only convey and treat a fraction of the total wet-weather flow generated within the system. Hydraulic relief points, consisting of regulator or diversion structures and CSO outfalls, were strategically located to limit the flow to both the interceptor sewers and treatment plant. While CSO discharges are legal, communities with combined systems are required to develop plans to eliminate or greatly reduce the frequency and magnitude of these wet-weather discharges so that the water quality standards of the receiving waters are met. In some cases where the combined system is undersized, flooding or surcharging (surcharging results when the pipeline capacity is exceeded) may occur at various upstream locations within the system, which create potential threats to public health.

Effects of Combined System Flowrates. The effects of combined system flowrates are illustrated on Fig. 3–7. The catchment hydrograph (flow versus time), as illustrated on Fig. 3–7(b), closely resembles that of the variations in the rainfall hyetograph [see Fig. 3–7(a)]. The short response time between the rainfall event and the increase in the flowrate can be taken as an indication of a short travel time for flow from all points in the upstream combined system. In contrast, the hydrograph at the treatment plant [see Fig. 3–7(c)] shows less distinct flow peaks and a lag time for flows to return to normal dry weather levels following rainfall cessation. The higher flows at this location are due to the larger contributing combined system, and the smoothed peaks result from loss of flow through CSO outfalls and hydraulic routing effects. The peak flowrates and accompanying mass loadings, however, must be accounted for in the hydraulic design of the treatment plant or dedicated CSO control facilities and in the selection of appropriate unit operations and processes.

Figure 3–7

Flow variations in a combined collection system during wet weather; (a) rainfall hyetograph, (b) typical catchment flowrate, and (c) observed treatment plant flowrate.



Direct Measurement of Combined Sewer Flowrates and Wastewater Characteristics

Combined wastewater flows and characteristics can be monitored at various points within the collection system, including in the combined sewers, at regulator structures, CSO outfalls, dedicated CSO control facilities, and the wastewater treatment plant. When performing receiving water impact studies, monitoring of the flow and characteristics in the CSO outfalls is desired. Monitoring points in the collection or interceptor system may be needed for a number of other reasons, including defining the flow to be controlled, diverted, or treated.

Temporary Flow Monitoring. In performing studies of combined wastewater collection systems, temporary monitoring facilities are installed and left in place for several storm events. Flow metering in such installations is typically performed using portable, battery-operated, depth-and-velocity–sensing instrumentation [see Figs. 3–1(a) and (b)]. Similarly, wastewater samples are taken using portable, battery-operated, programmable sampling devices. These samplers are preset for desired sampling time intervals and are level or flow actuated.

Permanent Flow Monitoring. Permanent flow monitoring installations are used in some systems to allow continuous flow records to be obtained at critical points. Also, these installations can allow centralized control of transport system facilities to maximize storage of combined wastewater in the system or to control flow to the downstream treatment plant. The flow data recorded at the site may be periodically recovered manually, or the data may be telemetered to a central location for data analysis or as inputs into real time control systems.

Need to Collect Rainfall Data. To understand how combined wastewater flowrate and characteristics respond to a storm event, rainfall data must be obtained. Therefore, it is often necessary to install temporary rainfall monitoring equipment in close proximity to the drainage area tributary to the monitoring location. Continuous recording rain gauges capable of monitoring the rainfall depth over time should be used. The tipping bucket rain gauge is one type that can be used to record rainfall continuously in 0.25 mm (0.01 in.) increments on a clock-driven recorder chart. If the combined system being monitored encompasses a large area, installation of several rain gauges may be necessary to record spatial variation of rainfall characteristics across the entire area. Sophisticated radar-rainfall systems are now used typically for large regional systems where SSO or CSO monitoring is essential to the mitigation planning.

Calculation of Combined Sewer Flowrates

Calculation of flowrates in a combined system is a complicated and challenging undertaking. The variability in weather patterns and changing nature of rainfall events (e.g., short-duration high-intensity rainfall events) that have been observed in recent years, especially on the Midwest and East Coast, has further complicated the task. The first step in the process involves quantifying wastewater, rainfall-runoff, and other sources of flow such as groundwater infiltration. These sources of flow are then combined and routed through the various components of the system. Finally, the volumes of flow exiting the system through CSO outlets, entering the downstream treatment facility, or being transported to other points in the system are determined.

Computer Modeling. Due to the complexity of combined systems, it is normally necessary to use computer models to simulate the complete combined system including dry weather wastewater flows, hydraulic routing through the piping system, discharges through the outlets, and the flow through the interceptor and to the treatment plant. New systems are typically separated, but existing combined systems may require evaluation and design relative to increased sanitary wastewater inputs and, mostly, relative to CSO control. The models used for combined sewer systems need to be transient to simulate flow variations during storms. There are a number of models available, with ever-increasing capabilities such as graphical user interfaces, GIS interaction (for model development), multi-user functionality, semi-automatic calibration, graphical results displays, animations, and two-dimensional above-ground flow simulation.

The USEPA Stormwater Management Model (SWMM) is a public domain model that has seen widespread use and upgrades since its development in the 1970s. Several proprietary models or user interfaces are based on SWMM, including PC-SWMM, XP-SWMM, and InfoSWMM. A number of independent proprietary models have also been used widely, including Mike Urban, InfoWorks, and SewerGEMS. These models are also applicable to separate systems where infiltration and inflow (I/I) is similar to runoff, except that it can only be simulated empirically based on flow monitoring data. Software capabilities are now such that large, complex systems can be simulated for extended periods of time. But, for any application, model calibration with flow monitoring data is essential to ensure reliability of the results, which are often the basis of large capital investments.

Model Calibration and Verification. The process of calculating flows in a combined system using any of the computer models normally involves comparison of measured versus predicted flows at selected locations in the system. During model calibration, the model is run with rainfall data collected from one storm, and the calculated results are compared with the observed field results. Estimated input parameters are then adjusted within reasonable bounds to obtain best fit between predictions and measurements. During verification, data sets from other storms are used, and no adjustments of parameters are allowed. This calibration and verification process is essential in assessing the predictive capability of the model.

3–3 ANALYSIS OF WASTEWATER FLOWRATE DATA

Because the hydraulic design of both collection and treatment facilities is affected by variations in wastewater flowrates, the flowrate characteristics have to be analyzed carefully from existing records. In cases where only flowrate data in the collection system are available, it must be recognized that the flowrates may differ somewhat from the flowrate entering the treatment plant because of the flow dampening effect of the wastewater collection system. The statistical analysis of flowrate data and the determination of design parameters are considered in this section.

Statistical Analysis of Flowrate Data

The statistical analysis of wastewater flowrate and constituent concentration data involves the determination of statistical parameters used to quantify a series of measurements. The statistical parameters and graphical techniques used for the analysis of wastewater management data are summarized in Appendix D.

Type of Probability Distribution. The two most common types of probability distributions encountered in the statistical analysis of flowrate data are (1) the standard normal distribution and (2) the log-normal distribution, in which log of the values is distributed normally. If the data are distributed normally, the statistical measure used to define the distribution include the mean, variance, skewness, and coefficient of kurtosis. Skewness and coefficient of kurtosis are needed to quantify the nature of a given distribution. If a distribution is highly skewed, as determined by the coefficient of skewness, normal statistics cannot be used. Another term used to assess the relative variability in the data is *coefficient of* *variation* (see Appendix D). If the data are distributed log-normally, the statistical measure used to define the distribution include the geometric mean and the geometric standard deviation (see Appendix D). In general, most flowrate data are distributed log-normally because of the wide range of wet-weather flowrates as compared to the average dry-weather flowrates. The statistical analysis of flowrate data is illustrated in Example 3–4.

EXAMPLE 3–4 **Statistical Analysis of Wastewater Flowrate Data** Using the following weekly flowrate data obtained, from an industrial discharger, for the dry (May–October) and wet (November–April) periods, determine the statistical characteristics and estimate the maximum weekly flowrate that will occur during each period.

	Flowrate, m^3/wk			Flowrate, m^3/wk	
Week	Dry period	Wet period	Week	Dry period	Wet period
1	13,500[a]	20,000[b]	14	37,000	51,600
2	25,900	16,250	15	30,100	41,250
3	28,750	40,350	16	21,250	35,000
4	10,750	18,600	17	23,500	30,750
5	12,500	18,300	18	16,750	23,900
6	9850	18,750	19	8350	16,350
7	13,900	21,800	20	18,100	30,200
8	15,100	20,200	21	9250	21,100
9	23,400	23,750	22	9900	21,750
10	21,900	42,500	23	8750	20,800
11	23,700	32,000	24	15,500	24,500
12	18,000	28,300	25	7600	14,400
13	26,400	28,300	26	8700	15,200

[a] First wk of May.
[b] First wk of November.

Solution

1. Determine the nature of the distribution by plotting the data on arithmetic and log-probability paper.
   a. Set up a data analysis table with four columns as described below.
      i. In column 1, enter the rank serial number starting with number 1
      ii. In column 2, enter the probability plotting position (see Appendix D)
      iii. In columns 3 and 4, arrange the weekly flowrate data in ascending order

		Flowrate, m^3/wk				Flowrate, m^3/wk	
No.	Plotting position, %[a]	Dry period	Wet period	No.	Plotting position, %[a]	Dry period	Wet period
1	3.7	7600	14,400	14	51.9	16,750	23,750
2	7.4	8350	15,200	15	55.6	18,000	23,900
3	11.1	8700	16,250	16	59.3	18,100	24,500
4	14.8	8750	16,350	17	63.0	21,250	28,300

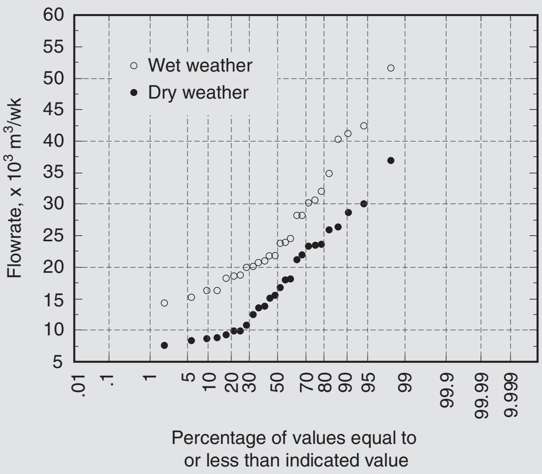
(*continued*)

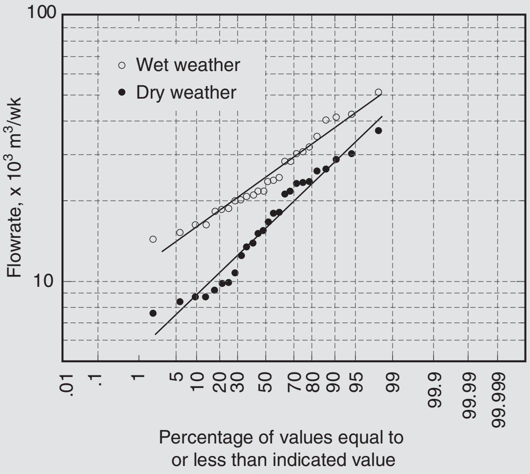
(*Continued*)

No.	Plotting position, %[a]	Flowrate, m^3/wk		No.	Plotting position, %[a]	Flowrate, m^3/wk	
		Dry period	Wet period			Dry period	Wet period
5	18.5	9250	18,300	18	66.7	21,900	28,300
6	22.2	9850	18,600	19	70.4	23,400	30,200
7	25.9	9900	18,750	20	74.1	23,500	30,750
8	29.6	10,750	20,000	21	77.8	23,700	32,000
9	33.3	12,500	20,200	22	81.5	24,600	35,000
10	37.0	13,500	20,800	23	85.2	25,900	40,350
11	40.7	13,900	21,100	24	88.8	28,750	41,250
12	44.4	15,100	21,750	25	92.6	30,100	42,500
13	48.2	15,500	21,800	26	96.3	37,000	51,600

[a] Plotting position, % = $\left(\frac{m}{n+1}\right) \times 100$, where $n = 26$ [Equation (D–10), Appendix D].

b. Plot the weekly flowrates expressed in m^3/wk versus the plotting position. The resulting plots are presented below. Because the data fall on a straight line on log-probability paper, they are log-normally distributed.





2. Determine the geometric mean for the dry and wet periods and the corresponding geometric standard deviation using Eq. (D–9) from Appendix D.

$$s_g = \frac{P_{84.1}}{M_g} = \frac{M_g}{P_{15.9}}$$

Period	M_g	$P_{84.1}$	s_g
Dry	15,948	25,198	1.58
Wet	24,504	34,391	1.40

Based on the value of the geometric standard deviation, it can be concluded that the observed variation is large.

3. Estimate the probable annual maximum weekly flowrate during the dry and wet periods.
   a. Determine the probability factor

$$\text{Peak week} = \left(\frac{m}{n+1}\right) \times 100 = \left(\frac{26}{26+1}\right) \times 100 = 96.3$$

   b. Determine the flowrate from the figure given in Step 1b at the 96.3 percentile
      Peak dry week flowrate = 35,948 m^3/wk
      Peak wet week flowrate = 44,900 m^3/wk

Comment The statistical analysis of data is important in establishing the design conditions for wastewater treatment plants. The application of statistical analysis to the selection of design flowrates and mass loadings is considered in the following section.

Developing Design Parameters from Flowrate Data

Quantifying the variations in flowrates is important in the design and operation of wastewater treatment plants. Before considering the quantification of flowrate variations, it will be helpful to define some of the parameters that are used commonly to quantify the observed variations.

Flowrate Parameters. The principal parameters used to quantify the observed variations in flowrate are defined in Table 3–11. As will be discussed in Sec. 3–7, these terms are also of importance in the selection and sizing of individual unit treatment processes and operations. As reported in Table 3–11 the parameters used to describe flowrate variations can be grouped into five categories: (1) average values including wet- and dry-weather and annual flows, (2) various peak values, (3) maximum values, (4) minimum values, and (5) sustained values. Using a 1-d record for the purposes of illustration, the following parameters are identified on Fig. 3–8: average daily flowrate, instantaneous peak, peak hour, minimum hour, minimum, and sustained 13.5-h flowrate. Obviously, a two- or three-year record is needed to establish the parameters shown on Fig. 3–8 and the long-term parameters identified in Table 3–11.

Flowrate Ratios. Because it is difficult to compare numerical peak flow values from different wastewater treatment plants, peak flowrate values are normalized by dividing by the long-term average flowrate. The resultant ratio, known as a peaking factor, is defined as follows.

$$\text{Sustained peaking factor, PF} = \frac{\text{peak flowrate (e.g., hourly, daily, monthly)}}{\text{long-term average flowrate}} \tag{3–1}$$

Peaking factors are applied most frequently to determine the peak hourly flowrate. For example, the sustained hourly peaking factor relative to the average flowrate for the daily flowrate record given on Fig. 3–8 is 1.72 [(183 m^3/d)/(106 m^3/d)]. Where flowrate records are available, at least three years of data should be analyzed to define the peak to average day peaking factor. The peaking factor is particularly useful in estimating the maximum hydraulic conditions that might occur and have to be accommodated. Peaking factors can also be applied to mass loadings.

Table 3–11

Parameters used to quantify observed variations in flowrate and constituent concentrations[a]

Parameter	Description[b]
Average dry weather flow (ADWF)	The average of the daily flow data for dry weather periods[c]
Average wet weather flow (AWWF)	The average of the daily flow for wet weather periods[c]
Average daily flow	The average flow occurring over a 24-h period based on total annual flowrate data
Instantaneous peak flowrate	Highest recorded flowrate occurring for a period consistent with the reporting period for the metering equipment. In many situations the recorded peak flow may be considerably below the actual peak flow because of metering and recording equipment limitations
Peak hourly flowrate	The peak sustained hourly flowrate occurring during a 24-h period based on annual operating data (see also Instantaneous peak flow)
Maximum day flow	The maximum flow occurring over a 24-h period based on annual operating data
Maximum monthly flowrate	The maximum daily flow sustained for a period of 1 mo in the record examined. In practice, the maximum month is typically the maximum 30-d value that occurs in the reporting period per the NPDES permit. Although not statistically correct, it is the value that is reported
Minimum hourly flowrate	The minimum sustained hourly flowrate occurring over a 24-h period based on annual operating data
Minimum daily flow	The minimum flow that occurs over a 24-h period based on annual operating data
Minimum monthly flow	The minimum daily flow that occurs over a period of 1 mo based on annual operating data (see Maximum month above)
Sustained flow or load	The flow or mass loading rate sustained or exceeded for a specified period of time (e.g., 1 h, 1 d, or 1 mo) based on annual operating data

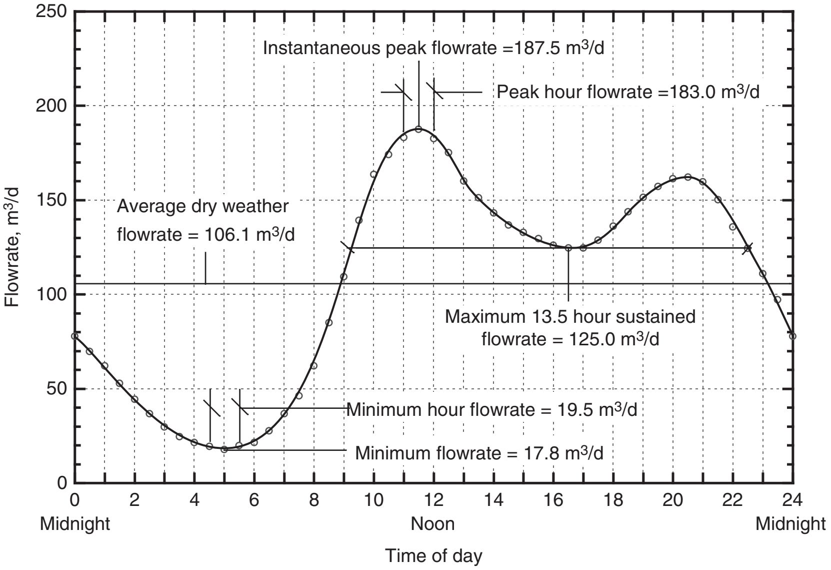
[a] Adapted in part from Crites and Tchobanoglous (1998).
[b] The definitions can also be applied to constituent mass loadings.
[c] In some parts of the country, the distinction between wet and dry periods is becoming blurred due to climate change effects.

Observed Variability in Influent Flowrates

The influent flowrate to a treatment facility, as noted previously, is dependent on factors such as the time of day, season, size and characteristics of the contributing population, and infiltration/inflow to and exfiltration from the collection system. In large cities the wastewater flow is distributed more evenly because there is a greater diversity of lifestyles and a high amount of activity at night. In contrast, wastewater treatment plants used for small residential communities are more likely to experience higher peak flow relative to mean flow values. Peaking factors, as discussed above, are used to estimate the maximum values that would be expected. One method used to characterize the variability of wastewater parameters and treatment processes is the use of the geometric standard deviation, s_g, as computed in Example 3–5. The value of s_g can be used to approximate an entire distribution of all expected values if a mean value is known or can be estimated. As discussed in

Figure 3–8

Identification of flowrate parameters based on variations observed on a typical weekday.



Appendix D, the greater the numerical value of s_g, the greater the observed range in the measured values.

Peaking factors are also related to s_g by specification of a frequency value. The peaking factor is calculated as the value at a given frequency divided by the mean value. For example, the peak day value, which corresponds to one event per year, is the value that occurs at a frequency of 99.7 percent [(364/365) × 100]. The typical ranges of observed values for s_g for influent flowrates for small, medium, and large capacity wastewater treatment plants are given in Table 3–12. The relationship between s_g values and the peaking factors for peak day, week, and month can be determined using the curves given on Fig. 3–9. An example of the use of the s_g value and the curves given on Fig. 3–9 is illustrated subsequently in Example 3–9.

Figure 3–9

Relationship of s_g values to peaking factors for peak day, week and month: (a) diagram for facilities with large peak to mean variations and (b) expanded portion of diagram (a) for facilities with small peak to mean variations.

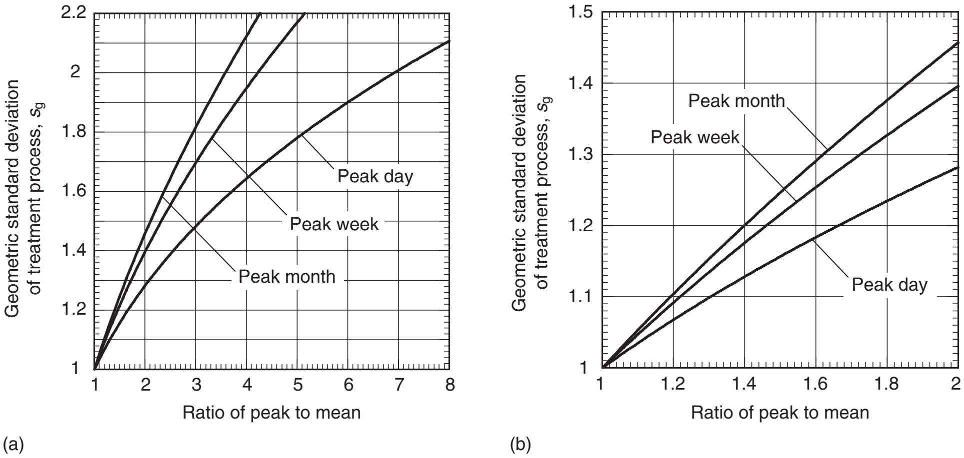


Table 3–12

Ranges of geometric standard deviations (s_g) for influent wastewater flowrates and selected constituents observed at small, intermediate, and large wastewater treatment facilities

	Ranges of s_g values for typical wastewater treatment facilities[a]					
	Small[b]		Medium[c]		Large[d]	
Parameter	Range	Typical	Range	Typical	Range	Typical
Flowrate	1.4–2.0	1.6	1.1–1.5	1.25	1.1–1.2	1.15
BOD	1.4–2.1	1.6	1.3–1.6	1.3	1.1–1.3	1.27
COD	1.5–2.2	1.7	1.4–1.8	1.4	1.1–1.5	1.30
TSS	1.4–2.1	1.6	1.3–1.6	1.3	1.1–1.3	1.27

[a] Excluding systems with large amounts of infiltration in the collection system.

[b] Flowrate of 4000–40,000 m^3/d (1–10 Mgal/d).

[c] Flowrate of 40,000–400,000 m^3/d (10–100 Mgal/d).

[d] Flowrate >400,000 m^3/d (>100 Mgal/d).

3–4 ANALYSIS OF WASTEWATER CONSTITUENTS

The complete analysis of wastewater data involves the determination of the flowrate, constituent concentrations, and constituent mass loading and their variations. The analysis may involve determining the concentrations of specific constituents, mass loadings (flowrate times concentration), or sustained mass loadings (loadings that occur over a defined period of time). From the standpoint of treatment processes, one of the most serious deficiencies results when the design of a treatment plant is based on average flowrates and average BOD and TSS loadings, with little or no recognition of peak conditions and other factors that may affect the average values.

In many communities, peak influent flowrates and BOD and TSS loading rates can reach two or more times average values. It must also be emphasized that, in nearly all cases, peak flowrates and BOD and TSS loading rates do not occur at the same time. Analysis of current records is the best method of arriving at appropriate peak and sustained mass loadings. The principal factors responsible for loading variations are (1) the established habits of community residents, which cause short-term (hourly, daily, and weekly) variations; (2) seasonal conditions, which usually cause longer-term variations; and (3) industrial activities, which cause both long- and short-term variations.

Wastewater Constituents Discharged By Individuals

The physical, chemical, and biological characteristics of wastewater vary throughout the day. An adequate determination of the waste characteristics will result only if the sample tested is representative. Typically, composite samples made up of portions of samples collected at regular intervals during a day are used (see Fig. 3–10, see also Fig. 2–2 in Chap 2). The amount of liquid collected for each sample is proportional to the flowrate at the time the sample was collected. Adequate characterization of mass of the various constituents discharged by individuals is of fundamental importance in the design of treatment and disposal processes.

In the past, it was quite common practice to report measured constituent concentrations, most commonly as mg/L. In the twenty-first century this practice is less useful because, as noted previously in the discussion of flowrates, the per capita flowrates are decreasing as a result of conservation and the use of water conserving appliances and fixtures. Use of current measured concentration values for future projections can be misleading because future concentration values will be understated, due to the impacts of

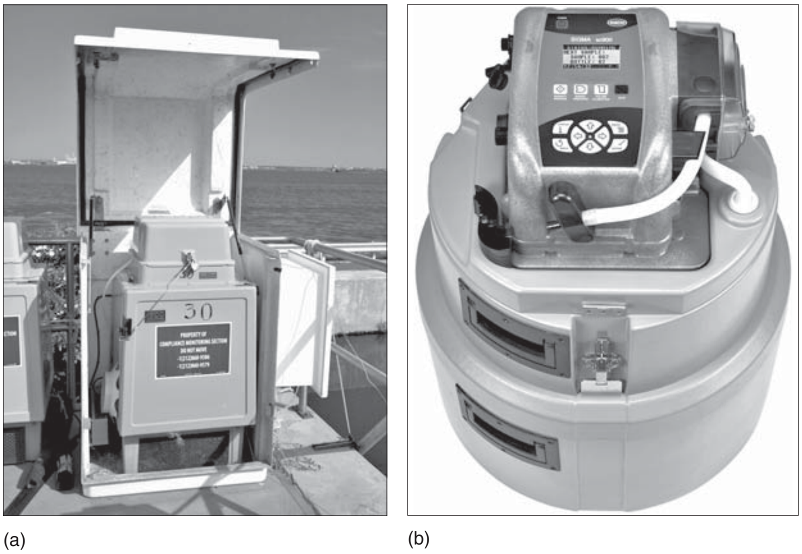

Figure 3–10

Samplers used to collect wastewater samples: (a) refrigerated, locked, and enclosed sampler used for the collection of treatment plant effluent compliance samples (see Fig. 2–2 for view of internal workings of sampler) and (b) portable sampler used to collect individual hourly samples throughout a day to assess process performance and to study potential benefits of process modifications (courtesy of Hach Company, www.hach.com). Portable samplers are also used to conduct collection system evaluations.

(a) (b)

continued water conservation. A more rational approach is to consider the constituent mass discharge rate on a per capita basis. With the availability of such data, the corresponding wastewater concentrations can be determined easily. In what follows typical constituent mass data are presented for the United States and for foreign countries.

Per Capita Mass Constituent Discharges in the United States. Typical data on the total mass of waste discharged per person per day (dry weight basis) from individual residences are reported in Table 3–13. The data presented in Table 3–13 have been gathered from numerous sources. The values reported in Table 3–13 represent the combined total for feces and urine. The reason that the range of values for the individual constituents is much greater than that observed in other countries (see Table 3–14) is due to the fact that about 37.5 percent of all adults in the United States are classified as obese (Ogden et al., 2012). The total number of pathogenic organisms discharged will depend on whether an individual is ill and is shedding pathogens. If one or more members of a family are ill and shedding pathogens, the number of measured organisms can increase by several orders of magnitude. The data given in Table 3–13 will be used subsequently to determine constituent concentrations based on various volumes of water. In the future, it is anticipated that constituent mass per capita data, as given in Table 3–13, will be used as a basis for determining expected constituent concentrations for the design of treatment plant upgrades as well as for new plants.

Per Capita Mass Constituent Discharges in Countries Outside of the United States. The amounts of waste discharged by individuals in other countries can vary significantly due to cultural and socioeconomic differences. Constituent data for 12 other countries as compared to the United States are reported in Table 3–14. The difference in the range of constituent values for other countries as compared to the United States is striking and, as described above, is largely cultural. Water use by individuals also differs significantly in other countries; in most cases the quantities used are significantly less. Consequently, the strength of the wastewater may be much higher than found in the United States and can affect significantly wastewater treatability. In some cases, the wastewater composition may be high in organic content but low in alkalinity and thus cannot be nitrified fully. Concentrations of TSS and BOD for another culture compared to the United States are illustrated in Example 3–5.

Table 3–13

Quantity of waste discharged by individuals on a dry weight basis in the United States[a]

	Value, lb/capita·d			Value, g/capita·d		
Constituent (1)	**Range (2)**	**Typical without ground up kitchen waste (3)**	**Typical with ground up kitchen waste (4)**	**Range (5)**	**Typical without ground up kitchen waste (6)**	**Typical with ground up kitchen waste (7)**
BOD_5	0.11–0.26	0.15	0.20	50–120	70	93
COD	0.30–0.65	0.40	0.50	110–295	180	230

Characteristics of Urine. Because there is increased interest in urine separation and its implications for wastewater treatment and recovery for use as a fertilizer, typical composition data for urine are reported in Table 3–15. The values in the table are identified as approximate because the composition of urine will vary for each individual depending on the amount of water ingested, the amount and composition of the food ingested, the time of day, general health, blood pressure, and the temperature. As noted earlier the bulk of the nutrients (i.e., nitrogen, phosphorus, and potassium) in wastewater are present in urine.

Table 3–15

Approximate properties and overall composition of urine[a,b]

		Value, mg/L[c]	
Constituent	**Formula**	**Range**	**Typical**
Organic molecules			
Urea	CON_2H_4	9000–23,000	20,000
Creatinine	$C_4H_9N_3O_2$	900–1200	1000
Uric acid	$C_5H_4N_4O_3$	200–400	300
Trace organics			
Inorganic elements			
Ammonium	NH_4^+	400–600	500
Bicarbonate	HCO_3^-	20–600	300
Calcium	Ca^{2+}	100–300	150
Chloride	Cl^-	1600–8000	1900
Magnesium	Mg^{2+}	80–120	100
Potassium	K^+	1200–1700	1500
Sodium	Na^+	5000–7000	6000
Inorganic compounds			
Sulphates	SO_4^{2-}	1600–2000	1800
Phosphates	$H_2PO_4^-$, HPO_4^{2-} PO_4^{3-}	1000–1500	1200
Overall composition			
Urea	CON_2H_4	16,000–24,000	20,000
Organic compounds	various	4000–8000	6000
Organic ammonium salts	various	4000–6000	5000
Inorganic salts	various	12,000–16,000	15,000
Other	various	2500–6000	4000
Solids	%	4–7	5
Water	%	93–96	95
Density	g/mL	1.002–1.030	1.010

[a] Adapted in part from Putnam (1971); Ryan (1966); Gotaas (1956); and numerous other sources.

[b] Values in the table are identified as approximate because the composition of urine will vary for each individual depending on the amount of water ingested, the amount and composition of the food ingested, the time of day, general health, blood pressure, and the temperature.

[c] Per capita amount of urine discharged per day will vary from 0.8 to 1.3 L/capita·d.

Constituent Concentrations Based on Individual Mass Discharges

The corresponding constituent concentrations for the United States, assuming the per capita mass quantities of waste constituents given in Table 3–13, are reported in Table 3–16. In preparing Table 3–16, it was assumed that (1) 25 percent of the homes were equipped with kitchen food waste grinders and (2) the constituent mass quantities were diluted in 190 and 460 L (50 and 120 gal) of water. Two different dilutions are used to illustrate the impact that the dilution has on the resulting constituent concentrations.

The method used to determine the constituent concentration values is illustrated in Example 3–5.

EXAMPLE 3–5 **Estimate Waste Constituent Concentration** Using data from Table 3–14, determine the BOD, TSS, and ammonia nitrogen concentrations for the West Bank and the Gaza Strip assuming the water supply is intermittent and the wastewater flowrate is 60 L/capita·d.

Solution

1. From Table 3–15, use the following average constituent contributions:
   a. BOD = 50 g/capita·d
   b. TSS = 62 g/capita·d
   c. NH_3-N = 4 g/capita·d
2. Compute BOD concentration.

$$\text{BOD} = \left[\frac{(50\ \text{g/capita·d})}{(60\ \text{L/capita·d})}\right]\left(\frac{10^3\ \text{L}}{1\ \text{m}^3}\right) = 833\ \text{g/m}^3$$

3. Compute TSS concentration.

$$\text{TSS} = \left[\frac{(62\ \text{g/capita·d})}{(60\ \text{L/capita·d})}\right]\left(\frac{10^3\ \text{L}}{1\ \text{m}^3}\right) = 1033\ \text{g/m}^3$$

4. Compute the NH_3-N concentration.

$$\text{NH}_3\text{-N} = \left[\frac{(4\ \text{g/capita·d})}{(60\ \text{L/capita·d})}\right]\left(\frac{10^3\ \text{L}}{1\ \text{m}^3}\right) = 66.7\ \text{g/m}^3$$

Comment In many parts of the world where water usage is low, constituent concentrations for BOD and TSS may range up to 1000 g/m^3 (mg/L). In the above example, the concentrations of BOD and TSS are nearly 2 to 4 times the BOD and TSS concentrations found typically in the United States (see Table 3–16). Ammonia nitrogen (NH_3-N) concentrations may also be higher, perhaps on the order of two times or more of those in the United States.

Mineral Increase Resulting from Water Use

Data on the increase in the mineral content of wastewater resulting from water use and the variation of the increase within a collection system are especially important in evaluating the reuse potential of wastewater. Typical data on the incremental increase in mineral content that can be expected in municipal wastewater resulting from domestic use are reported in Table 3–17. Increases in the mineral content of wastewater may be due in part from addition of highly mineralized water from private wells and groundwater and from

Table 3–16

Typical unit loading factors and expected wastewater constituent concentrations from individual residences in the United States[a]

Constituent	Typical value[b], g/capita·d	Concentration, mg/L Volume, L/capita·d (gal/capita·d) 190(50)	380(100)
BOD_5	76.0	399.0	199.0
COD	193.0	1013.0	507.0
TSS	74.0	391.0	195.0
NH_3 as N	7.7	40.0	20.0
Org. N as N	5.5	29.0	14.0
TKN as N	13.2	70.0	35.0
Org. P as P	1.2	6.4	3.2
Inorg. P as P	0.9	4.7	2.4
Total P as P	2.1	11.0	5.6
Potassium	6.1	32.0	16.0
Oil and grease	29.0	153.0	76.0

[a] Adapted from Tchobanoglous et al. (2003).
[b] Data from Table 3–13, Columns 6 and 7, assuming 25 percent of the homes have kitchen waste food grinders. For example, $BOD_5 = [70 + (93 - 70)(0.25)]$ mg/L = 76 mg/L.

industrial use. Domestic and industrial water softeners also contribute significantly to the increase in mineral content and, in some areas, may represent the major source. Occasionally, water added from private wells and groundwater infiltration will (because of its high quality) serve to dilute the mineral concentration in wastewater.

Composition of Wastewater in Collection Systems

Typical data on the composition of untreated domestic wastewater as found in wastewater collection systems (in the United States) are reported in Table 3–18. The data presented in Table 3–18 for medium strength wastewater are based on an average flow of 460 L/capita·d (120 gal/capita·d) and include constituents added by commercial, institutional, and industrial sources. Typical concentrations for low-strength and high strength wastewater, which reflect different amounts of infiltration, are also given. Because there is no "typical" wastewater, it must be emphasized that the typical data presented in Table 3–18 *should only be used as a guide*.

Variations in Constituent Concentrations

Several types of constituent concentrations can occur depending upon the characteristics of the contributors to the wastewater collection system.

Short-Term Variation in Constituent Concentrations. Constituent concentrations variations change significantly during the course of a day. An example of typical

Table 3–17

Typical mineral increase from domestic water use

Constituent	Typical increment range[a, b] Mass, g/capita·d	Concentration, mg/L[c]
Anions:		
Bicarbonate (HCO_3)	23–46	60–121
Carbonate (CO_3)	0–5	0–13
Chloride (Cl)	9–23	24–60
Sulfate (SO_4)	7–14	18–37
Cations:

Aluminum (Al)	0.04–0.09	0.11–0.24
Boron (B)	0.04–0.09	0.11–0.24
Fluoride (F)	0.09–0.2	0.24–0.53
Manganese (Mn)	0.09–0.2	0.24–0.53
Silica (SiO_2)	0.9–5	2.4–13
Total alkalinity (as $CaCO_3$)	28–55	74–145
Total dissolved solids (TDS)	69–175	182–460

[a] Values do not include commercial and industrial additions.
[b] Excluding the addition from domestic water softeners.
[c] Based on 380 L/capita·d (100 gal/capita·d) as used in Tables 3–16 and 3–18.

Note: mg/L = g/m^3.

variations in BOD and TSS in domestic wastewater are shown on Fig. 3–11. In general, the variations in BOD and TSS follow the flowrate variation. The peak BOD (organic matter) concentration typically occurs in the evening, whereas the peak TSS concentration occurs in the morning. The amplitude of the BOD and TSS variations depends on the size and characteristics of the community. Also, the time that the peak value occurs will depend on whether it is a weekday or the weekend [see Fig. 3–3(b)].

Seasonal Variation in Constituent Concentrations. For domestic flow only, and neglecting the effects of infiltration, the unit (per capita) loadings and the strength of the wastewater from most seasonal sources, such as resorts, will remain about the same on a daily basis throughout the year even though the total flowrate varies. The total mass of BOD and TSS of the wastewater, however, will increase directly with the population served.

Infiltration/inflow, as discussed earlier in this chapter, is another source of water flow into the collection system. In most cases, the presence of this extraneous water tends to decrease the concentrations of BOD and TSS, depending on the characteristics of the water entering the sewer. In some cases, concentrations of some inorganic constituents may actually increase where the groundwater contains high levels of dissolved constituents.

Table 3–18

Typical composition of untreated domestic wastewater

		Concentration[b]		
Constituent	Unit	Low strength	Medium strength	High strength
Solids, total (TS)	mg/L	537	806	1612
Dissolved, total (TDS)	mg/L	374	560	1121

Suspended solids, total (TSS)	mg/L	130	195	389
Fixed	mg/L	29	43	86
Volatile	mg/L	101	152	304
Settleable solids	mL/L	8	12	23
Biochemical oxygen demand, 5-d, 20°C BOD	mg/L	133	200	400
Total organic carbon (TOC)	mg/L	109	164	328
Chemical oxygen demand (COD)	mg/L	339	508	1016
Nitrogen (total as N)	mg/L	23	35	69
Organic	mg/L	10	14	29
Free ammonia	mg/L	14	20	41
Nitrites	mg/L	0	0	0
Nitrates	mg/L	0	0	0
Phosphorus (total as P)	mg/L	3.7	5.6	11.0
Organic	mg/L	2.1	3.2	6.3
Inorganic	mg/L	1.6	2.4	4.7
Potassium	mg/L	11	16	32
Chlorides[c]	mg/L	39	59	118
Sulfate[c]	mg/L	24	36	72
Oil and grease	mg/L	51	76	153
Volatile organic compounds (VOCs)	μg/L	<100	100–400	>400
Total coliform	No./100 mL	10^6–10^8	10^7–10^9	10^7–10^{10}
Fecal coliform	No./100 mL	10^3–10^5	10^4–10^6	10^5–10^8
Cryptosporidium oocysts	No./100 mL	10^{-1}–10^1	10^{-1}–10^2	10^{-1}–10^3
Giardia lamblia cysts	No./100 mL	10^{-1}–10^2	10^{-1}–10^3	10^{-1}–10^4

[a] Adapted from Tchobanoglous et al. (2003).

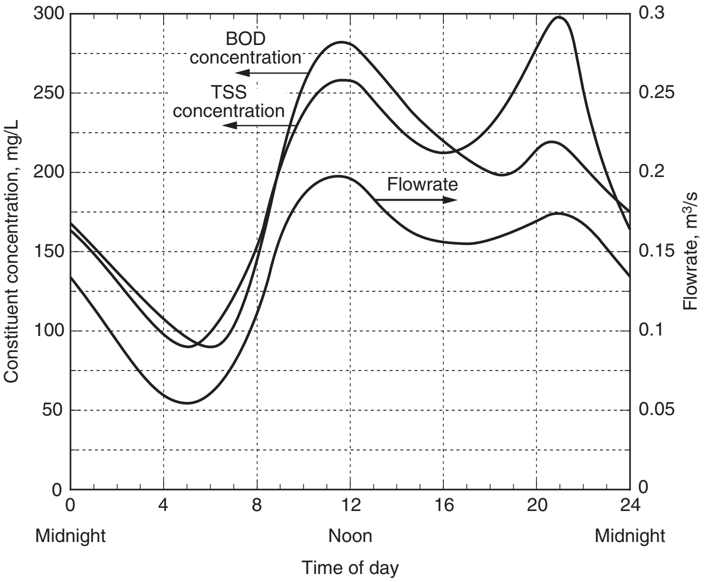
[b] Low strength is based on an approximate wastewater flowrate of 570 L/capita·d (150 gal/capita·d). Medium strength is based on an approximate wastewater flowrate of 380 L/capita·d (100 gal/capita·d). High strength is based on an approximate wastewater flowrate of 190 L/capita·d (50 gal/capita·d).

[c] Values should be increased by amount of constituent present in domestic water supply.

Note: mg/L = g/m^3.

Figure 3–11

Typical hourly variations observed in flow and BOD and TSS concentrations in domestic wastewater.



Variations in Industrial Wastewater. The composition of wastewater from industrial operations varies widely depending on the function and activity of the particular industry. Examples of the constituent concentration variability are illustrated in Table 3–19. From these examples, it can be observed that flow values and water quality measurements may vary by several orders of magnitude over a period of a year. Because of this variation, it is often difficult to define "typical operating conditions" for industrial activities.

The concentrations of both BOD and TSS, as well as a wide range of other constituents, in industrial wastewater can vary significantly throughout the day. For example, the BOD and TSS concentrations contributed from vegetable-processing facilities during the noon wash-up period may far exceed those contributed during working hours. Problems with high short-term loadings most commonly occur in small treatment plants that have limited reserve capacity to handle these so-called "shock loadings." The seasonal impact of industrial wastes such as canneries can cause both the flow and BOD loading to increase from two to five times average conditions.

If industrial wastes are to be discharged to the collection system for treatment in a municipal wastewater facility, it will be necessary to characterize the wastes adequately to identify the ranges in constituent concentrations and mass loadings. Such characterization is also needed to determine if pretreatment is required before the waste is permitted to be discharged into the collection system. If pretreatment is needed, the effluent from the pretreatment facilities must also be characterized. Further, any proposed future process changes should also be assessed to determine what effects they might have on the wastes to be discharged. Where data are not available, every effort should be made to obtain information from similar facilities. With sufficient characterization of the wastewater from industrial discharges, suitable pretreatment facilities can be provided and plant upsets can be avoided.

Variations in Constituent Concentrations in Combined Collection Systems. Flowrates, constituent concentrations, and mass loads emanating from combined collection systems can vary widely from community to community, season to season,

Table 3–19

Typical examples of the range of effluent flowrates and constituent concentrations for two industrial activities[a]

		Wool textile mill		Tomato cannery	
Constituent	Unit	Annual average	Daily maximum	Peak season[b]	Off season[c]

[a] Adapted from Tchobanoglous et al. (2003).

[b] Peak season is from early July to late September, when fresh-harvest tomatoes are canned. Treatment consists of screening and sedimentation.

[c] Off-season is from November to June, when canned tomatoes are remanufactured into tomato paste, tomato sauce, and other tomato products (e.g., salsa, ketchup, spaghetti sauce). Treatment typically consists of screening, aeration, and sedimentation.

[d] Median value.

Note: $m^3/d \times 0.264 \times 10^{-3} = Mgal/d$.

storm to storm and within a storm. Typical factors influencing the characteristics of wastewater from combined collection systems are shown in Table 3–20. Example variations of BOD, TSS, and fecal coliform measured in a combined system are shown on Fig. 3–12, during and after a storm event. As shown, the BOD and fecal coliform bacteria concentrations are low during the storm when runoff flows are high. After the storm, when runoff subsides and the flow consists primarily of wastewater, concentrations rise significantly. When this rise occurs, it can be concluded that the BOD and fecal coliform concentrations in the stormwater are significantly lower than in the wastewater component. The characteristics of combined wastewater and stormwater as compared to municipal wastewater are shown in Table 3–21.

Unlike BOD and fecal coliform bacteria, TSS concentrations rise slightly during the storm and remain unchanged after the storm, indicating that TSS concentrations from stormwater runoff and wastewater are similar. The slight rise in the TSS concentration during the peak flow may be due to a phenomenon common to many combined sewer systems known as the “first flush.” The first flush has often been observed following the initial phase of a rainfall event in which much of the accumulated surface contaminants are washed into the combined system. In combined collection systems, the increased flows may be capable of resuspending material deposited previously during low flow periods.

Table 3–20

Typical factors influencing the characteristics of combined wastewater

Parameter	Quantity-related factors	Quality-related factors
Precipitation	Rainfall depth (volume) Storm intensity Storm duration	Antecedent dry weather Atmospheric quality
Wastewater sources	Peak flowrate and variability Land use	Contributing sources (domestic, industrial, commercial, etc.)
Drainage basin characteristics	Size, shape, slope, time of concentration Land use Impervious area Soil characteristics Stormwater management practices	Effectiveness of best management practices/minimum controls with respect to street cleaning and litter control Pollutant buildup and wash-off Stormwater management practices
Sewer system, interceptor design and condition	Pipe size, slope and shape Quantity of base infiltration Number and location of inflow sources (catch basins, roof leaders, etc.) Surcharging or backwater conditions Type of flow regulation or diversion structures including pumping station overflows Capacity reduction from sediment build-up River or tidal inflow	Effectiveness of best management practices/minimum controls with respect to catch basin and sewer cleaning Pollutant buildup and resuspension Chemical and biological transformations

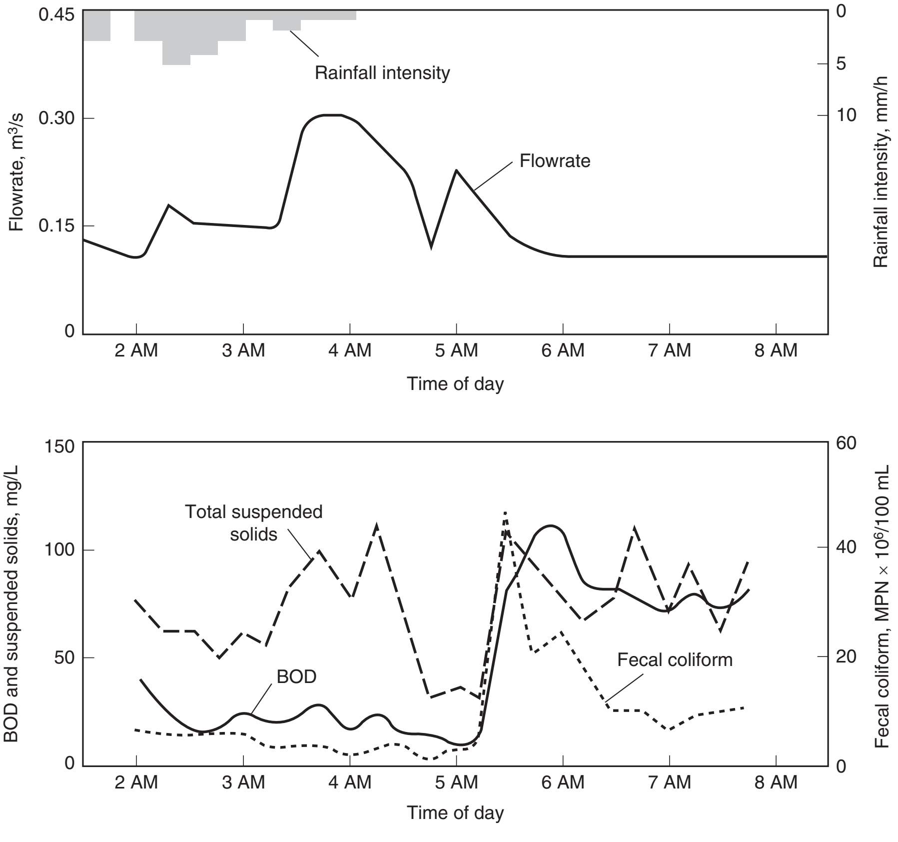

Figure 3–12

Typical variations of flowrate, BOD, TSS, and fecal coliform in a combined collection system during a storm event.

Table 3–21

Comparison of characteristics of combined wastewater with other sources[a]

Parameter	Unit	Rainfall	Stormwater runoff	Combined wastewater	Municipal wastewater
Total suspended solids, TSS	mg/L	<1	67–101	270–550	120–400
Biochemical oxygen demand, BOD	mg/L	1–13	8–10	60–220	110–350
Chemical oxygen demand, COD	mg/L	9–16	40–73	260–480	250–800
Nitrogen (as N)					
Total Kjeldahl nitrogen, TKN	mg/L		0.40–1.00	4–17	20–70
Nitrate, NO_3	mg/L		0.05–1.0	0.48–0.91	0
Phosphorus (total as P)	mg/L	0.02–0.15	0.67–1.66	1.2–2.8	4–12

Copper, Cu	μg/L		27–33		
Lead, Pb	μg/L	30–70	30–144	140–600	
Zinc, Zn	μg/L		135–226		
Fecal coliform bacteria	MPN/100 mL		10^3–10^4	10^5–10^6	10^5–10^8

[a] Adapted from Tchobanoglous et al. (2003).

Together, the resuspended material and contaminants washed off surfaces result in high contaminant concentrations. Factors known to contribute to the magnitude and frequency of the first flush effect include combined sewer slopes, street and catch basin cleaning frequency and design, rainfall intensity, duration, and surface buildup of debris and contaminants.

Wastewater from combined collection systems usually contains more inorganic matter than wastewater from sanitary collection systems because of the larger quantities of stormwater runoff that enter the combined sewer system. This observation is particularly true in snowbelt states where sand is used to treat the streets during snow and ice conditions.

Statistical Analysis of Constituent Concentrations

The statistical analysis of constituent concentration data is essentially the same as described previously for flowrate data in Sec. 3–3 and illustrated in Example 3–4. The most common type of probability distribution encountered in the statistical analysis of constituent concentration data is the log-normal distribution, in which log of the constituent concentration is normally distributed. In general, wastewater constituents that can be altered biologically are distributed log-normally. Inorganic constituents, such as chloride and sulfate, can be distributed both normally or log-normally.

Observed Variability in Influent Constituent Concentrations

The influent constituent concentrations to a treatment facility, as noted above, and illustrated on Fig. 3–12, are also quite variable depending on the time of day, season, size and characteristics of the contributing population, and infiltration to and exfiltration from the collection system. The variability observed in constituent concentrations can be quantified using the geometric standard deviation, s_g, as computed in Example 3–4. The value of s_g can be used to approximate an entire distribution of all expected values if a mean value is known or can be estimated. For example, the peak day value, which corresponds to one event per year, is the value that occurs at a frequency of 99.7 percent [(364/365) × 100]. The typical range of observed values for s_g for influent BOD, TSS, and COD concentrations for small-, medium-, and large-capacity wastewater treatment plants are given in Table 3–12, presented previously. The application of the s_g values given in Table 3–12 is illustrated subsequently in Example 3–9.

3–5 ANALYSIS OF CONSTITUENT MASS LOADING DATA

The analysis of wastewater constituent data involves the determination of simple average or flow-weighted average concentrations, mass loadings rates, and sustained peak mass loading rates.

Simple Average

The simple or arithmetic average of a number of individual measurements is given by

$$\bar{x} = \frac{1}{n}\sum_{i=1}^{n} x_i \tag{3–2}$$

Where $\bar{x}$ = arithmetic average of individual measurements
n = number of measurements
x_i = average value of measurement during the ith time period

To analyze the BOD and TSS data given on Fig. 3–6, for example, the usual procedure is to divide the day's record into 24 1-h increments, sum the 24 individual average hourly values, and divide by 24. Although arithmetic averages are still used, they are of little value because the magnitude of the flow at the time of the measurement is not taken into account. If the flowrate remains constant, the use of a simple average is acceptable.

Flow-Weighted Average

Flow-weighted constituent concentrations are obtained by multiplying the flow (typically hourly values over a 24-h period) times the corresponding constituent concentration, summing the results, and dividing by the summation of the flows as given by Eq. 3–3.

$$C_W = \frac{\sum_{i=1}^{n} q_i C_i}{\sum_{i=1}^{n} q_i} \tag{3–3}$$

where C_w = flow-weighted average constituent concentration
n = number of observations
q_i = average flowrate during ith time period
C_i = average concentration of the constituent during ith time period

Whenever possible, flow-weighted constituent concentrations should be used because they are a more accurate representation of the actual wastewater strength that must be treated.

Determination of the simple arithmetic average and flow-weighted constituent concentrations is illustrated in Example 3–6.

EXAMPLE 3–6 **Calculation of Flow-Weighted BOD and TSS Concentrations** Compute the flow-weighted BOD and TSS values using the data provided below for a community of about 5000 persons. Compare the flow-weighted values to the simple arithmetic averages. What is the significance of the difference?

Time	Flowrate, m^3/s	BOD, g/m^3	TSS, g/m^3	Time	Flowrate, m^3/s	BOD, g/m^3	TSS, g/m^3
Mid	0.120	165	175	Noon	0.195	255	280
1 a.m.	0.115	150	155	1 p.m.	0.180	242	265
2	0.095	130	135	2	0.170	229	265
3	0.075	110	120	3	0.164	230	235
4	0.060	100	110	4	0.160	212	222
5	0.055	90	100	5	0.158	217	210
6	0.060	100	90	6	0.159	234	200
7	0.085	120	110	7	0.163	250	200
8	0.115	150	150	8	0.169	270	212
9	0.160	190	210	9	1.174	295	216
10	0.187	238	253	10	0.164	250	203
11	0.195	256	273	11	0.155	199	189
12	0.195	255	280	12	0.135	165	175

Solution

1. Create a spreadsheet for calculating the flow-weighted values with columns for time, flowrate, BOD, TSS, q × BOD, and q × TSS. Enter the time intervals (e.g., Noon–1 p.m.) in column 1. The required table is presented.
2. For each time period, calculate the average flowrate value during the interval and enter the value in column 2. For example, the average flowrate value during the first interval (12–1 a.m.) is

   Value at beginning of interval = 0.120 m^3/s
   Value at end of interval = 0.115 m^3/s

   $$\text{Average flowrate} = \frac{(0.120\ \text{m}^3/\text{s} + 0.115\ \text{m}^3/\text{s})}{2} = 0.118\ \text{m}^3/\text{s}$$

   The average flowrate values for each successive time interval are entered in column 2.
3. Enter the average values for BOD and TSS in columns 3 and 4, respectively.
4. For each time period, multiply the average flowrate value (column 2) times the average BOD (column 3), and enter the results in column 5.
5. For each time period, multiply the average flowrate (column 2) value by the average TSS (column 4), and enter the results in column 6.
6. Calculate the sum and simple arithmetic average for columns 2 through 6.

7. Divide the sum of the values in columns 5 and 6 (q × BOD and q × TSS, respectively) by the sum of the values in column 2 (flowrate) to obtain the flow-weighted average for BOD and TSS. The resulting values are given in the last two lines of the spreadsheet.

Time interval (1)	Flowrate, q m^3/s (2)	BOD, g/m^3 (3)	TSS, g/m^3 (4)	q × BOD, kg/d (5) = (2) × (3)	q × TSS, kg/d (6) = (2) × (4)
12–1 a.m.	0.118	157.5	165.0	18.59	19.47
1–2	0.105	140.0	145.0	14.70	15.23
2–3	0.085	120.0	127.5	10.20	10.84
3–4	0.068	105.0	115.0	7.14	7.82
4–5	0.058	95.0	105.0	5.51	6.09
5–6	0.058	95.0	95.0	5.51	5.51
6–7	0.073	110.0	100.0	8.03	7.30

8–9	0.138	170.0	180.0	23.46	24.84
9–10	0.174	214.0	231.5	37.24	40.28
10–11	0.191	247.0	263.0	47.18	50.23
11–12	0.195	255.5	276.5	49.82	53.92
12–1 p.m.	0.188	248.5	272.5	46.72	51.23
1–2	0.175	235.5	265.0	41.21	46.38
2–3	0.167	229.5	250.0	38.33	41.75
3–4	0.162	221.0	228.5	35.80	37.02
4–5	0.159	214.5	216.0	34.11	34.34
5–6	0.159	225.5	205.0	35.85	32.60
6–7	0.161	242.0	200.0	38.96	32.20
7–8	0.166	260.0	206.0	43.16	34.20
8–9	0.172	282.5	214.0	48.59	36.81
9–10	0.169	272.5	209.5	46.05	35.41
10–11	0.160	224.5	196.0	35.92	31.36
11–12	0.145	182.0	182.0	26.39	26.39
Totals	3.346	4682	4578	711.96	694.19
Average	0.139	195.1	190.8		
Flow-weighted concentration values				212.8[a]	207.5

[a] $C_W = \sum_{i=1}^{n} q_i C_i / \sum_{i=1}^{n} q_i = 711.96/3.346 = 212.8.$

Comment When comparing the computation of a simple average to a flow-weighted value, the differences can be significant. In this example, if simple averages were used, the BOD loading would have been understated by 17.7 mg/L (8.3 percent), and the TSS loading by 16.7 mg/L (8.1 percent). If simple averages had been used in establishing process loading values, the treatment facilities could be under designed by about 8 percent in this case.

Mass Loading Rates

Constituent mass loading rates are usually expressed in kilograms per day (kg/d)[pounds per day (lb/d)] and may be computed using Eq. (3–4a) when the flowrate is expressed in cubic meters per day (m^3/d), or Eq. (3–4b) when the flowrate is expressed in million gallons per day (Mgal/d). Note that in the SI system of units, the concentration expressed in milligrams per liter (mg/L) is equivalent to grams per cubic meter (g/m^3).

$$\text{Mass loading rates, kg/d} = \frac{(\text{concentration, g/m}^3)\ (\text{flowrate, m}^3\text{/d})}{(10^3\ \text{g/1 kg})} \tag{3–4a}$$

$$\text{Mass loading rates, lb/d} = (\text{concentration, mg/L})(\text{flowrate, Mgal/d})\left[\frac{8.34\ \text{lb}}{\text{Mgal}\cdot(\text{mg/L})}\right] \tag{3–4b}$$

To design treatment processes to function properly under varying loading conditions, data must be available for the sustained peak mass loading rates of constituents that are to be expected. In the past, such information has seldom been available. When the data are not available, curves similar to those shown on Fig. 3–13 can be used. The curves for BOD, TSS, TKN (total Kjeldahl nitrogen), NH_3 (ammonia), and phosphorus were derived from an analysis of the records of over 50 treatment plants throughout the country. It should be noted that significant variations will be observed from plant to plant, depending on the size of the system, the percentage of combined wastewater, the size and slope of the interceptors, and the types of wastewater contributors.

The procedure used to develop the mass loading rate curves shown on Fig. 3–13 is as follows. First, the average mass loading rate is determined for the period of record. Second, the records are reviewed for the highest and lowest sustained one-day mass loading rate. These values are divided by the average mass loading rate and the numbers are plotted. Third, the same procedures are followed for two consecutive days, three consecutive days, etc., sustained loadings until ratio values are found for the period of interest (usually 10 to 30 d).

The daily mass loading rates for the various plants were developed using hourly data and the following expression:

$$\text{Daily mass loading rate, kg/d} = \sum_{i=1}^{24} \frac{(\text{concentration, g/m}^3)(\text{flowrate, m}^3\text{/d})}{(10^3\ \text{g/1 kg})} \tag{3–5a}$$

$$\text{Daily mass loading rate, lb/d} = \sum_{i=1}^{24} (\text{concentration, mg/L})(\text{flowrate, Mgal/d})\left[\frac{8.34\ \text{lb}}{\text{Mgal}\cdot(\text{mg/L})}\right] \tag{3–5b}$$

The development of a sustained peak mass loading curve is illustrated in Example 3–7.

EXAMPLE 3–7 **Development of BOD Sustained Mass Loading Rate Values** Develop a sustained BOD peak mass loading curve for a treatment plant with a design flowrate of 1 m^3/s (22.8 Mgal/d) and using sustained peak loading rate factors from Fig. 3–13(a). Assume that the long-term daily average BOD concentration is 200 g/m^3.

Solution

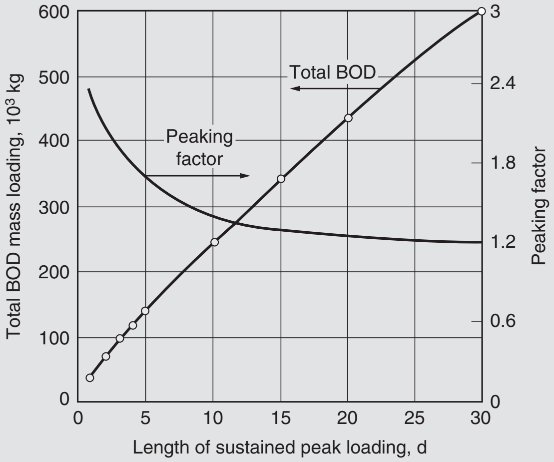
1. Compute the daily mass loading rate value for BOD.

$$\text{Daily BOD mass loading rate, kg/d} = \frac{(200\ \text{g/m}^3)(1\ \text{m}^3\text{/s})(86{,}400\ \text{s/d})}{(10^3\ \text{g/1 kg})} = 17{,}280\ \text{kg/d}$$

2. Set up a computation table for the development of the necessary information for the peak sustained BOD mass loading curve (see following table).
3. Obtain the sustained peak BOD loading rate factors from Fig. 3–13(a), and determine the sustained mass loading rates for various time periods (see table, cols. (1), (2), and (3)).
4. Develop data for the sustained mass loading curve and prepare a plot of the resulting data (see following figure).

Length of sustained peak, d (1)	Peaking factor[a] (2)	Peak BOD mass loading rate, kg/d (3)	Total mass loading, kg[b] (4)
1	2.4	41,472[c]	41,472
2	2.1	36,288	72,576
3	1.9	32,832	98,496
4	1.8	31,104	124,416
5	1.7	29,376	146,880
10	1.4	24,192	241,920
15	1.3	22,464	336,960
20	1.25	21,600	432,000
30	1.21	19,872	596,160
365	1.0	17,280	

[a] From Fig. 3–13a.
[b] Col. 1 × col. 3 = col. 4.
[c] 41,472 = 17,280 × 2.4.



Comment The interpretation of the curve plotted for this example is as follows. If the sustained peak loading period were to last for 10 d, the total amount of BOD that would be received at a treatment facility during the 10-d period would be 241,695 kg. The corresponding amounts for sustained peak periods of 1 and 2 d would be 41,401 and 72,451 kg, respectively. Computations for an example of this type are normally done using a spreadsheet program.

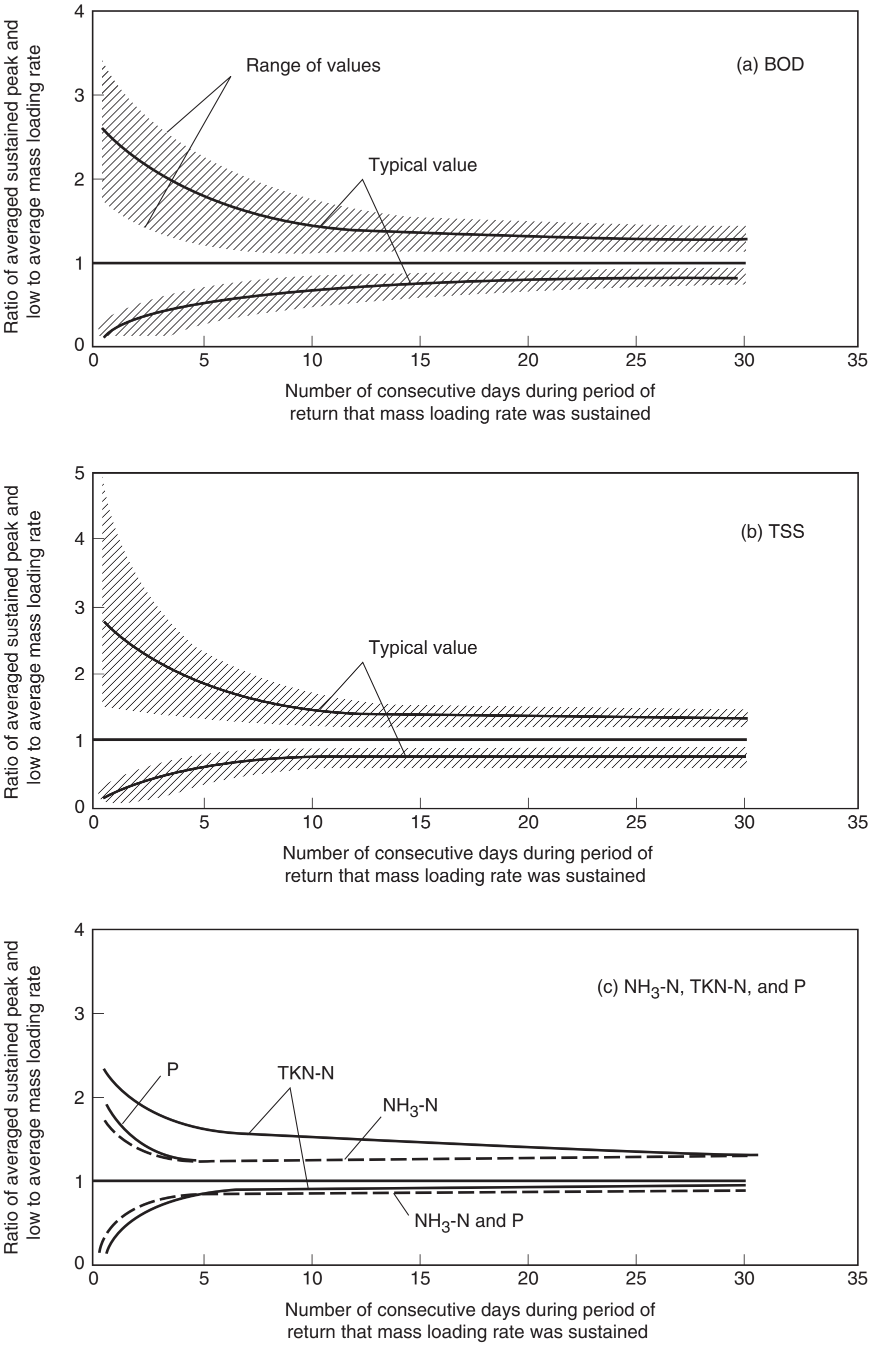


Figure 3–13

Typical information on the ratio of averaged peak and low-to average mass loading rates for: (a) biochemical oxygen demand, BOD; (b) total suspended solids,TSS; and (c) ammonia nitrogen, NH_3-N, total Kjeldahl nitrogen, TKN-N, and phosphorus, P.

Effect of Mass Loading Variability on Treatment Plant Performance

During the course of a day, the mass loading rate that is received by the treatment plant can vary widely as illustrated on Fig. 3–14. The variations are more pronounced in small collection systems where the collection system storage capacity does not provide a significant dampening effect. The impact of these load variations is seen most dramatically in the effects on

Figure 3–14

Illustration of typical hourly variations observed in flow and BOD and TSS concentrations and the corresponding BOD and TSS and mass loading rates. (Typical hourly variations are from Fig. 3–11.)

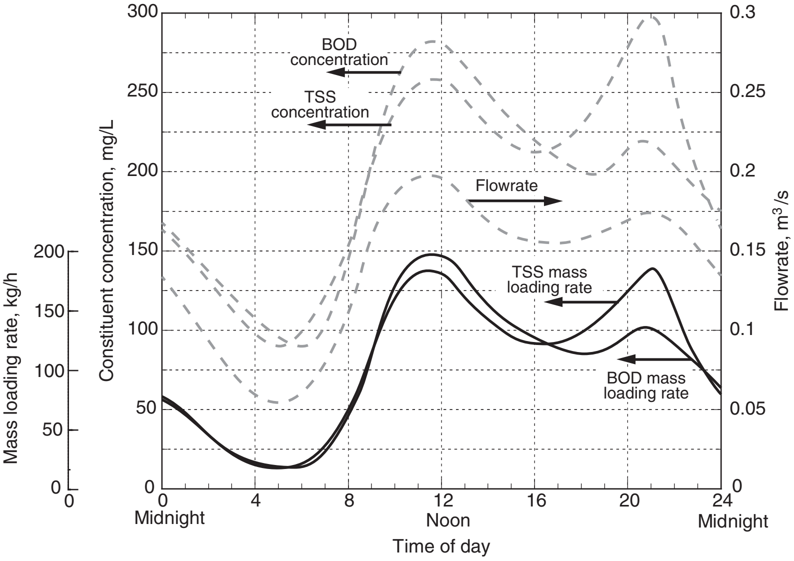

Figure 3–15

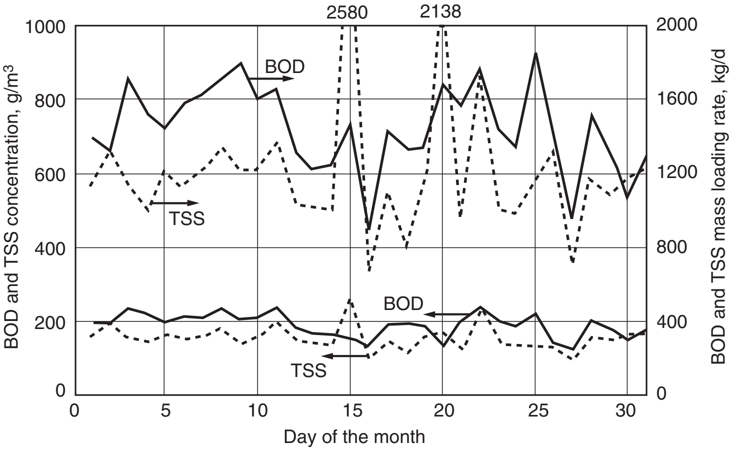
Example variations of TSS and BOD concentrations and mass loading rates over a monthly period.



biological treatment operating conditions. The maximum hourly BOD loading rate may vary as much as 3 to 4 times the minimum hourly BOD loading rate in a 24-h period. Over longer periods of time, the mass loading rates can also vary widely (see Fig. 3–15). These types of variations have to be accounted for in the design of the biological treatment system. In extreme cases, flow or load equalization may be required.

3–6 SELECTION OF DESIGN FLOWRATES AND MASS LOADINGS

The rated capacity of wastewater treatment plants is normally based on the average annual daily flowrate at the design year plus an allowance for future growth. As a practical matter, however, wastewater treatment plants have to be designed to meet a number of conditions that are influenced by flowrates, wastewater characteristics and constituent concentrations, and a combination of both flowrate and concentration (mass loading). Conditions that must be considered include peak and minimum hydraulic flowrates and the maximum, minimum, and sustained process constituent mass loading rates. The importance of wastewater flowrates in process design and operation is considered in this section; mass loadings are discussed in a following section.

Additionally, periods of initial operation and low flows and loads must be taken into consideration in design. Typical flowrate and mass loading factors that are important in the design and operation of wastewater treatment facilities are described in Table 3–22. The overall objective of wastewater treatment is to provide a wastewater treatment system that

Table 3–22

Typical flowrate and mass loading factors used for the design and operation of wastewater treatment facilities[a]

Flowrate factor	Purpose for design and operation
Flowrate	
Average daily flow	Development of flowrate ratios and for estimating pumping and chemical costs. Also used to estimate operator staffing requirements
Peak hour	Sizing of pumping facilities and conduits; sizing of physical unit processes: grit chambers, sedimentation tanks, and filters; sizing chlorine contact tanks. Getting the peak hourly flowrate through the treatment plant without flooding channels and weirs is a major design challenge. Also important in developing process control strategies.
Maximum day	Sizing of equalization basins, sedimentation tank and clarifier effluent troughs and weirs, chlorine contact tanks, and sludge pumping system. Also important in developing process control strategies for managing high flows
Maximum month	Record keeping and reporting; selection of maximum number of operating units required during high flow periods; sustained high flow operational strategies; and sizing of chemical storage facilities
Minimum hour	Sizing turndown of pumping facilities and chemical feed systems and determining low range of plant flowmeter(s)
Minimum day	Sizing of influent channels to control solids deposition; sizing effluent recycle requirements for trickling filters
Minimum month	Selection of minimum number of operating units required during low flow periods; scheduling shutdown for maintenance
Mass loading	
Minimum month	Process turndown requirements
Minimum day	Sizing of trickling filter recycle rates
Maximum day	Sizing of selected process units
Maximum month	Sizing of sludge storage facilities; sizing of composting requirements
Maximum 15-d	Sizing anaerobic and aerobic digesters
Sustained loading	Sizing of selected process units and ancillary process equipment

[a] Adapted from Tchobanoglous et al. (2003).

is capable of coping with a wide range of probable wastewater conditions while complying with the overall performance requirements.

Design Flowrates

The development and forecasting of flowrates is necessary to determine the design capacity as well as the hydraulic requirements of the treatment system. Flowrates need to be developed both for the initial period of operation and for the future (design) period. Consideration of the flowrates during the early years of operation is often overlooked, and oversizing of equipment and inefficient operation can result. The focus of the following discussion is on the development of various design flowrates.

Rationale for the Selection of Flowrates. The rationale for selecting flowrates is based on hydraulic and process considerations. As stated, the process units and hydraulic conduits must be sized to accommodate the anticipated peak flowrates that will pass through the treatment plant. Provisions have to be made to ensure bypassing of wastewater does not occur either in the collection system or at the treatment plant. Many of the process units are designed based on detention time or overflow rate (flowrate per unit of surface area) to achieve the desired removal rates of BOD and TSS. Because the performance of these units can be affected significantly by varying flowrate conditions and mass loadings, minimum and peak flowrates must be considered in design.

Forecasting Flowrates. In determining the design flowrate, elements to be considered are (1) the existing base flows; (2) estimated future flows for residential, commercial, institutional, and industrial sources; and (3) non-excessive infiltration/inflow. Existing base flows equal actual metered flowrates minus excessive infiltration/inflow (defined as infiltration/inflow that can be controlled by cost-effective improvements to the collection system).

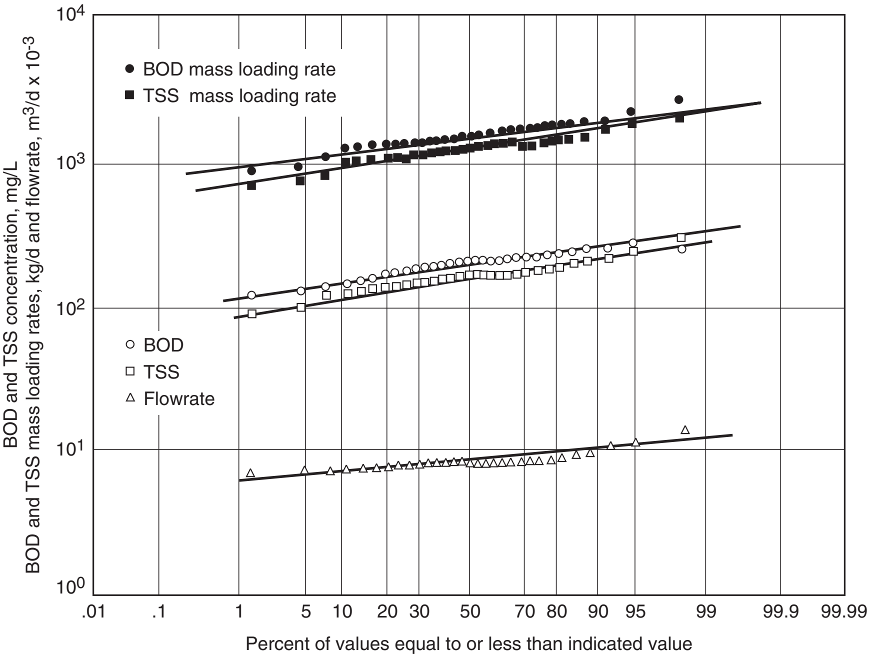
A yardstick by which total dry-weather base flow can be measured where infiltration is not excessive is 420 L/capita·d (110 gal/capita·d). This base flow includes 230 L/capita·d (60 gal/capita·d) for domestic flows, 40 L/capita·d (10 gal/capita·d) for commercial and small industrial flows, and 150 L/capita·d (40 gal/capita·d) for infiltration.

A useful technique in forecasting flowrates is probability analysis, discussed earlier in this chapter. Where flowrate data are available, preferably for at least two years, future flowrates for design can be predicted with a reasonable certainty. An example of a probability analysis of flowrates, as well as BOD and TSS concentrations and mass loadings, is shown on Fig. 3–16. The probability analysis can be used to estimate occurrences of peak flows and loads, and to establish a basis for selecting design flows and loads. For example, a maximum one-day occurrence can be determined based on a 99.7 percent probability; the value will not be equaled or exceeded in the time period analyzed. A probability value, such as the 95th percentile, can also be established for forecasting the design loadings to meet permit requirements.

Minimum Flowrates. As noted in Table 3–22, low flowrates are also of concern in treatment plant design, particularly during the initial years of operation when the plant is operating well below the design capacity, and in designing pumping stations. In cases where very low nighttime flow is expected, provisions for recycling treated effluent may have to be included to sustain the process, (e.g., biological treatment processes such as trickling filters, and to maintain optimal flowrates through ultraviolet disinfection systems). In absence of measured flowrate data, minimum daily flowrates may be assumed to range from 30 to 90 percent of average flowrates for small to large size communities, respectively [see also Fig. 3–3(c)] (WEF, 2010).

Figure 3–16

Typical probability plots for flowrate, BOD, and TSS.



Sustained Flowrates. Sustained flowrates are those that are equaled or exceeded for a specified number of consecutive days based on annual operating data. Data for sustained flowrates may be used in sizing equalization basins and other plant hydraulic components. An example plot of sustained and low flowrates is shown on Fig. 3–17. When developing plots similar to Fig. 3–17, the longest available period should be used.

Peak Flowrate Factors. The flowrate peaking factors (the ratio of peak flowrate to average flowrate) most frequently used in design are those for peak hour and maximum day (see Table 3–22). Peak hourly flowrates are used to size the hydraulic conveyance system and other facilities such as sedimentation tanks and chlorine contact tanks where little volume is available for flow dampening. Other peaking factors such as maximum week or maximum month may be used for treatment facilities such as pond systems that have long detention times or for sizing solids and biosolids processing facilities that also

Figure 3–17

Typical ratios of averaged sustained peak and low daily flowrates to average annual daily flowrates for time periods up to 30 d.

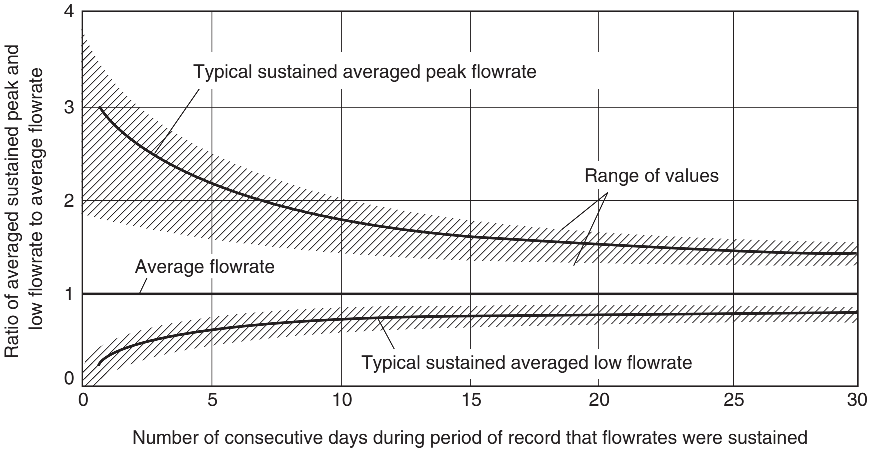


Figure 3–18

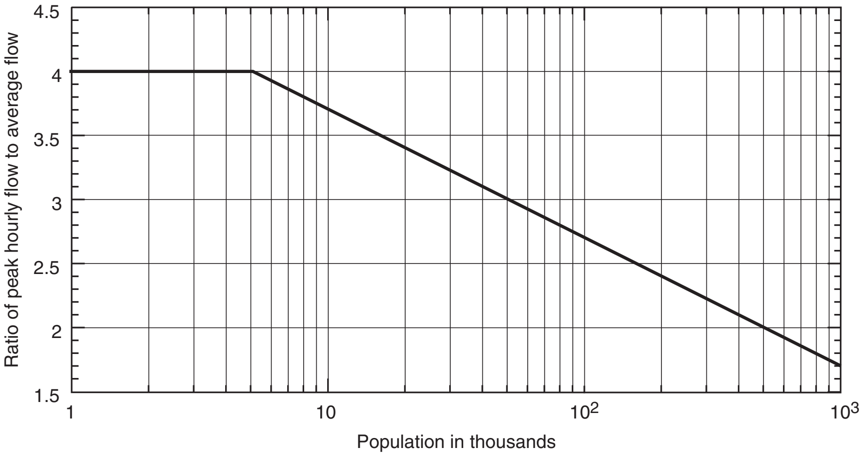
Peaking factor curve (ratio of peak hourly to average daily flow).



have long detention times or ample storage. Peaking factors may be developed from flowrate records or based on published curves or data from similar communities.

If flow measurement records are inadequate to establish peaking factors, published information may be used. Many sources for peaking factor data are available including state agencies, cities, and special districts that provide wastewater collection and treatment services, and professional publications from national organizations such as the Water Environment Federation and the American Society of Civil Engineers. (An example peaking factor curve is given on Fig. 3–18, and it may be used for estimating peak hourly flowrates from domestic sources.) The curve given on Fig. 3–18 was developed from analysis of the records of numerous communities throughout the United States. The curve is based on average residential flowrates, exclusive of infiltration/inflow, and includes small amounts of commercial flows and industrial wastes.

In developing factors for peak hourly flowrates, the characteristics of the collection system serving the wastewater treatment plant must be considered carefully. Improvements to or rehabilitation of the collection system may also increase or decrease the peaking factors. For pumped flows where reliable metering data are not available, factors to be considered include

- Interviews with operators regarding observations of operating conditions
- Review of pumping records (historical data on number of pumps in service and running time, if available)
- Operating speed of pumps
- Condition of pumps from maintenance records (unit output will be lower if impellers are worn)

Field testing at pumping stations can also be performed to measure the combined output of a simulated historical high flow event. Assistance in performing pump tests is often available from the local energy service provider.

Where flow to the treatment plant is by gravity, the peak flowrate can be estimated based on the following:

- Capacity of the influent sewers
- Investigation of upstream access ports (i.e., manholes) to determine if a high water mark is visible
- Interviews with operating staff and review of any documented field records

Forecasting design flowrates, including the use of peaking factors, is illustrated in Example 3–8.

EXAMPLE 3–8 **Forecasting Design Flowrates** A residential community with a current population of 15,000 is planning to expand its wastewater treatment plant. In 20 y, the population is estimated to increase to 25,000. Given the following information, estimate the future average, peak, and minimum design flowrate at plus 10 and 20 y.

Current situation:

1. Population is 15,000 persons
2. Average daily wastewater flowrate is 7500 m^3/d.
3. Infiltration/inflow has been determined to be non-excessive. Infiltration is estimated to be 100 L/capita·d at average flowrate and 150 L/capita·d at peak flowrate.
4. Municipal use is estimated to be 40 L/capita·d at average flowrate and 60 L/capita·d at peak flowrate.
5. An industry contributes an average flowrate of 1000 m^3/d with a peak flowrate of 1500 m^3/d.

Future situation:

1. Population is estimated to increase linearly to 25,000 in 20 y.
2. Residential water use in new homes is expected to be 20 percent less than the existing residences because of the installation of water saving appliances and fixtures as new homes are built and old homes are renovated.
3. The per capita wastewater from existing homes will decrease by 20 percent linearly over 20 y.

Other assumptions:

1. Current wastewater peaking factor is 3.0, which is expected to decrease linearly to 2.0 in 20 y.
2. Current ratio of minimum to average flowrate is 0.35, which is expected to increase to 0.45 in 20 y.

Solution

1. Compute the present and future per capita wastewater flowrates.
   a. For current conditions, compute the average domestic flowrate excluding infiltration and municipal use.
      i. Compute infiltration

$$\text{Infiltration} = (15{,}000 \text{ persons})(100 \text{ L/capita·d})\left(\frac{1 \text{ m}^3}{10^3 \text{ L}}\right) = 1500 \text{ m}^3/\text{d}$$

      ii. Compute average municipal flowrate

$$\text{Municipal flow} = (15{,}000 \text{ persons})(40 \text{ L/capita·d})\left(\frac{1 \text{ m}^3}{10^3 \text{ L}}\right) = 600 \text{ m}^3/\text{d}$$

      iii. Compute average domestic flowrate

$$\begin{aligned}\text{Domestic flow, m}^3/\text{d} &= \text{total} - \text{infiltration} - \text{municipal} - \text{industrial}\\ &= 7500 - 1500 - 600 - 1000 = 4400 \text{ m}^3/\text{d}\end{aligned}$$

b. Compute present per capita flowrate by dividing the existing domestic flowrate by the present population.

$$\text{Per capita flowrate} = \frac{(4400\ \text{m}^3/\text{d})}{15{,}000\ \text{persons}} = 0.29\ \text{m}^3/\text{capita}\cdot\text{d}$$

c. For future conditions, reduce existing per capita flowrate by 20%.

$$\text{Future per capita flowrate} = 0.29 \times 0.8 = 0.232\ \text{m}^3/\text{capita}\cdot\text{d}$$

2. Compute future average flowrate.

	Flowrate, m^3/d		
Flowrate	Current	Plus 10	Plus 20
From current residents	4400	3960	3520
From future residents (5000 × 0.232 m^3/capita·d)		1160	
From future residents (10,000 × 0.232 m^3/capita·d)			2320
Subtotal residential	4400	5120	5840
Industrial flowrate	1000	1000	1000
Infiltration (15,000)(100 L/capita·d)(1 $m^3/10^3$ L)	1500		
Infiltration (20,000)(100 L/capita·d)(1 $m^3/10^3$ L)		2000	
Infiltration (25,000)(100 L/capita·d)(1 $m^3/10^3$ L)			2500
Municipal (15,000)(40 L/capita·d)(1 $m^3/10^3$ L)	600		
Municipal (20,000)(40 L/capita·d)(1 $m^3/10^3$ L)		800	
Municipal (25,000)(40 L/capita·d)(1 $m^3/10^3$ L)			1000
Total average flowrate =	7500	8920	10,340
Average per capita flowrate	0.50	0.45	0.41

3. Compute future peak flowrate.

	Flowrate, m^3/d		
Flowrate	Current	Plus 10	Plus 20
Residential peak flowrate (4400 × 3.0)	13,230		
Residential peak flowrate (5120 × 2.5)		12,800	
Residential peak flowrate (5840 × 2.0)			11,680
Industrial peak flowrate	1500	1500	1500
Infiltration (15,000)(150 L/capita·d)(1 $m^3/10^3$ L)	2250		
Infiltration (20,000)(150 L/capita·d)(1 $m^3/10^3$ L)		3000	
Infiltration (25,000)(150 L/capita·d)(1 $m^3/10^3$ L)			3750
Municipal (15,000)(60 L/capita·d)(1 $m^3/10^3$ L)	900		
Municipal (20,000)(60 L/capita·d)(1 $m^3/10^3$ L)		1200	
Municipal (25,000)(60 L/capita·d)(1 $m^3/10^3$ L)			1500
Total peak flowrate	17,880	18,500	18,430
Peak per capita flowrate	1.19	0.93	0.74

4. Compute the minimum flowrate

Flowrate	Flowrate, m^3/d Current	Plus 10	Plus 20
Residential minimum flowrate (4400 × 0.35)	1323		
Residential minimum flowrate (5120 × 0.40)		2048	
Residential minimum flowrate (5840 × 0.45)			2628
Industrial (facilities are shut down at night)	0	0	0
Infiltration (15,000)(100 L/capita·d)(1 $m^3/10^3$ L)	1500		
Infiltration (20,000)(100 L/capita·d)(1 $m^3/10^3$ L)		2000	
Infiltration (25,000)(100 L/capita·d)(1 $m^3/10^3$ L)			2500
Municipal (600 × 0.35)	210		
Municipal (800 × 0.40)		320	
Municipal (1000 × 0.45)			450
Total minimum flowrate	3033	4368	5578
Peak per capita minimum flowrate	0.2	0.22	0.22

Comment In this example, infiltration/inflow contributes about 50 percent of the minimum flowrate and 20 percent of the average flowrate, an illustration of the influence of extraneous flows on treatment plant design. If wastewater flow records are not adequate or are unavailable, future average daily flow may be calculated based on the future population and unit wastewater flowrates, given in Sec. 3–1. Appropriate adjustments should be made in the calculations to account for any special conditions such as flow reduction, infiltration/inflow allowances, and industrial flows. When peak flowrates for more than one flow component are calculated, some adjustment in the total peak flowrate should be made if the peaks from the components do not occur simultaneously.

Upstream Control of Peak Flowrates. Planning wastewater plants to handle peak flowrates may involve other considerations, including (1) improvements to the collection system to reduce peak flow related to infiltration/inflow (I/I) and (2) installation of flow equalization facilities to provide storage either in the collection system or at the treatment plant. Other alternatives for peak flowrate control at the treatment plant, namely provision for flow splitting and bypass facilities, are discussed in Sec. 3–7.

Improvement to the collection system may involve a lengthy and costly process and may not have an immediate effect on significantly reducing peak flowrates. In some cases, the amount of flow reduction resulting from collection system rehabilitation has been less than anticipated, particularly if infiltration is a significant component of the total flow stream. In unusual circumstances, the flowrates have actually increased after completion of the collection system improvement program. Therefore, safety factors should be considered when estimating possible peak flowrate reduction resulting from collection system improvements.

Flow equalization can be an effective measure in reducing peak flows. Benefits derived by upstream flow equalization include (1) reduced hydraulic loading on already overtaxed collection facilities, (2) reduced collection system overflows (and reduced public health threats), and (3) reduced peak hydraulic loading of the treatment plant.

Equalization depends on available volume and may be of limited value in extreme peak flow conditions. Siting of equalization facilities in the collection system is often difficult because of limited available space at locations that are compatible with the system hydraulics. Operation and maintenance may also be difficult to manage, particularly in remote areas. Ease of operation, maintenance, and control and environmental factors are major reasons that many equalization facilities are located at treatment plants. The analysis for sizing flow equalization facilities is presented in Sec. 3–7.

Design Mass Loading Rates

The importance of mass loading rates in the design of wastewater treatment plants is identified in Table 3–22. For example, the sizing of aeration facilities and the amounts of solids and biosolids produced are related directly to the mass of BOD that must be processed. Further, the performance of the preliminary and primary treatment facilities have to be taken into account as ineffective operation of these facilities can result in the transfer of greater organic loads to the biological treatment system. Peak process loading rates are also important in sizing the process units and their support systems so that treatment plant performance objectives can be achieved consistently and reliably. The performance of primary sedimentation tanks is discussed in Chap. 5.

EXAMPLE 3–9 Estimation of Variability of Influent Wastewater Design Parameters

Compute the expected maximum values for the influent parameters flowrate, BOD, COD, and TSS for the case of a small and large size wastewater treatment facility. Assume the following mean design values apply:

		Mean design values	
Parameter	Unit	Small	Large
Flowrate	m^3/d	10,000	500,000
BOD	mg/L	250	250
COD	mg/L	600	600
TSS	mg/L	200	200

Determine the maximum value of the influent parameters for maximum day and maximum month. Comment on the importance of the results.

Solution

1. Select s_g values from Table 3–12 that correspond to the wastewater parameters of interest. In the absence of site and regionally specific information, use the typical values given in Table 3–12 as follows:

	Parameter			
Size of facility	Flowrate	BOD	COD	TSS
Small	1.6	1.6	1.7	1.6
Large	1.15	1.27	1.30	1.27

2. Locate the selected s_g value on Fig. 3–9 for a given frequency and determine the corresponding peaking factor.

Using the s_g values determined in Step 1, the corresponding peaking factors for peak day and peak month can be found on Fig. 3–9(a) for a small facility and Fig. 3–9(b) for a large facility. The peaking factors are summarized in the following table.

	Small facility			Large facility		
		Peaking factor			Peaking factor	
Parameter	s_g	d	mo	s_g	d	mo
Flowrate	1.6	3.70	2.35	1.15	1.48	1.29
BOD	1.6	3.70	2.35	1.27	1.95	1.55
COD	1.7	4.40	2.65	1.30	2.20	1.62
TSS	1.6	3.70	2.35	1.27	1.95	1.55

3. To obtain the maximum values for a specified frequency, multiply the peaking factors determined in step 2 by the mean value from the table given in the problem statement.
   a. For the peak day flowrate for the small facility the peaking factor is 3.70 and the mean design value is 10,000 m^3/d:

      $(3.70)(10{,}000\ m^3/d) = 37{,}000\ m^3/d$

   b. The design values for the two facilities are summarized in the following table.

		Design values					
		Small facility			Large facility		
Parameter	Unit	Mean	Peak d	Peak mo	Mean	Peak d	Peak mo
Flowrate	m^3/d	10,000	37,000	23,500	500,000	740,000	645,000
BOD	mg/L	250	925	587.5	250	487.5	387.5
COD	mg/L	600	2640	1590	600	1320	972
TSS	mg/L	200	740	470	200	390	310

Comment As shown in the summary table presented in Step 3, the smaller facility must be designed to accommodate a larger range in influent wastewater parameters relative to the large facility.

3–7 FLOW AND CONSTITUENT LOAD EQUALIZATION

The variations of influent wastewater flowrate and characteristics at wastewater treatment facilities were discussed in Secs. 3–4 and 3–6. Flow equalization is a method used to overcome the operational problems caused by flowrate variations, to improve the performance of the downstream processes, and to reduce the size and cost of downstream treatment facilities. Similarly, load equalization is a method used to reduce capital and operating cost of downstream treatment facilities. A variation of flow equalization involves the use of large offline storage basins or tunnels that are built specifically to capture and temporally store excess stormwater flow that would otherwise be discharged through CSO outfalls (see Fig. 3–19). The discussion below, however, focuses primarily on flow equalization as it pertains to wastewater treatment plant design.

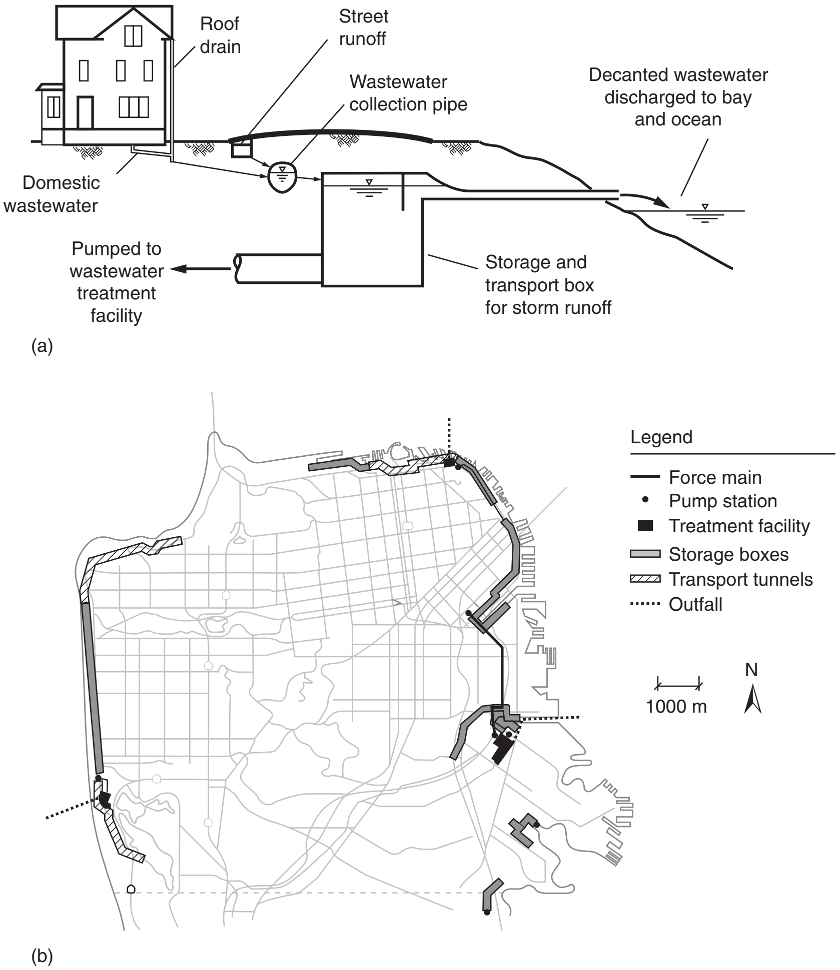


Figure 3–19

Details of combined collection system in the City of San Francisco, CA. (a) domestic wastewater, water from roof drains, and street runoff are collected in a combined collection system. Excess stormwater is discharged to large stormwater transport/storage boxes and tunnels. Once the stormwater flow has receded and treatment capacity becomes available, the wastewater from the storage boxes is treated before being discharged to San Francisco Bay or the Pacific Ocean, and (b) location of transport/storage boxes and tunnels around the periphery of the city (courtesy of City of San Francisco, CA).

Description/Application of Flow Equalization

Flow equalization simply is the dampening of flowrate variations to achieve a constant or nearly constant flowrate and can be applied in a number of different situations, depending on the characteristics of the collection system. The principal applications are for the equalization of (1) dry-weather flows to reduce peak flows and loads, (2) wet-weather flows in sanitary collection systems experiencing inflow/infiltration, or (3) combined stormwater and sanitary system flows as briefly noted above.

The application of flow equalization in wastewater treatment is illustrated in the two flow diagrams given on Fig. 3–20. In the inline arrangement [see Fig. 3–20(a)], all of the flow passes through the equalization basin. This arrangement can be used to achieve a considerable amount of constituent concentration and flowrate dampening. In the offline arrangement [see Fig. 3–20(b)], only the flow above some predetermined flow limit is diverted into the equalization basin. Although pumping requirements are minimized in this arrangement, the amount of constituent concentration dampening is considerably reduced. Offline equalization is sometimes used to capture the "first flush" from combined collection systems.

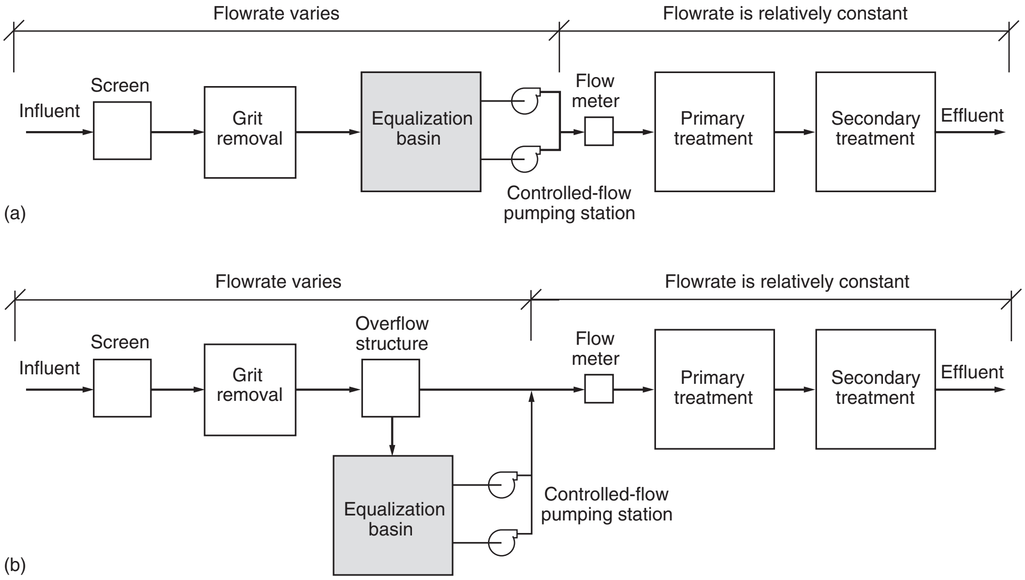

Figure 3–20

Typical wastewater treatment plant flow diagram incorporating flow equalization (a) inline equalization and (b) offline equalization.

The Benefits of Flow Equalization

The principal benefits that are cited as deriving from application of flow equalization are (1) biological treatment is enhanced, because shock loadings are eliminated or can be minimized, inhibiting substances can be diluted, and pH can be stabilized; (2) the effluent quality and thickening performance of secondary sedimentation tanks following biological treatment is improved through improved consistency in solids loading and the elimination of flow surges; (3) effluent filtration, or other tertiary treatment systems, surface area or volumetric requirements are reduced, performance is improved, and, for filtration systems, more uniform filter-backwash cycles are possible by lower hydraulic loading; and (4) in chemical treatment, dampening of mass loading improves chemical feed control and process reliability. Apart from improving the performance of most treatment operations and processes, flow equalization is an attractive option for upgrading the performance of overloaded treatment plants. Disadvantages of flow equalization include (1) relatively large land areas or sites are needed, (2) additional operation and maintenance is required, (3) potential for odors, and (4) increased capital cost. The use of, benefits, advantages, and disadvantages of flow equalization in municipal wastewater treatment were reviewed in an early U.S. EPA report (Ongerth, 1979).

Design Considerations

The design of flow equalization facilities is concerned with the following questions:

1. Where in the treatment process flowsheet should the equalization facilities be located?
2. What type of equalization flowsheet should be used, inline or offline?
3. What is the required equalization volume?
4. What are the features that should be incorporated into design?
5. How can the deposition of solids and potential odors be controlled?

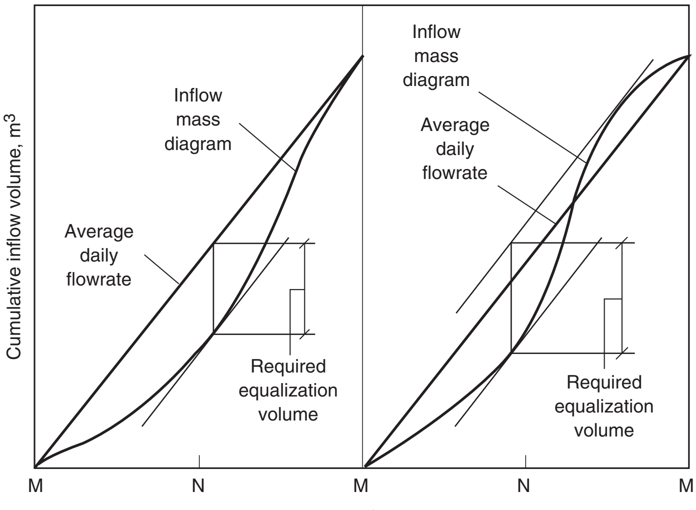
Location of Flow Equalization Facilities. The optimal location for siting equalization facilities must be determined for each system. Because the location will vary depending upon the characteristics of the collection system and the wastewater to be handled, land requirements and availability, and the type of treatment required, detailed studies should be performed for several locations throughout the system. Where equalization facilities are considered for location adjacent to the wastewater treatment plant, it is necessary to evaluate how they could be integrated into the treatment process flowsheet. In some cases, equalization after primary treatment and before biological treatment may be appropriate. Equalization after primary treatment causes fewer problems with solids deposits and scum accumulation. If flow equalization systems are to be located ahead of primary settling and biological systems, the design must provide for sufficient mixing to prevent solids deposition and concentration variations, and aeration to prevent odor problems.

Determination of Volume Requirements for Equalization Basin. The volume required for flowrate equalization is determined by using an inflow cumulative volume diagram in which the cumulative inflow volume is plotted versus the time of day. The average daily flowrate, also plotted on the same diagram, is the straight line drawn from the origin to the end point of the diagram. Diagrams for two typical flowrate patterns are shown on Fig. 3–21.

To determine the required volume, a line parallel to the coordinate axis, defined by the average daily flowrate, is drawn tangent to the mass inflow curve. The required volume is then equal to the vertical distance from the point of tangency to the straight line representing the average flowrate [see Fig. 3–21(a)]. If the inflow mass curve goes above the line representing the average flowrate [see Fig. 3–21(b)], the inflow mass diagram must be bounded with two lines that are parallel to the average flowrate line and tangent to extremities of the inflow mass diagram. The required volume is then equal to the vertical distance between the two lines. The determination of the required volume for equalization is also illustrated in Example 3–10. The procedure is exactly the same as if the average hourly volume were subtracted from the volume flow occurring each hour, and the resulting

Figure 3–21

Schematic mass diagrams for the determination of the required equalization basin storage volume for two typical flowrate patterns.



(a) Flowrate pattern A (b) Flowrate pattern B cumulative volumes were plotted. In this case, the low and high points of the curve would be determined using a horizontal line.

The physical interpretation of the diagrams shown on Fig. 3–21 is as follows. At the low point of tangency (flowrate pattern A) the storage basin is empty. Beyond this point, the basin begins to fill because the slope of the inflow mass diagram is greater than that of the average daily flowrate. The basin continues to fill until it becomes full at midnight. For flowrate pattern B, the basin is filled at the upper point of tangency.

In practice, the volume of the equalization basin will be larger than that theoretically determined to account for the following factors:

1. Continuous operation of aeration and mixing equipment will not allow complete drawdown, although special structures can be built.
2. Volume must be provided to accommodate the concentrated plant recycle streams that are expected, if such flows are returned to the equalization basin (a practice that is not recommended because of the potential to create odors).
3. Some contingency should be provided for unforeseen changes in diurnal flow.

Although no fixed value can be given, the additional volume will vary from 10 to 20 percent of the theoretical value, depending on the specific conditions.

EXAMPLE 3–10 **Determination of Flowrate Equalization Volume Requirements and Effects on BOD Mass Loading** For the flowrate and BOD concentration data given in following table, determine (1) the inline storage volume required to equalize the flowrate graphically (Note: the analytical spreadsheet solution is left to the reader) and (2) the effect of flow equalization on the BOD mass loading rate.

	Given data		Derived data	
Time period	Average flowrate during time period, m^3/s	Average BOD concentration during time period, mg/L	Cumulative volume of flow at end of time period, m^3	BOD mass loading during time period, kg/h
M–1	0.275	150	990	149
1–2	0.220	115	1782	91
2–3	0.165	75	2376	45
3–4	0.130	50	2844	23
4–5	0.105	45	3222	17
5–6	0.100	60	3582	22
6–7	0.120	90	4014	39
7–8	0.205	130	4752	96
8–9	0.355	175	6030	223
9–10	0.410	200	7506	295
10–11	0.425	215	9036	329
11–N	0.430	220	10,584	341
N–1	0.425	220	12,114	337

(*continued*)

(*Continued*)

	Given data		Derived data	
Time period	Average flowrate during time period, m^3/s	Average BOD concentration during time period, mg/L	Cumulative volume of flow at end of time period, m^3	BOD mass loading during time period, kg/h
1–2	0.405	210	13,572	306
2–3	0.385	200	14,958	277
3–4	0.350	190	16,218	239
4–5	0.325	180	17,388	211
5–6	0.325	170	18,558	199
6–7	0.330	175	19,746	208
7–8	0.365	210	21,060	276
8–9	0.400	280	22,500	403
9–10	0.400	305	23,940	439
10–11	0.380	245	25,308	335
11–M	0.345	180	26,550	224
Average	0.307			213

Note: $m^3/s \times 35.3147 = ft^3/s$
$m^3 \times 35.3147 = ft^3$
$mg/L = g/m^3$.

Solution

1. Determine the volume of the inline basin required for the flow equalization.
   a. The first step is to develop a cumulative volume curve of the wastewater flowrate expressed in cubic meters. The cumulative volume curve is obtained by converting the average flowrate (q_i) during each hourly period to cubic meters, using the following expression, and then cumulatively by summing the hourly values to obtain the cumulative flow volume.

$$\text{Volume, m}^3 = (q_i, \text{ m}^3/\text{s})(3600 \text{ s/h})(1.0 \text{ h})$$

For example, for the first three time periods shown in the data table, the corresponding hourly volumes are as follows:
For the time period M–1:

$$V_{M-1} = (0.275 \text{ m}^3/\text{s})(3600 \text{ s/h})(1.0 \text{ h})$$
$$= 990 \text{ m}^3$$

For the time period 1–2:

$$V_{1-2} = (0.220 \text{ m}^3/\text{s})(3600 \text{ s/h})(1.0 \text{ h})$$
$$= 792 \text{ m}^3$$

The cumulative flow, expressed in m^3, at the end of each time period is determined as follows:
At the end of the first time period M–1:

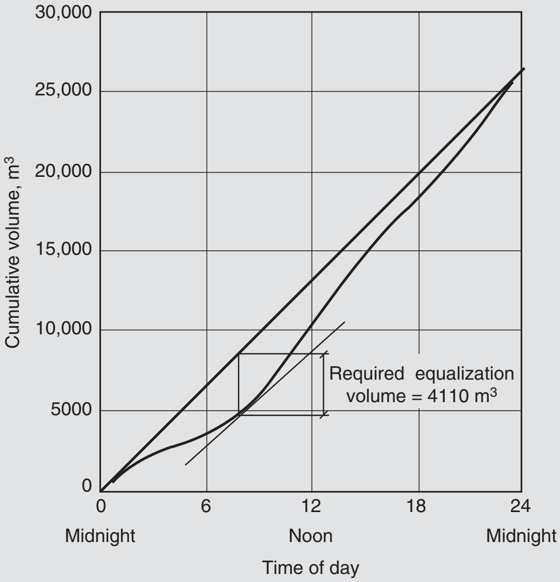
$$V_1 = 990 \text{ m}^3$$

At the end of the second time period 1–2:

$$V_2 = 990 + 792 = 1782 \text{ m}^3$$

The cumulative flows for all the hourly time periods are computed in a similar manner (see derived data in data table)

b. The second step is to prepare a plot of the cumulative flow volume, as shown in the following diagram. As will be noted, the slope of the line drawn from the origin to the end point of the inflow mass diagram represents the average flowrate for the day, which in this case is equal to 0.307 m^3/s.



c. The third step is to determine the required inline storage volume. The required storage volume is determined by drawing a line parallel to the average flowrate tangent to the low point of the inflow mass diagram. The required volume is represented by the vertical distance from the point of tangency to the straight line representing the average flowrate. Thus, the required volume is equal to

Volume of equalization basin, $V \sim 4100\ m^3\ (144{,}790\ ft^3)$

2. Determine the effect of the equalization basin on the BOD mass loading rate. Although there are alternative computation methods, perhaps the simplest way is to perform the necessary computations starting with the time period when the equalization basin is empty. Because the equalization basin is empty at about 8:00 a.m., the necessary computations will be performed starting with the 8–9 time period.

a. The first step is to compute the liquid volume in the equalization basin at the end of each time period. The volume required is obtained by subtracting the equalized hourly flowrate expressed as a volume from the inflow flowrate also expressed as a volume. The volume corresponding to the equalized flowrate for a period of 1 h is $0.307\ m^3/s \times 3600\ s/h = 1106\ m^3$. Using this value, the volume in storage is computed using the following expression:

$$V_{sc} = V_{sp} + V_{ic} - V_{oc}$$

where V_{sc} = volume in the equalization basin at the end of current time period
V_{sp} = volume in the equalization basin at the end of previous time period
V_{ic} = volume of inflow during the current time period
V_{oc} = volume of outflow during the current time period

Thus, using the values in the original data table, the volume in the equalization basin for the time period 8–9 is as follows:

$$V_{sc} = 0 + 1278 \text{ m}^3 - 1106 \text{ m}^3 = 172 \text{ m}^3$$

For time period 9–10:

$$V_{sc} = 172 \text{ m}^3 + 1476 \text{ m}^3 - 1106 \text{ m}^3 = 542 \text{ m}^3$$

The volume in storage at the end of each time period has been computed in a similar way (see following computation table)

Time period	Volume of flow during time period, m^3	Volume in storage at end of time period, m^3	Average BOD concentration during time period, mg/L	Equalized BOD concentration during time period, mg/L	Equalized BOD mass loading during time period, kg/h
8–9	1278	172	175	175	193
9–10	1476	542	200	197	218
10–11	1530	966	215	210	232
11–N	1548	1408	220	216	239
N–1	1530	1832	220	218	241

Average					213

Note: $\text{m}^3 \times 35.3147 = \text{ft}^3$
kg × 2.2046 = lb
$\text{g/ m}^3 = \text{mg/L}$.

b. The second step is to compute the average concentration leaving the storage basin. Using the following expression, which is based on the assumption that the contents of the equalization basin are mixed completely, the average concentration leaving the storage basin is

$$C_{oc} = \frac{(V_{ic})(C_{ic}) + (V_{sp})(C_{sp})}{V_{ic} + V_{sp}}$$

where C_{oc} = average concentration of BOD in the outflow from the storage basin during the current time period, g/m^3 (mg/L)
V_{ic} = volume of wastewater inflow during the current period, m^3
C_{ic} = average concentration of BOD in the inflow wastewater volume, g/m^3
V_{sp} = volume of wastewater in storage basin at the end of the previous time period, m^3
C_{sp} = concentration of BOD in wastewater in storage basin at the end of the previous time period, g/m^3

Using the data given in column 2 of the above computation table, the effluent concentration is computed as follows:
For the time period 8–9:

$$C_{oc} = \frac{(1278 \text{ m}^3)(175 \text{ g/m}^3) + (0)(0)}{1278 \text{ m}^3}$$
$$= 175 \text{ g/m}^3 \text{ (mg/L)}$$

For the time period 9–10:

$$C_{oc} = \frac{(1476 \text{ m}^3)(200 \text{ g/m}^3) + (172 \text{ m}^3)(175 \text{ g/m}^3)}{(1476 + 172) \text{ m}^3}$$
$$= 197 \text{ mg/L}$$

All the concentration values computed in a similar manner are reported in the above computation table.

c. The third step is to compute the hourly mass loading rate using the following expression:

$$\text{Mass loading rate, kg/h} = \frac{(C_{oc}, \text{ g/m}^3)(q_i, \text{ m}^3\text{/s})(3600 \text{ s/h})}{(1000 \text{ g/kg})}$$

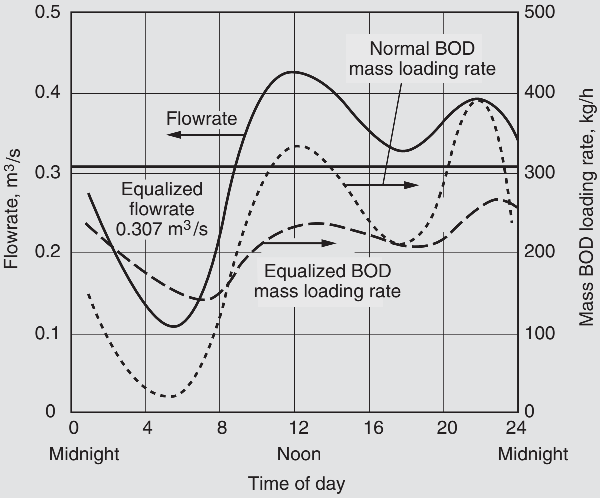
For example, for the time period 8–9, the mass loading rate is

$$\frac{(175 \text{ g/m}^3)(0.307 \text{ m}^3\text{/s})(3600 \text{ s/h})}{(1000 \text{ g/kg})} = 193 \text{ kg/h (426 lb/h)}$$

All hourly values are summarized in the computation table. The corresponding values without flow equalization are reported in the original data table.

d. The effect of flow equalization can be shown best graphically by plotting the hourly unequalized and equalized BOD mass loading (see the following plot). The following flowrate ratios, derived from the data presented in the table given in the problem statement and the computation table prepared in Step 2a, are also helpful in assessing the benefits derived from flow equalization:

	BOD mass loading	
Ratio	Unequalized	Equalized
$\frac{\text{Peak}}{\text{Average}}$	$\frac{439}{213} = 2.06$	$\frac{271}{213} = 1.27$
$\frac{\text{Minimum}}{\text{Average}}$	$\frac{17}{213} = 0.08$	$\frac{132}{213} = 0.62$
$\frac{\text{Peak}}{\text{Minimum}}$	$\frac{439}{17} = 25.82$	$\frac{271}{132} = 2.05$

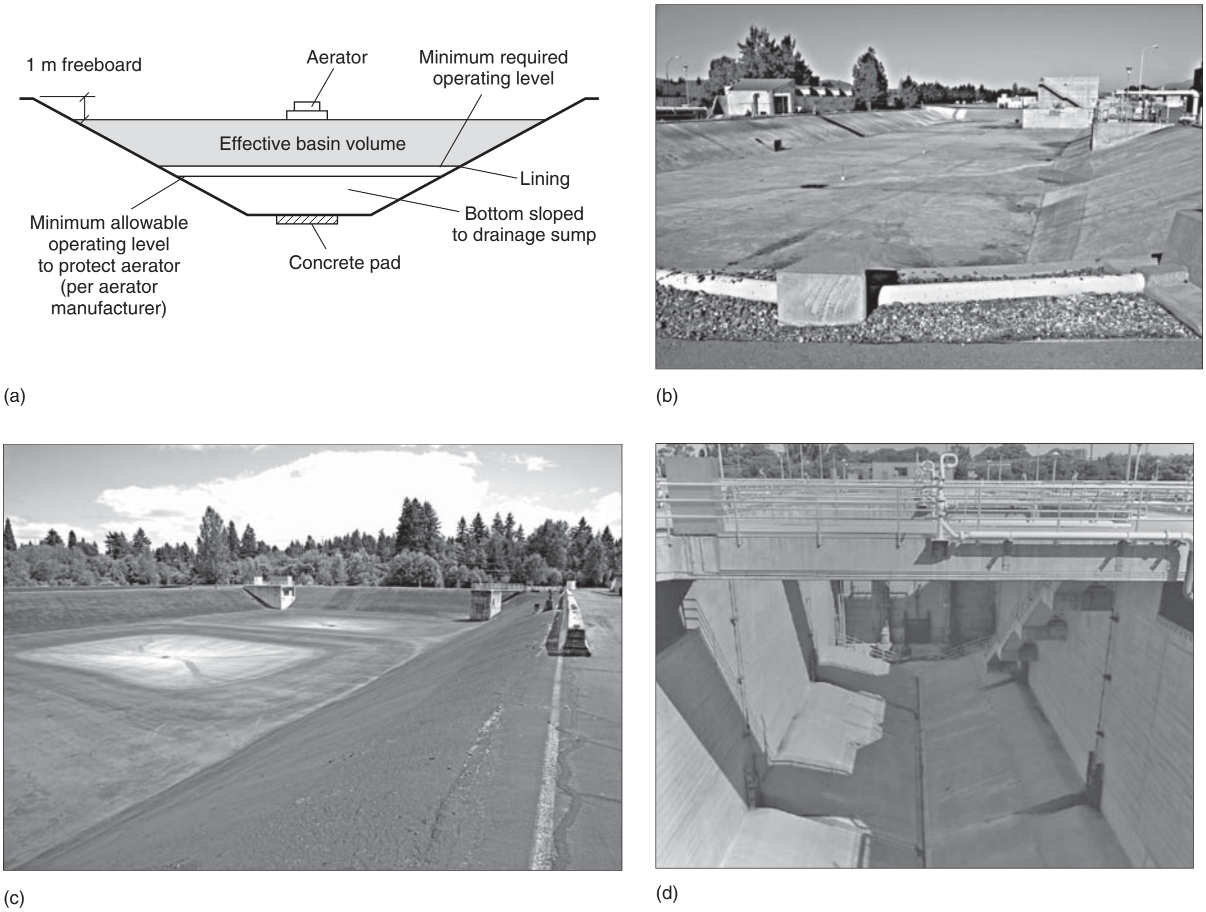


Comment Where inline flow equalization basins are used, additional dampening of the BOD mass loading rate can be obtained by increasing the volume of the basins. Alternatively, offline storage can be used to further reduce the variability of the BOD mass loading rate to the biological treatment process. Although the flow to a treatment plant was equalized in this example, flow equalization would be used, more realistically, in locations with high infiltration/inflow or peak stormwater flows.

Basin Configuration and Construction. In equalization basin design, the principal factors that must be considered are (1) basin geometry; (2) basin construction including cleaning, access, and safety; (3) mixing and air requirements; (4) operational appurtenances; and (5) pump and pump control systems.

Basin Geometry. The importance of basin geometry varies somewhat, depending on whether inline or offline flowrate equalization is used. If inline equalization is used to dampen both the flow and the mass loadings, it is important to use a geometry that allows the basin to function as a continuous-flow stirred-tank reactor. Therefore, elongated designs should be avoided, and the inlet and outlet configurations should be arranged to minimize short circuiting. Discharging the influent near the mixing equipment usually minimizes short circuiting. If the geometry of the basins is controlled by the available land area and an elongated geometry must be used, it may be necessary to use multiple inlets and outlets. Provisions should be included in the basin design for access by cleaning equipment such as front end loaders. Multiple compartments are also desirable to reduce cleaning costs and for odor control.

Basin Construction. New basins may be of earthen, concrete, or steel construction; earthen basins are generally the least expensive (see Fig. 3–22). Depending on local conditions, the interior side slopes may vary between 3:1 and 2:1. A section through a typical earthen basin is shown on Fig. 3–22(a). In most installations, a liner is required to prevent groundwater contamination [see Figs. 3–22(b) and (c)]. Basin depths will vary depending on land availability, groundwater level, and topography. If a liner is used in areas of high groundwater, the effects of hydraulic uplift on the liner have to be considered. The freeboard required depends on the surface area of the basin and local wind conditions. If a floating aerator is used to provide mixing and prevent septicity and odor formation, a minimum operating level is needed to protect the aerator. Typically, the minimum water depth can vary from 1.5 to 2 m (5 to 6 ft). With floating aerators, a concrete pad should be provided below the aerators to minimize erosion. To prevent wind-induced erosion in the



(a)

(b)

(d)

Figure 3–22

Typical flow equalization basins: (a) typical cross-section shallow flow equalization basins, (b) and (c) shallow lined earthen basins, and (d) deep concrete basin.

upper portions of the basin, it may be necessary to protect the slopes with riprap, soil cement, or a partial concrete layer. Fencing should also be provided to prevent public access to the basins.

In areas of high groundwater, drainage facilities should be provided to prevent embankment failure. To further ensure a stable embankment, the tops of the dikes should be of adequate width. The use of an adequate dike width will facilitate the use of mechanical equipment for maintenance and will also reduce construction costs, especially where mechanical compaction equipment is used.

Mixing and Air Requirements. The proper operation of both inline and offline equalization basins generally requires proper mixing and aeration. Mixing equipment should be sized to blend the contents of the tank and to prevent deposition of solids in the basin. To minimize mixing requirements, grit removal facilities should precede equalization basins where possible. Mixing requirements for blending a medium strength municipal wastewater (see Table 3–18), having a suspended solids concentration of approximately 210 mg/L, range from 0.004 to 0.008 kW/m^3 (0.02 to 0.04 $hp/10^3$ gal) of storage. Aeration is required to prevent the wastewater from becoming septic and odorous. To maintain aerobic conditions, air should be supplied at a rate of 0.01 to 0.015 $m^3/m^3 \cdot min$ (1.25 to 2.0 $ft^3/10^3$ $gal \cdot min$). In equalization basins that follow primary sedimentation and have short detention times (less than two hours), aeration may not be required.

Where mechanical aerators are used, baffling may be necessary to ensure proper mixing, particularly with a circular tank configuration. To protect the aerators in the event of excessive level drawdown, low-level shutoff controls should be provided. Because it may be necessary to dewater the equalization basins periodically, the aerators should be equipped with legs or draft tubes that allow them to come to rest on the bottom of the basin without damage. Various types of diffused air systems may also be used for mixing and aeration including static tube, jet, and aspirating aerators (see Sec. 5–12).

Operational Appurtenances. Among the appurtenances that should be included in the design of equalization basins are (1) facilities for flushing any solids and grease that may tend to accumulate on the basin walls, (2) an emergency overflow in case of pump failure, (3) a high water takeoff for the removal of floating material and foam, and (4) water sprays to prevent the accumulation of foam on the sides of the basin and to aid in scum removal. Solids removed from equalization basins should be returned to the head of the plant for processing.

Pumps and Pump Control. Because flow equalization imposes an additional head requirement within the treatment plant, pumping facilities are frequently required. Pumping may precede or follow equalization, but pumping into the basin is generally preferred for reliability of treatment operation. In some cases, pumping of both basin influent and equalized flows will be required. For offline flow equalization basins designed for the control of wet-weather peak flows, pump-in configurations may have very high and costly pumping requirements. If the hydraulic grade line allows, a gravity-in, pump out configuration is the most cost-effective. The pumps used to empty an offline, peak-flow equalization basin are usually much smaller than the pumps that would be required to pump flow into the basin.

An automatically controlled flow-regulating device will be required where gravity discharge from the basin is used. Where basin effluent pumps are used, instrumentation should be provided to control the preselected equalization rate. Regardless of the discharge method used, a flow measuring device should be provided on the outlet of the basin to monitor the equalized flow.

Equalization of Constituent Mass Loading Rates

While the focus of this section has been on flow equalization, it is important to note that equalization of constituent (e.g., BOD and TSS) mass loading rates is another approach that can be used to enhance biological treatment. The benefits of constituent load equalization include (1) improved biological treatment, because shock constituent loadings are eliminated or can be minimized, (2) improved utilization of aeration equipment, (3) reduced peak power requirements, and (4) reduced capacity of aeration blowers and related equipment.

Process Description. Constituent mass loading equalization is accomplished most effectively with offline storage facilities. Functionally, a portion of the flow is diverted during the period when the constituent concentrations are high (i.e., typically in the mid to late morning and early evening hours). The diverted flow and constituents are fed back into the system during periods when the aeration facilities are not used fully, typically in the late evening and early morning hours. Operationally, information must be available on the typical variation in the flowrate and constituent concentrations. Flowrate metering is routine. Also, new online continuous suspended solids meters are now available. The quantity of flow that must be diverted would be based on a control strategy utilizing flowrate and TSS measurements in conjunction with an appropriate algorithm.

Recent Development. Another approach to load equalization is to utilize primary effluent filtration, an old idea that has resurfaced because of the availability of new filter technologies. Operationally, the primary effluent filtration would only be used during periods when the concentration of the constituents in the influent wastewater is increasing such as in the mid to late morning hours or in the early evening hours. The mostly organic solids in the filter backwash water would be diverted to a relatively small storage facility. The organic solids from the storage facility would then be returned to the treatment process during periods when the aeration equipment is underutilized as described above. The diverted organic solids could also be sent to a fermenter for the production of volatile fatty acids needed for enhanced phosphorus removal.

Equalization of Sludge and Biosolids Processing Return Flows

Return flows from solids processing operations including sludge thickening, digester supernatant, and centrate and/or filtrate from biosolids dewatering historically have been returned to the headworks of the biological treatment process for reprocessing. However, as more restrictive wastewater treatment standards are being implemented, the practice of returning these flows to the headworks has made it difficult to achieve low discharge limits, especially for nitrogen and phosphorus. The impact of return flows is even greater because most of the return flows are reintroduced during the daytime hours when the biosolids dewatering facilities are normally operated.

The need to improve plant performance has lead to the implementation of flow equalization and/or separate treatment facilities for return flows. Flow equalization facilities are used most commonly at smaller treatment plants, whereas separate treatment and flow equalization facilities are more common at larger treatment plants. The sizing for flow equalization facilities can done using the principles outlined in this section. Flow equalization facilities for return flows at smaller treatment plants are designed to capture all of the return flows during the day so that the stored return flows can be added to the plant inflow over a 12-h period starting in the evening hours or when the incoming loadings to the plant are reduced. If space is limited, it may only be possible to reduce the peak of the return flows. Use of inactive treatment process tankage has proven to be effective. The separate treatment of return flows is considered in Chap. 15.

PROBLEMS AND DISCUSSION TOPICS

3–1 A community is rapidly approaching the design capacity of its wastewater treatment plant. As an alternative to expanding the plant, a water conservation program has been proposed. If the current average residential unit flowrate is 320 L/capita·d and the proposed water conservation rate reduction is 25, 35, 40 percent (to be selected by instructor), is the proposal reasonable? State your justification.

3–2 A new commercial development is being considered, and four developers have submitted competing proposals. An Environmental Assessment Report is being prepared to evaluate the wastewater flows from each of the competing proposals. Estimate the average daily and peak wastewater flowrates from one of the proposed developments (to be selected by instructor). The proposals consist of the following elements:

Type of facility	Units	Developer			
		1	2	3	4
Hotel	Number of guest rooms	120	80	60	250
	Number of employees	25	16	14	40
Department stores	Number of toilet rooms	8	12	16	
	Number of employees	40	60	80	
Self-service laundry	Number of machines		20	16	18
Restaurant, no bar	Number of seats	125	100	100	50
Restaurant, with bar	Number of seats	100	125	75	80
Theater (indoor)	Number of seats	500	400		350

3–3 Estimate the average and maximum flowrates from a recreational area (to be selected by instructor) with the following facilities. State all of your assumptions clearly.

Type of facility	Units	Recreational area			
		1	2	3	4
Visitor center	No. of visitors	250	300	400	500
Motel with kitchen	No. of guests		60	100	60
Resort cabins	No. of guests		100	40	
Cottages	No. of guests	60		60	120
Campground (toilets only)	No. of persons	140	120		200
Recreational vehicle park	Number of individual connections	40	50	20	50
Self-service laundry	Number of machines	8	10	6	10
Shopping center	Number of employees	10	15	15	20
	Number of parking spaces	30	40	40	60
Automobile service station	Number of vehicles	80	120	160	200
Restaurant with bar	Number of customers	200	300	400	500

3–4 A college dormitory complex, with four separate dormitories, is planning to institute a water conservation program to reduce its wastewater flows. Using the data given below, develop a water conservation program that will accomplish the flowrate reduction goal for one of the dormitories (to be selected by instructor).

		Dormitory			
Characteristics	Unit	1	2	3	4
Wastewater flowrate	m^3/d	125	105	140	160
Number of beds	No.	300	250	300	350
Existing fixture flowrates					
Toilets,	L/use	9	10	11	11
Showerheads,	L/min·use	18	20	23	23
Faucets,	L/capita·d	10	8	9	11
Flowrate reduction required	%	15	20	25	25

3–5 Compute the flow-weighted BOD and TSS concentrations from one of the following flowrate regimes (to be selected by instructor).

			Flowrate, m^3/d		
			Flowrate regime		
Time	BOD, mg/L	TSS, mg/L	1	2	3
02:00	130	150	8000	7200	10,000
04:00	110	135	6000	6400	8400
06:00	160	150	9400	9800	13,600
08:00	220	205	12,800	13,500	19,200
10:00	230	210	13,000	13,800	19,500
12:00	245	220	14,400	14,500	21,800
14:00	225	210	12,000	12,500	18,500
16:00	220	200	9600	10,000	14,800
18:00	210	205	11,000	10,500	15,000
20:00	200	210	8000	8500	11,500
22:00	180	185	9000	8200	12,600
24:00	160	175	8400	7700	11,600

3–6 The data in the table below consist of population values for a city, and average monthly influent flow values at the city wastewater treatment plant, from 2007 through 2010. The city is located in an area of high groundwater. Using these data answer the following questions.

a. What is the nature of the distribution of the monthly flowrate values? Use the plotting position method used in Example 3–4 [see Eq. (D–10) in Appendix D] to plot the monthly influent values versus the corresponding probabilities for each year on arithmetic- and log-probability paper, and check for linearity.

b. What is the average annual flow, average dry-weather flow (ADWF), and average wet-weather flow (AWWF) for each year? If the data are arithmetically distributed, use the arithmetic mean; if the data are log-normally distributed, use the geometric mean (see Table D–1 in Appendix D). Assume the dry season occurs from June to October and the wet season occurs from November to May.

c. What is the per capita flow contribution from commercial and light industrial activities? Assume that the residential contribution to the dry weather flow is 260 L/capita·d, and that commercial and light industrial activities make up the remaining flow.

d. What is the per capita flow contribution from infiltration and inflow for each year? Assume that the difference between the wet and dry weather flows is due to infiltration and inflow.

Community population and average monthly influent flowrate data for the period from 2007 through 2010

Year	2007	2008	2009	2010
Population	8690	9400	11,030	12,280
Month	Influent flowrate, m^3/d			
January	8800	13,900	8300	10,000
February	6200	9900	11,800	18,400
March	6800	8100	9400	13,000
April	4000	4200	6500	5000
May	4000	5700	5300	7600
June	3600	3600	4800	4600
July	2400	2600	3300	3800
August	2000	1500	3800	3100
September	2800	2000	2800	2200
October	3200	4800	4400	4400
November	4800	3200	6000	6500
December	5200	6700	7300	8600

3–7 Consider the city described in Problem 3–6. Assume that the build-out population for the community is 16,000 persons, and that the residential wastewater flowrate will be 300 L/capita·d. The commercial flowrate in 2010 (1000 m^3/d) is 80 percent of what it will be at build-out. Due to high infiltration and inflow (I/I) rates, a sewer repair program will be implemented. The I/I contribution will be either 500, 400, 300, or 200 L/cap·d (to be selected by instructor), depending on the degree of repair achieved. Estimate the ADWF, AWWF, and the average annual flow that will be received at the community treatment plant at build out. Justify the use of the AWWF as the nominal design capacity for the treatment plant.

3–8 Consider the treatment plant for the city described in Problem 3–6. Use the plotting position method illustrated in Example 3–4 [see Eq. (D–10) in Appendix D] to plot the monthly influent values versus the corresponding probabilities for each year. Determine the nature of the distribution by plotting the values on arithmetic- and log-probability paper and checking for linearity. If the average annual flow to the treatment facility at build-out is estimated to be 8000 m^3/d, what will the peak monthly flow be? (Hint: the average annual flow occurs at the 50 percent line on the probability graph. Use the slope of the wettest year to pass a line through the 50 percent line at 8000 m^3/d, and read the flow value for the highest month from the graph.)

3–9 Use the following influent data for a wastewater treatment plant to conduct the statistical analyses described in Problem 3–6, steps a, b, c, and d. If the data in the table below are not distributed either arithmetic-normally or log-normally, suggest a method for determining the required parameters.

Community population and average monthly influent flowrate data for the period from 2007 through 2010

Year	2007	2008	2009	2010
Population	17,040	17,210	17,380	17,630
Month	Influent flowrate, m^3/d			
January	8800	7760	9360	7600
February	9440	7280	7920	7840
March	8640	7200	8800	7680
April	7840	6960	8080	7440
May	7440	6800	7680	7280
June	7200	6880	7520	7360
July	7120	6960	7280	7200
August	7040	6720	7200	7280
September	6880	6880	7040	7200
October	6960	6800	7280	7440
November	7120	7120	7360	7680
December	7360	7600	7680	8000

3–10 A treatment plant is planned to be installed in a recreational resort that contains a developed campground for 200 persons, lodges and cabins for 100 persons, and resort apartments for 150 persons. Assume that persons staying in lodges use the dining hall for 3 meals per day and that a 50-seat cafeteria with 4 employees and an estimated 200 customers per day has been constructed. Daily attendance at the visitor center is 500 persons. Other facilities include a 10-machine laundromat, a 20-seat cocktail lounge, and three gas stations (1100 L/d per station). Determine the average wastewater flowrate in L/d using the unit flows assuming the housing facilities are at maximum capacity.

3–11 Obtain an annual report or one year of flow and BOD data from your local wastewater treatment facility. From these records, prepare probability plots for the flowrate and mass loadings. Determine the values at 50 and 95 percent probability.

3–12 From the flowrate data obtained for Problem 3–11, determine the mean and standard deviation.

3–13 The wastewater treatment plant has been experiencing high wastewater flowrates during the wet-weather months. The average monthly flows for four flow regimes are reported below (flow regime to be selected by instructor). The rapid increase in flows during the winter months is due mainly to increased infiltration/inflow. Infiltration is estimated to be 67 percent of the excess flow. The lengths of the collection system pipelines that need to be repaired are also listed below. The average repair cost is \$200,000/km and the repair will be effective in reducing the infiltration by 30 percent. How many years from now will it take to pay back the cost of the sewer repair program based on the annual savings in treatment cost, assuming the future annual flowrates are equal to those in the table below? The current cost of treatment is \$1.50/m^3 and the future cost of treatment is estimated to escalate at 6 percent per year. Assume the sewer repair will be complete in three years for Areas 1 and 2, and four years for Areas 3 and 4.

	Average monthly flowrate, m^3/d			
	Flowrate regime			
Month	1	2	3	4
January	293,000	410,000	460,000	470,000
February	328,000	459,000	440,000	485,000
March	279,000	391,000	515,000	560,000
April	212,000	296,000	333,000	400,000
May	146,000	204,000	230,000	300,000
June	108,000	151,000	170,000	225,000
July	95,000	133,000	150,000	200,000
August	89,000	125,000	141,000	188,000
September	93,000	130,000	140,000	165,000
October	111,000	155,000	167,000	192,000
November	132,000	185,000	200,000	240,000
December	154,000	215,000	225,000	215,000
Length of collection system, km	300	400	450	600

3–14 Nine months of flow records have been collected for a new wastewater treatment plant. Inspection of the records indicates that weekend flowrates tend to be higher than weekday flowrates. The weekday and weekend flowrates have been averaged and arranged in ascending order as given below. Develop arithmetic- and log-probability plots for both the weekday and weekend data for either flowrate regime 1 or 2 (to be selected by instructor) and comment on the skewness of the data. Determine the mean and 95th percentile values for each set of flow data, and determine the probable one day maximum flowrate. Discuss the significance of the data analysis.

	Flowrate regime 1		Flowrate regime 2	
Number	Weekend average flowrate, m^3/d × 10^3	Weekend average flowrate, m^3/d × 10^3	Weekend average flowrate, m^3/d × 10^3	Weekend average flowrate, m^3/d × 10^3
1	39.7	42.8	55.7	56.4
2	40.5	43.1	56.1	57.5
3	40.9	43.5	56.6	58.1
4	41.3	43.9	57.2	58.6

28	51.1	56.8	73.9	74.6
29	52.2	57.2	74.5	76.2
30	53.0	58.3	75.9	77.5
31	53.2	59.1	76.9	78.6
32	54.3	60.6	78.9	80.7
33	55.3	60.9	79.2	82.8
34	56.0	61.7	80.3	85.0
35	60.6	62.1	80.8	88.4
36	62.5	63.6	82.8	91.1

3–15 Land use in a new development is given in the following first table. A new school being built will have 1500 students. The average flowrate is 75 L/student, and the peaking factor (ratio of peak flowrate to average flowrate) is 4.0. Average flowrate allowances and the peaking factors for the other developments are shown in the second table. Determine the peak wastewater flowrate from one of the areas (to be selected by instructor).

	Area, ha			
Type of development	1	2	3	4
Residential	125	150	150	160
Commercial	11	10	15	16
School	4	4	4	4
Industrial	6	8	20	10

Type of development	Average flowrate, $m^3/ha \cdot d$	Peaking factor
Residential	40	3.0
Commercial	20	2.0
Industrial	30	2.5

3–16 Using the flowrate data presented below (city to be selected by instructor), estimate the size of an offline equalization tank needed to reduce the flowrate variation. The maximum hourly flowrate to the treatment process should not exceed 1.25, 1.5, and 1.75 times the average daily flowrate (ratio to be selected by instructor).

Time period	Average flowrate during time period, m^3/s		Time period	Average flowrate during time period, m^3/s	
	City 1	City 2		City 1	City 2
M–1	0.300	0.250	N–1	0.460	0.330
1–2	0.220	0.190	1–2	0.420	0.310
2–3	0.180	0.165	2–3	0.390	0.305
3–4	0.160	0.160	3–4	0.355	0.310
4–5	0.160	0.165	4–5	0.331	0.330
5–6	0.185	0.175	5–6	0.315	0.370
6–7	0.240	0.210	6–7	0.320	0.400
7–8	0.300	0.270	7–8	0.346	0.420
8–9	0.385	0.340	8–9	0.362	0.440
9–10	0.440	0.370	9–10	0.392	0.420
10–11	0.480	0.375	10–11	0.360	0.390
11–N	0.480	0.355	12–M	0.300	0.300

3–17 Using the information given in the data table presented in Example 3–10 determine (a) the offline storage volume needed to equalize the flowrate and (b) the effect of flow equalization on the BOD mass loading rate. How does the BOD mass loading rate curve determined in this problem compare with the curve shown in step 2d of Example 3–10? In your estimation, does the difference in the mass loading rate justify the cost of the larger basin required for inline storage?

3–18 Using the information given in the data table presented in Example 3–10 estimate the inline volume required to reduce the variation in the BOD mass loading rate between the peak and minimum from the existing ratio of 25.8.1:1 to a peak value of 5:1.

Wastewater Treatment Process Selection, Design, and Implementation

WORKING TERMINOLOGY

Term	**Definition**
Bench-scale tests	Tests conducted in the laboratory with small quantities of samples to answer specific treatment questions.
Biosolids	Sludge from wastewater treatment processes that has been stabilized to meet the criteria in the U.S. EPA's 40 CFR 503 regulations and, therefore, can be used beneficially.
CCA	Critical component analysis. A method used to determine which mechanical components in the wastewater treatment plant will have the most immediate impact on effluent quality should failure occur.
Class A Biosolids	Biosolids that contain less than 1000 most probable number (MPN)/g of fecal coliforms and less than 3 MPN/4g of Salmonella bacteria and meet one of six stabilization alternatives given in 40 CFR 503. The material also must meet the pollutant limits and vector attraction reduction requirements set forth in 40 CFR 503.
ENRCCI	Engineering News-Record Construction Cost Index used to adjust construction cost information.
Flow diagram	The graphical representation of a particular combination of unit processes used to achieve specific treatment objectives.
Hydraulic profile	A graphical representation of the elevation of the free surface and hydraulic grade line of wastewater as it flows through the various treatment units.
NPDES	National Pollution Elimination Discharge System (NPDES), established based on uniform technological minimums with which each point source discharger has to comply.
Peaking factor	A factor that is applied customarily to average long term (typically flowrate and mass loading rate values) to determine maximum values.
Plant layout	The spatial arrangement of the physical facilities of the treatment plant identified in the flow diagram.
Pilot plant studies	Studies conducted at test beds at a scale larger than bench-scale, to establish the suitability of a process in the treatment of a specific wastewater under specific environmental conditions and to obtain data that can be used for full-scale design.
POTW	Publicly Owned Treatment Works.
Priority pollutants	Organic and inorganic compounds defined under Section 307 of Clean Water Act and listed in the Code of Federal Regulations at 40 CFR 401.15. Priority pollutants are selected on the basis of their known or suspected carcinogenicity, mutagenicity, teratogenicity, or high acute toxicity.
Privatization	Private sector ownership and operation of facilities and services used by government entities in performing their public function.
Process design criteria	The criteria used as the bases for sizing individual unit processes and their support systems.
Reliability, treatment process	Probability of adequate performance for a specified period of time under specified conditions or the percent of the time that effluent concentrations meet specified permit requirements.

Solids balance	The identification of the quantities of solids entering and leaving each unit process.
Value engineering	An intensive review of a project to determine best value, or value improvement, which may or may not result in cost reduction. Typically conducted at the 20 to 30 percent design stage of the project.
Variability, inherent	Based on the laws of chance, all physical, chemical, and biological treatment processes exhibit some measure of variability with respect to the performance that can be achieved. Variability is inherent in biological treatment processes.

Since the early 1900s, when the field of environmental engineering was in its infancy in the United States, there has been a steady evolution and development in the methods used for wastewater treatment. Descriptions of the many methods and variations that have been tried to date would fill several large volumes. The approach followed in this text is to identify and discuss basic principles and their application to wastewater treatment. The purpose of this chapter is to provide perspective on how the principles presented in Chaps. 1 through 3 and 5 through 18, along with other subjects not discussed in detail in this textbook, fit into the overall design, construction, operation and maintenance, and implementation of new and existing wastewater management projects. The following topics are covered: (1) planning considerations for wastewater treatment plants, (2) process selection, (3) treatment process reliability and selection of design values, (4) elements of process design, (5) implementation of wastewater management programs, and (6) financing.

4–1 PLANNING FOR NEW AND UPGRADING EXISTING WASTEWATER TREATMENT PLANTS

Most of the wastewater plants implemented using federal grant funding were designed using empirical design guidelines and were sized to accommodate long-term population growth (a 20 to 30 y timeline was the norm). Plants were located typically in remote areas close to water bodies that provided natural buffer zones between the treatment facilities and the communities they served. As sanitary sewer collection systems use gravity flow to collect wastewater, treatment plants were often located in lowlands adjacent to the receiving waters. In many cases, municipal growth has encroached on the natural buffer zones so that treatment facilities that once were considered remote are now in close proximity to the community. Going forward, new wastewater treatment plants will be required (1) to support population growth; (2) to deal with changing demographics; (3) to deal with changing wastewater characteristics, especially increasing wastewater concentrations as discussed in Chap. 3; (4) to meet new and more stringent effluent discharge standards; (5) to meet water reuse needs, including potable reuse; (6) to meet new stormwater management objectives; and (7) to replace existing aging infrastructure.

Need to Upgrade Existing Wastewater Treatment Plants

Over the next decade, many existing treatment plants, built during the 1970s and 1980s, will need to be upgraded to maintain treatment efficiency, to provide higher levels of treatment when discharging to environmentally sensitive receiving waters, to meet new water reuse opportunities, and to meet new stormwater management objectives. As more wastewater reuse is being implemented, additional treatment processes, including advanced oxidation, may have to be implemented. Treatment plants must also be upgraded aesthetically to minimize odors, noise, and visual impacts to the neighboring community.

Climate change considerations are also of concern, especially with recurring stormwater flooding due to short-duration high-intensity rainfall events. Sea level rise, along with stormwater surges due to increased stream channelization, currently threatens wastewater facilities in coastal communities constructed in low-lying areas. Issues related to sea level rise will become more serious in the future. Clearly the range of issues that must be considered in the upgrading of existing facilities goes beyond the specifics of process design.

Planning for New Wastewater Treatment Plants

During the late 1980s and continuing onward to the present time (2012), the focus on wastewater engineering has changed from the goals of meeting secondary standards for the removal of solids and organic matter to the specific requirements for constituent removal for health and environmental protection. During the next decade as additional demands are placed on the quality and quantity of the nation's water supplies necessitating water reuse, greater emphasis will be placed on maintaining high standards of wastewater treatment plant performance consistently and reliably. Without federal grant financing, local governments will expect that new facilities be implemented considering not only the initial capital investment but with greater emphasis on the long-term financial impact on the community's resources.

In planning for new wastewater treatment plants (WWTPs), consideration must be given not only to the physical facilities required to produce a high quality effluent, as discussed above, but also to opportunities to minimize operating costs associated with labor, energy (both electrical and for heating), and byproduct stabilization and disposal/reuse. Recognizing that municipal wastewater is inherently a resource, the recovery of energy, nutrients, and potable water from wastewater will become a major focus of the design of future WWTPs. Further, as scientific research continues in defining wastewater constituents that may cause adverse effects, greater levels of treatment will be needed, and, in some cases, will require the use of new technologies. It is anticipated that many of these new technologies currently under development will revolutionize the treatment of wastewater, including many of the approaches discussed in this textbook.

Treatment Process Design Considerations

The design of wastewater treatment facilities is an iterative process that involves consideration of all viable process alternatives that meet the treatment objectives and regulations, as discussed above. Design considerations that must be factored into process selection decisions to ensure that treatment facilities meet their treatment objectives, are financially sustainable, and are aesthetically integrated into the communities they serve, as discussed in this section. Examples of treatment processes that can be considered to reliably and cost-effectively meet these objectives are shown on Fig. 4–1. Important issues that must be considered in the planning and design of new treatment facilities are summarized in Table 4–1 and highlighted in the following discussion.

Liquid Streams. One of the most important issues that the designer of new plants in the United States will have to face is the exceedance criterion for effluent discharges described in Sec. 4–3. The focus of treatment plant design will be on the nature and variability of the wastewater constituents and the processes that will be required to meet the treatment objectives. In some cases, it may be necessary to develop source control programs to limit the effects of both flow and constituent concentrations for discharge to the collection system. The source control program may also include curbing excessive extraneous flows such as infiltration/inflow and wet weather discharges to the collection system.

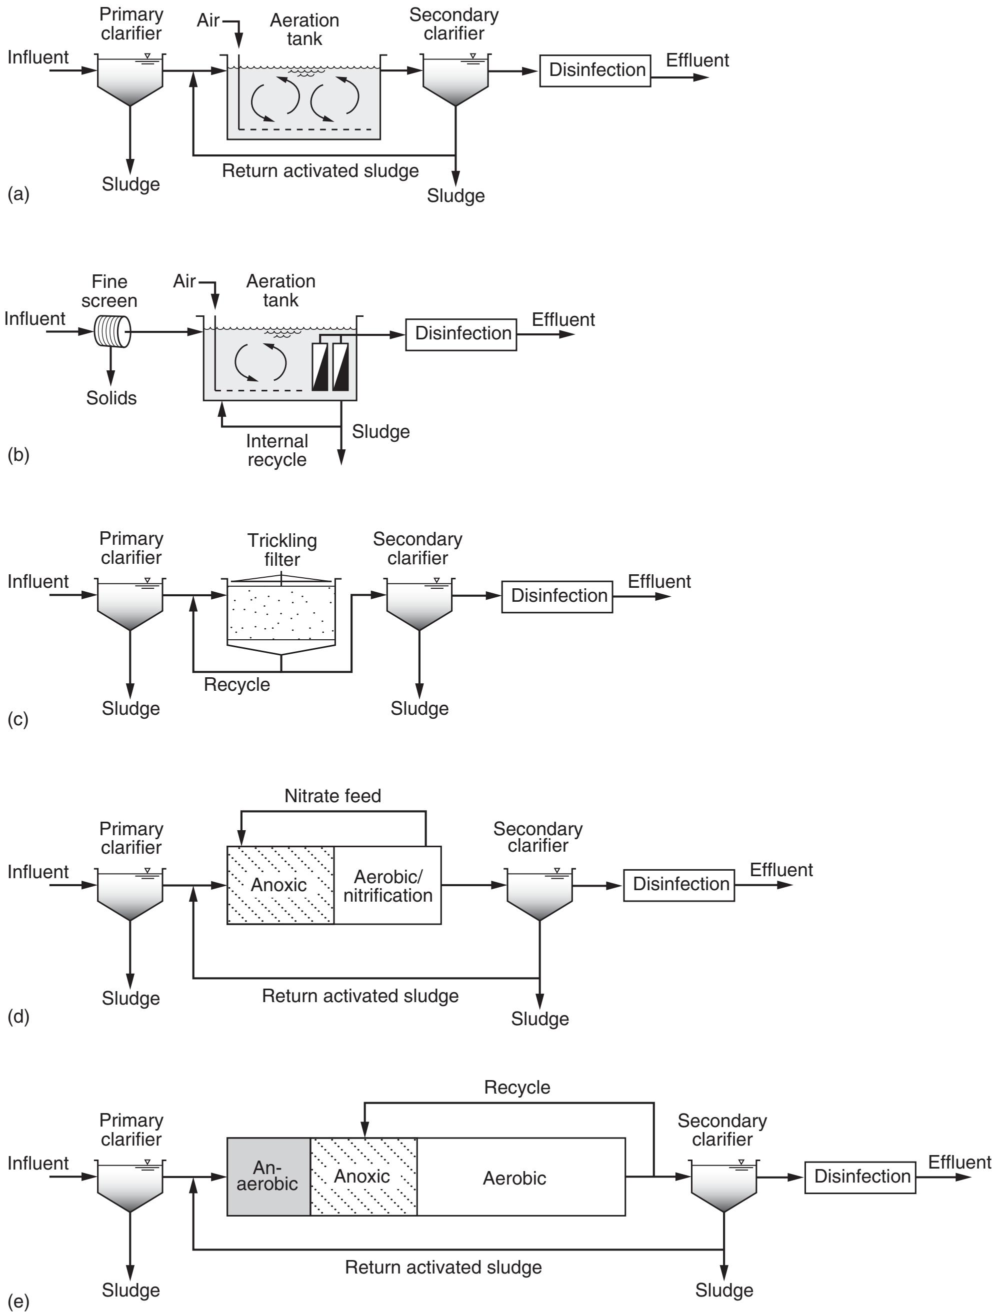

Figure 4–1

Generalized process flow diagrams for typical treatment processes all of which include disinfection for pathogen control: (a) activated sludge for TSS and BOD removal and nitrification; (b) membrane bioreactor for TSS and BOD removal and nitrification; (c) trickling filter for TSS and BOD removal; (d) suspended growth biological treatment for TSS, BOD, and nitrogen removal; and (e) suspended growth biological treatment for TSS, BOD, nitrogen, and phosphorus removal.

Table 4–1

Important considerations in the upgrading and design of new wastewater treatment plants

Issue	Description
Liquid stream processing	
Constituent and treatment process variability	New treatment processes should be designed to meet not-to-exceed permit limits taking into account constituent and treatment process variability
Flow equalization	Improved performance by eliminating flow surges through treatment facilities, especially wet-weather flows, typically required for reliably producing reclaimed water
Organic load equalization	Improved performance by equalizing organic loading rate to treatment processes throughout the day
Automatic process control	Provide provisions and facilities for automatic control of dissolved oxygen and solids retention time (SRT)
Enhanced disinfection for reuse	Improved and alternative technologies for disinfection and the control of disinfection byproducts
Advanced treatment processes	Processes for the removal of residual constituents and constituents not removed by conventional treatment
Conventional and advanced oxidation processes	Removal of specific constituents may require the use of advanced oxidation processes
Combined processes for specific constituents	To meet stringent not-to-exceed permit limits, two or more processes may have to be used in a series arrangement
Water reuse	Issues related to risk assessment will have to addressed
Treatment of wet-weather flows	Less costly to treat at WWTP as compared to individual treatment facilities at individual overflow locations
Energy management	Implementation of enough physical facilities, such as flow equalization, to allow for improved utilization of off-peak power for wastewater treatment
Solids processing	
Improved screening	Improved screening to remove extraneous materials that end up in the biosolids or foul treatment equipment such as aeration diffusers
Grit removal	Removal of grit that can settle in primary sedimentation tanks and digesters
Enhanced pathogen control	Enhanced pathogen control is needed to produce class A biosolids
Enhanced vector control	Enhanced vector control is needed to produce class A biosolids
Separate treatment of return flows	To improve the performance of liquid waste stream, especially with respect to the removal of nitrogen
Odor control	
Odor control in collection system	Implementation of source control program to minimize odors generated in collection system. Use of pure oxygen (see Fig. 16–3 in Chap. 16)
Odor formation in treatment facilities	Careful attention to hydraulic design to avoid dead zones with respect to flow, handling of return flows from solids processing facilities
Odor containment	Cover facilities to eliminate odors
Odor treatment	Separate or combined treatment of odorous gases from odor containment facilities
Process control	
Computer simulation models	Development of improved operational strategies through the use of mathematical simulation models
Pilot-plant testing	Ongoing program of testing new technologies

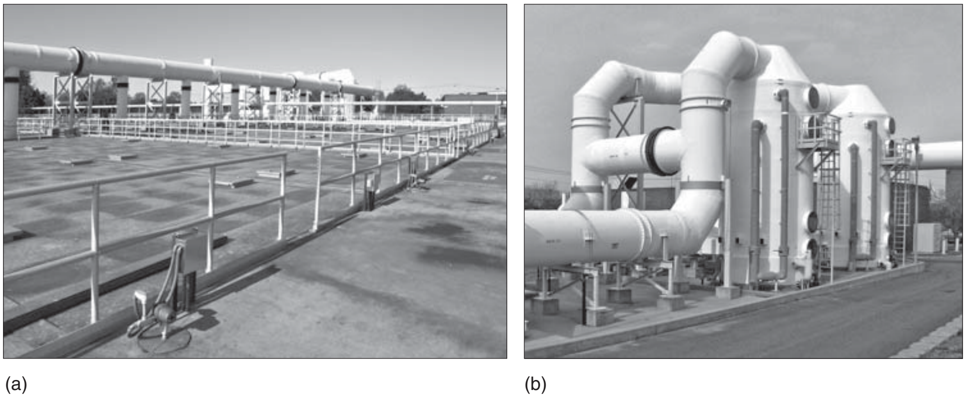
Upstream flow equalization may also be required. Facilities to handle in-plant variations of flows and loads including return flows will also have to be considered. Water reuse will also impose additional constraints on effluent management.

Solids Processing. In selecting the appropriate methods of solids processing, reuse, and disposal, consideration must be given to the appropriate regulations. In the United States, pollutant numerical limits and management practices for the reuse and disposal of solids generated from the processing of municipal wastewater are defined in the 40 CFR Part 503 regulations. The regulations are designed to protect public health and the environment from any reasonably anticipated adverse effects of pollutants contained in the biosolids. As many communities investigate options for solids processing, reuse, and disposal, greater emphasis is being placed on producing a cleaner product and meeting the Class A biosolids requirements. Important issues that have to be considered in solids processing are discussed in Chaps. 13 and 14. Control of pathogens and vectors is of special importance for the protection of public health.

Treatment of Return Flows and Recovery of Nutrients. As discharge standards for nitrogen and phosphorus become more stringent, it is clear that the practice of introducing return flows into the liquid processing facilities, typically before biological treatment, must be eliminated or modified if stringent nitrogen and phosphorus limits are to be achieved. Although flow equalization can be used to reduce the impact of return flows on treatment process performance, nutrient recovery can be a more effective solution. The subject of return flow treatment and nutrient recovery is considered in detail in Chap. 15.

Treatment of Wet-Weather (Stormwater) Flows. When new plants are being planned and existing plants are being upgraded, an important component of the analysis will be the management and treatment of wet-weather flows to minimize or eliminate untreated overflows. One of the approaches to controlling discharge of untreated overflows from the collection system is to maximize conveyance of wet-weather flows to the WWTP. Compared to other options, treatment of excess wet-weather flow at a new or existing WWTP can be an attractive option. Maximizing the use of unit processes at the WWTP can avoid or reduce the cost and impacts associated with controlling overflows at or near the point where excess flow is diverted in the collection system. While there are limitations on peaking factors that can be handled by WWTPs, particularly the biological treatment processes, options for WWTPs to handle increased quantities of wet-weather flow include (1) providing offline flow equalization storage to hold excess wet weather flow during periods of high flow, with the excess flow blended back into the treatment processes when flows drop and capacity is available; (2) increasing or expanding the capacities of conventional, continuous-flow unit processes, and either processing all flow through all unit processes or employing flow blending during peak flow periods; and (3) providing intermittent-use wet-weather treatment units that can process excess wet-weather flow which is blended with effluent processed through conventional, dry weather processes at the WWTP. Intermittent treatment facilities for wet-weather flows are considered in Sec. 18–5 in Chap. 18.

Control of Emissions. Gaining public acceptance for siting wastewater treatment plants will depend, to a large extent, on meeting community concerns over odors. The prevention, control, and treatment of odors are now mandatory parts of any treatment plant design (see Fig. 4–2). With proper planning for odor management, the need to correct odor



(a) (b)

Figure 4–2

Typical odor control facilities for new and existing wastewater treatment plants: (a) covered primary sedimentation facilities (b) odor control air scrubbers to treat odors from covered primary sedimentation tanks.

related issues after the fact and restore public confidence in facilities operation can be avoided. Important considerations in the control of emissions are discussed in Chap. 16.

Owner Needs

A factor often overlooked in the selection of a treatment process is the needs of the owner of the facilities. Owner needs may take the form of limitations of cost and the ability to pay for the project, operating capabilities where existing staff will be utilized, process preferences based upon personal experience, concerns about using proven processes or equipment that are not experimental, and concern about possible environmental impacts. Owner needs are especially important in small communities where there is a limited history of construction and operation of new treatment systems. For projects both large and small, it is important for the design engineer and the owner to reach an understanding about their mutual goals and objectives so that the needs of the owner are satisfied and the selected treatment process improvements meet the basic purposes for its selection, that is, meeting waste discharge regulations or effluent reuse in the most cost-effective manner and mitigating adverse environmental impacts.

Asset management is a management process to minimize the total cost of owning and operating the infrastructure assets while delivering the service levels needed. While it is not required to implement asset management in the United States, the long-term benefits have been recognized, and many organizations have been promoting the use of asset management. Asset management is discussed further in Chap. 18.

Environmental Considerations

The environmental impacts of a proposed wastewater treatment facility are as important as cost considerations if not more so. In addition to the potential impact of discharged effluent on the aquatic environment in the receiving waters, increasing efforts are being made to address the emission of greenhouse gas (GHG) from the treatment facility. These considerations are included in the triple bottom line (TBL) analysis which evaluates (1) economic, (2) environmental, and (3) social aspects of the project as part of a decision making process. While detailed environmental review procedures are not covered in this text, GHG emissions are considered in Chap. 16 and TBL is discussed briefly in Chap. 18.

National Environmental Policy Act. The protocol for evaluation of environmental impacts is set forth in the National Environmental Policy Act (NEPA) of 1969 (42 USC 4321–4347 as amended). Environmental evaluations should focus on social, technical, ecological, economic, political, legal, and institutional (STEEPLI) criteria.

Application of the NEPA regulations requires that an Environmental Impact Statement (EIS) be prepared for any proposed federal action which is determined to have a significant impact on the quality of the human environment. The development of an EIS is controlled by the Council on Environmental Quality (CEQ) Regulations for Implementing the Procedural Provisions of the National Environmental Policy Act (40 CFR 1500-1508).

The NEPA regulations ensure that the probable environmental effects are identified, that a reasonable number of alternative actions and their environmental impacts are considered, that the environmental information is available for public understanding and scrutiny, and that the public and governmental agencies participate as a part of the decision process. All pertinent regulations and the inherent protection afforded must be disclosed in the EIS. The NEPA neither prohibits nor permits any action, but requires full disclosure of environmental information and public participation in the decision-making process.

Environmental Information Document. The procedures and requirements for implementing the NEPA regulations for Municipal Wastewater Treatment Construction Grants Program under the Clean Water Act are set forth in Subpart E of the EPA regulations. The basic elements of the process include the Environmental Information Document (EID) generated by the grantee (owner) as an integral part of a facilities plan, consistent with Section 201 of the Clean Water Act. The EID is the basis for agency review of the environmental impacts of the facilities plan and preparation of an Environmental Assessment (EA). The EA must be of sufficient detail so as to be an adequate basis for EPA's independent review and decision to issue a Finding of No Significant Impact (FNSI) or to issue a notice of intent for an EIS and subsequent Record of Decision. If an EIS is required, then following development of a draft EIS and input based on public hearings, a final EIS is prepared. In the resultant Record of Decision the findings and the recommended actions selected are summarized.

Compatibility with Existing Facilities

An important consideration not to be overlooked in the expansion and upgrading of existing wastewater treatment facilities is the compatibility with existing process units including the impact of the new process on plant hydraulics (both at peak and low flow), impact on other unit processes, structural impacts, and impact on existing instrumentation and control system. The introduction of a new process into an existing facility represents new operating requirements and additional hiring and training of personnel for the proper operation and maintenance of a new process unit. Construction of the new facilities while operating the existing wastewater treatment plant to meet the discharge/reuse standards is another challenge. Often, equipment furnished by the same manufacturer as the existing installation permit fewer spare parts to be kept on hand, provided the equipment has a good record of service.

Energy and Resource Requirements

Concern over the rate of consumption of natural resources and energy has increased as shortages have occurred and worldwide demands have been increased. Because the operation of wastewater management facilities depends on energy resources to a large extent, it is important to appraise the requirements realistically. The operation of facilities is the main consumer of energy at treatment plants. Because energy consumption of different unit processes varies greatly and because there are innumerable combinations possible, data must be available for each prospective treatment process considered. Additionally, many opportunities exist for generating heat and power at the treatment plant that can be utilized to meet all or a part of the plant's demands. The recovery of heat energy from wastewater is also being incorporated both in collection systems (especially in Germany) and in new wastewater treatment plant designs. Considerations for energy management are further discussed in Chap. 17.

Energy Sources. The main energy sources are (1) electric power, (2) natural gas or propane, (3) diesel fuel or gasoline, and (4) recovered heat and power (see Chap. 17). Electric power is used mainly for running the electric motors for the process equipment and for providing lighting and power for various ancillary support systems. Natural gas or propane is used for building and digester heating and is used as a fuel source for standby engine-generators. Diesel fuel or gasoline is used similarly for standby engine-generators and for vehicle fuel. Recovered heat and power can meet all or part of the demands. Particular attention needs to be paid to the electrical energy costs because of the complex pricing structure used by utilities. In northern climates, where unit processes need to be covered, significant capital and operating costs can be associated with ventilation and heating.

Electric Energy Costs. Electric energy charges are commonly assessed based upon energy use, power factor charges, and demand charges. Power factor charges are concerns for plants having large electric motor–driven equipment. The demand charges are assessed by the utility companies when they commit sufficient power generating capacity to meet the entire demands of the treatment system. Peak power use for as little as 15 min may establish a demand charge for up to 12 mo. Demand charges can be reduced in some instances by providing power generating capability at the treatment plant. The recovery and use of digester gas for meeting energy needs and reducing demand is one example how both user charges and demand charges can be reduced with resulting cost savings to the treatment plant. Digester gas use is discussed in more detail in Chap. 13. As part of an energy cost evaluation, a sensitivity analysis should be considered to assess the impacts of future changes in energy costs on the overall cost of operation for the treatment facilities.

Cost Considerations

Of major significance in the selection and design of alternative wastewater treatment facilities, especially to the client, is the question of costs—not only initial construction costs but also annual operation and maintenance costs. Although cost estimating is not covered in this text, a few comments about the preparation of cost estimates are appropriate. Ordinarily, cost estimates are divided into three levels of detail: (1) order of magnitude estimates that are used for conceptual planning and are derived from cost curves and selected publications; (2) budget estimates (prepared during the preliminary design stage) derived from published or historical bid information, manufacturers' quotations, or limited quantity takeoffs; and (3) definitive estimates derived from detailed quantity takeoffs of completed plans and specifications. The accuracy of the estimates vary according to the level of detail; therefore, contingencies of varying percentages are added to the estimates to account for undefined items and for unforeseen conditions.

Construction Cost Estimates. When preparing estimates of construction cost particularly during times of high inflation, the same basis of comparison should be used to evaluate all the alternatives and for projecting future costs. Methods commonly used for projecting costs are (1) escalation based on an assumed rate of inflation or (2) a published cost index. The Engineering News-Record Construction Cost Index (ENRCCI), published in the magazine ENR (a McGraw-Hill publication) is used most commonly in the field of wastewater engineering.

Data in engineering reports and in the literature can be adjusted to a common basis for purposes of comparison by using the following relationship:

$$\text{Current cost} = \frac{\text{Current value of index}}{\text{Value of index at time of estimate}} \times \text{Estimated cost} \tag{4–1}$$

When possible, index values should also be adjusted to reflect current local costs. Both the ENRCCI and EPA indexes include costs for various geographical locations. The ENR publishes cost indexes for 20 cities. When using the ENRCCI, if the month of the year that the facilities were built is not given, it is common practice to use the June end-of-the-month index value. To project costs into the future, the following relationship can be used. The future value of the index is often projected to the one-third or mid-point of the construction period.

$$\text{Future cost} = \frac{\text{Projected future value of index}}{\text{Current value of index}} \times \text{Current cost} \tag{4–2}$$

It should be noted, however, that updating or projecting costs for periods of more than 3 to 5 y can result in gross inaccuracies, especially if the index has increased or decreased significantly.

Operations and Maintenance Cost Estimates. The annual costs for operations and maintenance (O&M) are important factors in the evaluation of alternative treatment processes. The principal elements of O&M costs are labor, energy, chemicals, and materials and supplies. Where possible, each of these elements should be estimated separately because costs of each may escalate at different rates. Energy costs should be estimated based on the estimated energy consumption by the process equipment and the appropriate energy rate obtained from the utility furnishing the energy. Chemical costs should be computed similarly based on the estimated amounts consumed and the appropriate unit price. Materials and supplies are estimated on predicted usage and should be included.

Cost Comparisons. In the evaluation of alternative treatment process flow diagrams, costs may be compared using present worth, total annual costs, or life cycle costs. In a present worth analysis, all future expenditures are converted to a present worth cost at the beginning of the planning period. A discount rate is used in the analysis and represents the time value of money (the ability of money to earn interest). In a total annual cost comparison, the capital costs are amortized based on probable interest rates for bonds and the duration of the bond issue. The annual fixed (amortized) cost is added to the annual operating and maintenance costs to determine the total annual cost. Life cycle costs are used to determine the total cost of a facility over its total useful life (up to 50 y for structures) and include the capital cost and the operating and maintenance costs. Life cycle costs are particularly useful in comparing the costs of a rehabilitated existing facility as compared to a new facility. However, when comparing costs between treatment alternatives, consideration should also be given to the level of accuracy of the estimate. For example, if the cost estimate accuracy carries a contingency of 40 percent, and all options are within 5 to 8 percent of each other, then the options could be considered equal.

Other Design Considerations

Additional important design considerations include (1) equipment availability, and (2) personnel requirements. Although a detailed discussion of equipment availability and personnel requirements is beyond the scope of this textbook, these subjects are introduced briefly below to provide a perspective on how they fit into the overall picture.

Equipment Availability. The availability of equipment plays an important part in process selection because of (1) the need to provide redundant systems when there are long delivery times for spare parts and replacement units and (2) when equipment delivery is critical to the construction schedule. Most of the equipment used in wastewater treatment is custom manufactured, other than for items such as small pumps, motors, and valves. Some items of equipment may be manufactured from alloy materials such as stainless steel that require special manufacturing techniques or are proprietary and only available from limited sources, perhaps even from overseas suppliers. Therefore, the design engineer should consider carefully the equipment components that make up the process or system to determine their potential effects upon the design, construction, and operation and maintenance of the facilities.

Personnel Requirements. In the selection of treatment processes, consideration must be given both to the numbers of operating and maintenance personnel needed and to the skills that may be required. The simpler and less complex the process, the fewer the number of highly skilled people are needed. Where facilities are being added to an existing treatment plant, capabilities of the existing personnel should be evaluated so that the new facilities can be added without causing major staffing problems and the need for extensive retraining.

Some of the more complex processes require high levels of automatic controls utilizing electronic instruments and devices (see Chap. 18). Proper instrumentation and controls can save labor and even allow some of the small plants to operate unattended. However, complex instrumentation and control systems may require the on-staff services of highly skilled instrumentation technicians. Instrumentation specialists may be difficult to recruit and maintain on staff because of the high demand for well-qualified technicians. The extent and complexity of the control systems and the staffing levels required have to be evaluated carefully.

4–2 CONSIDERATIONS IN PROCESS SELECTION

Process selection involves the detailed evaluation of the various factors that must be considered when evaluating unit processes and other treatment methods to meet current and future treatment objectives. The purpose of process analysis is to select the most suitable unit processes and the optimum operational criteria. The purpose of this section is to introduce the important factors that must be considered in process selection and to consider the basis for process design. The impact of treatment plant reliability on the selection of specific treatment process design criteria is examined in the following section.

Important Factors in Process Selection

The most important factors that must be evaluated in process analysis and selection are identified in Table 4–2. Each factor is important in its own right, but some factors require additional attention and explanation. The first factor, "process applicability," stands out above all others and reflects directly upon the skill and experience of the design engineer. Many resources are available to the designer to determine applicability, including past experience in similar type projects. Available resources include performance data from operating installations, published information in technical journals, manuals of practice published by the Water Environment Federation (WEF, 2010b), process design manuals published by WEF and U.S. EPA, and the results of pilot plant studies.

Table 4–2

Important factors that must be considered when evaluating and selecting unit processes

Factor	Comment
1. Process applicability	The applicability of a process is evaluated on the basis of past experience, data from full-scale plants, published data, and from pilot plant studies. If new or unusual conditions are encountered, pilot plant studies are essential.
2. Applicable flow range	The process should be matched to the expected range of flowrates. For example, stabilization ponds are not suitable for extremely large flowrates, in highly populated areas.
3. Applicable flow variation	Most unit operations and processes have to be designed to operate over a wide range of flowrates. Most processes work best at a relatively constant flowrate. If the flow variation is too great, flow equalization may be necessary.
4. Influent wastewater characteristics	The characteristics of the influent wastewater affect the types of processes to be used (e.g., chemical or biological) and the requirements for their proper operation.
5. Inhibiting and unaffected constituents	What constituents are present and may be inhibitory to the treatment processes? What constituents are not affected during treatment?
6. Climatic constraints	Temperature affects the rate of reaction of most chemical and biological processes. Temperature may also affect the physical operation of the facilities. Warm temperatures may accelerate odor generation and also limit atmospheric dispersion.
7. Process sizing based on reaction kinetics or process loading criteria	Reactor sizing is based on the governing reaction kinetics and kinetic coefficients. If kinetic expressions are not available process loading criteria are used. Data for kinetic expressions and process loading criteria usually are derived from experience, published literature, and the results of pilot plant studies.
8. Process sizing based on mass transfer rates or process loading criteria	Reactor sizing is based on mass transfer coefficients. If mass transfer rates are not available process loading criteria are used. Data for mass transfer coeficients and process loading criteria usually are derived from experience, published literature, and the results of pilot plant studies.
9. Performance	Performance is usually measured in terms of effluent quality and its variability, which must be consistent with the effluent discharge requirements.
10. Treatment residuals	The types and amounts of solid, liquid, and gaseous residuals produced must be known or estimated. Often, pilot plant studies are used to identify and quantify residuals.
11. Sludge processing	Are there any constraints that would make sludge processing and disposal infeasible or expensive? How might recycle loads from sludge processing affect the liquid unit operations or processes? The selection of the sludge processing system should go hand-in-hand with the selection of the liquid treatment system.
12. Environmental constraints	Environmental factors, such as prevailing winds and wind directions and proximity to residential areas, may restrict or affect the use of certain processes, especially where odors may be produced. Noise and traffic may affect selection of a plant site. Receiving waters may have special limitations, requiring the removal of specific constituents such as nutrients.
13. Chemical requirements	What resources and what amounts must be committed for a long period of time for the successful operation of the unit operation or process? What effects might the addition of chemicals have on the characteristics of the treatment residuals and the cost of treatment?
14. Energy requirements	The energy requirements, as well as probable future energy cost, must be known if cost-effective treatment systems are to be designed.
15. Other resource requirements	What, if any, additional resources must be committed to the successful implementation of the proposed treatment system using the unit operation or process being considered?
16. Personnel requirements	How many people and what levels of skills are needed to operate the unit operation or process? Are these skills readily available? How much training will be required?

(*continued*)

Table 4–2 (*Continued*)

Factor	Comment
17. Operating and maintenance requirements	What special operating or maintenance requirements will need to be provided? What spare parts will be required and what will be their availability and cost?
18. Ancillary processes	What support processes are required? How do they affect the effluent quality, especially when they become inoperative?
19. Reliability	What is the long-term reliability of the unit operation or process being considered? Is the operation or process easily upset? Can it stand periodic shock loadings? If so, how do such occurrences affect the quality of the effluent?
20. Complexity	How complex is the process to operate under routine or emergency conditions? What levels of training must the operators have to operate the process?
21. Compatibility	Can the unit operation or process be used successfully with existing facilities? Can plant expansion be accomplished easily?
22. Adaptability	Can the process be modified to meet future treatment requirements?
23. Economic life-cycle analysis	Cost evaluation must consider initail capital cost and long-term operating and maintenance costs. The plant with lowest Initail capital cost may not be the most effective with respect to operating and maintenance costs. The nature of the available funding will also affect the choice of process
24. Land availability	Is there sufficient space to accommodate not only the facilities currently being considered but possible future expansion? How much of a buffer zone is available to provide landscaping to minimize visual and other impacts?

Where the applicability of a process to a given situation is unknown or uncertain, pilot plant studies must be conducted to determine performance capabilities and to obtain design data upon which a full-scale design can be based. The following discussion will deal briefly with process design based on reaction kinetics, mass transfer, and the use of loading criteria. As part of the discussion, the conduct of bench and pilot plant studies is considered along with process variability. The other factors in Table 4–2 are discussed throughout the remainder of the book. They are identified here to indicate the diverse nature of the information that must be available to make a proper evaluation of unit processes used for the treatment of wastewater.

Process Selection Based on Reaction Kinetics

In process selection and sizing based on reaction kinetics, particular emphasis is placed on defining the nature of the reactions occurring within the process, the appropriate values of the kinetic coefficients, and the selection of the reactor type.

Selection of Appropriate Kinetic Rate Expression(s) and Coefficients. The nature of the reactions occurring within a process must be known to apply the reaction kinetics approach to design. For example, it is of critical importance to know if the reaction is zero, first, retarded first, or second order, or if the reaction is a saturation type. Reaction rates are discussed in Sec. 1–10 in Chap. 1. Selection of appropriate kinetic rate coefficients for the process that is to be designed is also based on (1) information obtained from the literature, (2) experience with the design and operation of similar systems, or (3) data derived from pilot plant studies. In cases where significantly different wastewater characteristics occur or new applications of existing technology or new processes are being considered, pilot plant testing is recommended. The various rate expressions that have been developed for biological treatment are considered in Chaps. 7 through 10. In addition, there are a number of commercially available models of the activated sludge process that take into account myriad of variables. Although comprehensive, the key issue with these models is to understand what the model output means. For example, does the output seem reasonable, real, or defensible? The subject of model output assessment is considered further in Chaps. 8 and 9.

Selection of Reactor Types. Operational factors that must be considered in the type of reactor or reactors to be used in the treatment process include (1) the nature of the wastewater to be treated, (2) the nature of the reaction kinetics governing the treatment process, (3) special process requirements, and (4) local environmental conditions. As noted previously, for biological treatment with the activated sludge process, for zero-order kinetics, there is no difference in the size of the reactor required (i.e., $V_{\text{complete-mix}} = V_{\text{plug-flow}}$). For example, a complete-mix reactor might be selected over a plug-flow reactor, because of its dilution capacity, if the influent wastewater is known to contain toxic constituents that cannot be removed by pretreatment. Alternatively, a plug-flow or multistage reactor might be selected over a complete-mix reactor to control the growth of filamentous microorganisms. In practice, the construction costs and operation and maintenance costs also affect reactor selection.

Process Selection Based On Mass Transfer

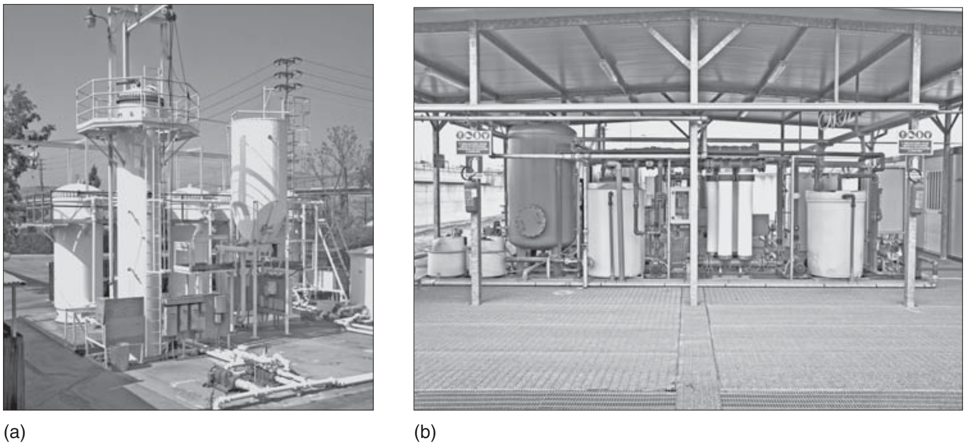
In addition to process selection based on reaction kinetics and loading criteria, a number of treatment processes will be based on mass transfer considerations, as introduced in Chap. 1. The principal operations in wastewater treatment involving mass transfer are aeration, especially the addition of oxygen to water; the drying of biosolids and sludge; the removal of volatile organics from wastewater; the stripping of dissolved constituents such as ammonia from digester supernatant; and the exchange of dissolved constituents as in ion exchange. Fortunately, there is a considerable body of literature on these subjects as well as a vast amount of practical experience. Additional details on these subjects are presented in the subsequent chapters.

Process Design Based on Loading Criteria

If appropriate reaction rate expressions and mass transfer coefficients cannot be developed, generalized loading criteria are used frequently. Early design loading criteria for activated sludge biological treatment systems were based on aeration tank capacity [e.g., kg of BOD/m^3 (lb BOD/10^3 ft^3)]. For example, if a process that is loaded at 10 kg/m^3 produces an acceptable effluent and one loaded at 20 kg/m^3 does not, the successful experience tends to be repeated. Unfortunately, records often are not well maintained, and the limits of such loading criteria are seldom defined. Examples of loading criteria are presented in the design chapters for unit processes. It should be noted that with the new activated sludge biological treatment process variations and new aeration equipment, the use of loading factors should be avoided.

Bench-Scale Tests and Test-Bed Pilot-Scale Studies

Where the applicability of a process for a given situation is unknown, but the potential benefits of using the process are significant, bench-scale or pilot-scale tests must be conducted. Bench-scale tests are conducted in the laboratory with small quantities of the wastewater in question. Pilot-scale tests are conducted typically with flows that can vary from 0.1 to 5 percent of the design flows. It is important to note that the term *pilot-scale*



(a) (b)

Figure 4–3

Typical example of a test-bed facility where a number of different technologies can be tested at pilot-scale: (a) test bed (a.k.a. pilot plant) for Pomona Virus Study conducted by the County Sanitation Districts of Los Angeles County (circa 1975–1977) and (b) test bed facility, Toranto, Italy.

is used typically to denote hydraulic capacity of the facility and not necessarily the scale of the physical facilities being tested. For example, a full-scale membrane filtration system may be comprised of 500 microfiltration units, whereas a pilot-scale facility might have 10 units or less. Where scale-up issues and computational methods are too complex, the individual units being tested are the same as those that will be used in the full-scale installation. The term *test-bed* is used to describe a physical facility (also a geographic location, urban area, or city) where technologies and concepts can be tested and evaluated. An example, a pilot-scale (i.e., reduced flow) test-bed facility for the evaluation of advanced treatment technologies, is illustrated on Fig. 4–3.

The purpose of conducting pilot-plant studies is to establish the suitability of the process in the treatment of a specific wastewater under specific environmental conditions and to obtain the necessary data on which to base a full scale design. Factors that should be considered in planning pilot-plant studies for wastewater treatment are presented in Table 4–3. The relative importance of the factors presented in Table 4–3 will depend on the specific application and the reasons for conducting the testing program. For example, testing of UV disinfection systems is typically done (1) to verify manufacturers performance claims, (2) to quantify effects of effluent water quality constituents on UV performance, (3) to assess the effect(s) of system and reactor hydraulics on UV performance, (4) to assess the effect(s) of effluent filtration on UV performance, and (5) to investigate photoreactivation and impacts.

Wastewater Discharge Permit Requirements

In most wastewater discharge permits, effluent constituent requirements are based on 7-d and 30-d average concentrations. Because wastewater treatment effluent quality is variable for a number of reasons (varying organic loads, changing environmental conditions, etc.), it is necessary to ensure that the treatment system is designed to produce effluent concentrations equal to or less than the permit limits. Two approaches in process selection and design are (1) the use of arbitrary safety factors, and (2) statistical analysis of treatment plant performance to determine a functional relationship between effluent quality and the probable frequency of occurrence. The latter approach, termed the "reliability concept," is preferred because it can be used to provide a consistent basis for analysis of uncertainty and a rational basis for the analysis of performance and reliability. Treatment process reliability is considered in the following section.

Table 4–3

Considerations in setting up pilot-plant testing programs

Item	Consideration
Reasons for conducting pilot testing	Test new process Simulation of another process Predict process performance Document process performance Optimize system design Satisfy regulatory agency requirements Satisfy legal requirements
Pilot plant size	Bench or laboratory-scale model Pilot-scale tests Full- (prototype) scale tests
Nonphysical design factors	Available time, money, and labor Degree of innovation and motivation involved Quality of water or wastewater Location of facilities Complexity of process Similar testing experience Dependent and independent variables
Physical design factors	Scale-up factors Size of prototype Flow variations expected Facilities and equipment required and setup Materials of construction
Design of pilot testing program	Dependent variables including ranges Independent variables including ranges Time required Test facilities Test protocols Statistical design of data acquisition program Phased approach to adjust protocol as data are collected and analyzed

4–3 TREATMENT PROCESS RELIABILITY AND SELECTION OF DESIGN VALUES

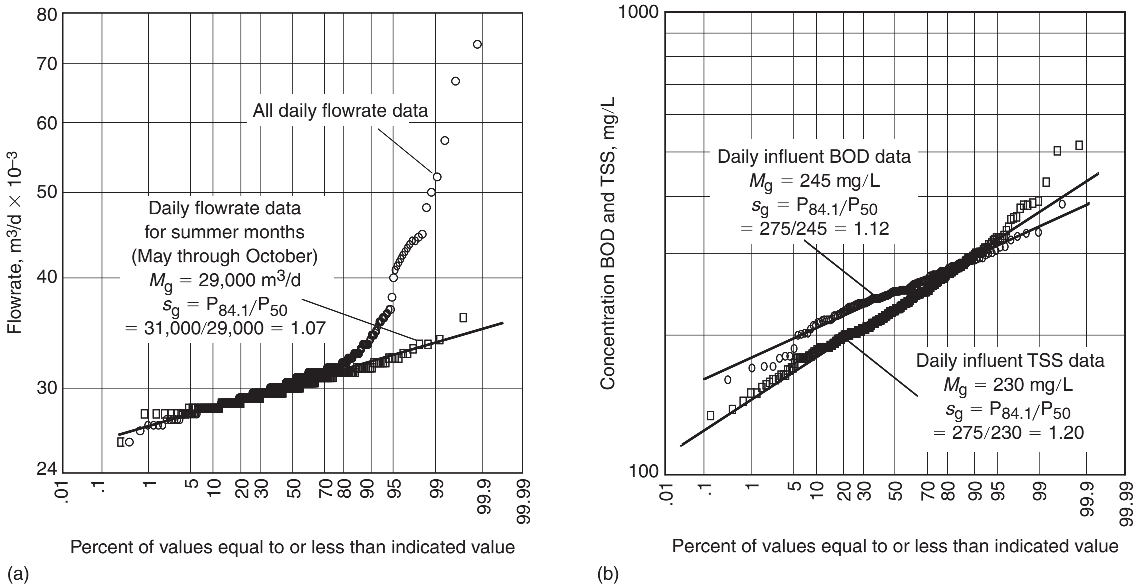
Important factors in process selection and design are treatment plant performance and reliability in meeting permit requirements. Reliability of a treatment plant or a treatment process may be defined as the probability of adequate performance for a specified period of time under specified conditions or, in terms of treatment plant performance, the percent of the time that effluent concentrations meet specified permit requirements. For example, a treatment process with a reliability of 99 percent is expected to meet the performance requirements 99 percent of the time. For one percent of the time, or three to four times per year, the not-to-exceed permit limits are expected to be exceeded. Such a level of performance may or may not be acceptable, depending on the permit requirements. For each specific case where the reliability concept is to be employed, the levels of reliability must be evaluated, including the cost of the facilities required to achieve the specified levels of reliability and the associated operating and maintenance costs. Thus, the purpose of this section is to examine how treatment process variability is assessed and how the performance of combined processes can be evaluated. The specific topics to be discussed are (1) variability in wastewater treatment, (2) selection of process design parameters, (3) the performance of combined processes, and (4) the development of input-output relationships.

Variability in Wastewater Treatment

Three categories of variability that can affect the design, performance, and reliability of a wastewater treatment plant are (1) variability of the influent wastewater flowrate and characteristics, (2) inherent variability in wastewater treatment processes, and (3) variability caused by mechanical breakdown, design deficiencies, and operational failures. Following a brief discussion of the characterization of variability in wastewater treatment, each of the above categories of variability is considered in the following discussion. Variability of the influent wastewater flowrate and characteristics was discussed in Chap. 3, and is reviewed here briefly for completeness.

Characterization of Parameter and Process Variability. One common method used to characterize the variability of wastewater parameters and treatment processes is the use of the geometric standard deviation, s_g (see Appendix D). The value of s_g can be used to approximate an entire distribution of all expected values if a mean value is known or can be estimated. As discussed in Appendix D, the greater the numerical value of s_g, the greater the observed range in the measured values.

Variability of Influent Wastewater Flowrates. As discussed in Sec. 3–3 in Chap. 3, the influent flowrate to a treatment facility is dependent on factors such as the time of day, season, size and characteristics of the contributing population, and infiltration to and exfiltration from the collection system. A typical example of the variability that can be observed in influent wastewater flowrates is illustrated on Fig 4–4(a).



(a) (b)

Figure 4–4

Probability distributions for daily influent wastewater characteristics collected over one year: (a) flowrate and (b) biochemical oxygen demand (BOD) and total suspended solids (TSS).

Table 4–4

Range of geometric standard deviations (s_g) for influent parameters observed at small, intermediate, and large wastewater treatment facilities

	Range of s_g for typical wastewater treatment facilities[a]					
	Small[b]		Intermediate[c]		Large[d]	
Parameter	Range	Typical	Range	Typical	Range	Typical
Flowrate	1.4–2.0	1.6	1.1–1.5	1.25	1.1–1.2	1.15
BOD	1.4–2.1	1.6	1.3–1.6	1.3	1.1–1.3	1.27
COD	1.5–2.2	1.7	1.4–1.8	1.4	1.1–1.5	1.30
TSS	1.4–2.1	1.6	1.3–1.6	1.3	1.1–1.3	1.27

[a] Excluding systems with large amounts of infiltration in the collection system.

[b] Flowrate of 4000–40,000 m^3/d.

[c] Flowrate of 40,000–400,000 m^3/d.

[d] Flowrate $>$ 400,000 m^3/d.

As shown on Fig. 4–4(a), the summer flowrates are very stable and follow a log-normal distribution, whereas the entire daily set of flowrate data is influenced significantly by the high winter flowrates and is, therefore, extremely variable. In fact, the complete daily flowrate data set cannot be modeled with either an arithmetic or a log-normal distribution. As will be discussed subsequently, such variability, which is not uncommon, is of concern where stringent discharge requirements must be met. In some cases, it may be necessary to reduce the amount of infiltration/inflow in the collection system and/or install flow equalization facilities (discussed in Chap. 3) to improve treatment process performance. The typical range of observed values for s_g for influent flowrates for small, medium, and large capacity wastewater treatment plants are given in Table 4–4.

Variability in Constituent Concentrations. The variability of the constituents in wastewater, discussed previously in Sec. 3–3, must be considered carefully in the design of biological treatment processes, especially with respect to the design of the aeration facilities [see Fig 4–4(b)]. Geometric standard deviation values for the variability observed in influent BOD, COD, and TSS constituent concentrations are given in Table 4–4 in terms of the s_g value. The range of s_g values given in Table 4–4 corresponds to the range of values reported in the literature and in the authors' experience.

Inherent Variability In Wastewater Treatment Processes. All physical, chemical, and biological treatment processes exhibit some measure of variability with respect to the performance that can be achieved. Typical ranges of mean effluent constituent values that can be achieved with various biological treatment processes are reported in Table 4–5. The range of variability observed in the effluent BOD and TSS performance of various activated sludge processes is illustrated graphically on Fig. 4–5. Further, as illustrated on Fig. 4–5 and discussed in Chap. 8, the physical characteristics of the secondary sedimentation facilities can have a significant impact on the observed performance of the activated sludge process. The variability in terms of s_g values for BOD, TSS, and turbidity for the three processes considered in Table 4–5 are presented in Table 4–6. The range of s_g values is representative of the values reported in the literature. Use of the data in Table 4–6 is illustrated in Example 4–1.

Table 4–5

Typical range of effluent quality after secondary treatment[a]

			Range of effluent quality after indicated treatment		
Constituent	**Unit**	**Untreated wastewater**	**Conventional activated sludge[b]**	**Activated sludge with BNR[c]**	**Membrane bioreactor**
Total suspended solids (TSS)	mg/L	120–400	5–25	5–20	≤1
Biochemical oxygen demand (BOD)	mg/L	110–350	10–30	5–15	<3
Chemical oxygen demand (COD)	mg/L	250–800	40–80	20–40	15–30
Total organic carbon (TOC)	mg/L	80–260	20–40	10–20	5–10
Ammonia nitrogen	mg N/L	12–45	1–10	0.7–3.0	0.7–3.0
Nitrate nitrogen	mg N/L	0–trace	10–30	2–10	2–10[d]
Nitrite nitrogen	mg N/L	0–trace	0–trace	0–trace	0–trace
Total nitrogen	mg N/L	20–70	15–35	5–10	3–10[d]
Total phosphorus	mg P/L	4–12	4–10	0.5–2.0	0.5–2.0[d]
Turbidity	NTU		2–15	2–8	≤1
Volatile organic compounds (VOCs)	mg/L	<100–>400	10–40	10–20	10–20
Metals	mg/L	1.5–2.5	1–1.5	1–1.5	trace
Surfactants	mg/L	4–10	0.5–2	0.1–1	0.1–0.5
Totals dissolved solids (TDS)	mg/L	270–860	500–700	500–700	500–700
Trace constituents[f]	mg/L	10–50	5–40	5–30	0.5–20
Total coliform	No./100 mL	10^6–10^9	10^4–10^5	10^4–10^5	<100
Protozoan cysts and oocysts	No./100 mL	10^1–10^4	10^1–10^2	0–10	0–1
Viruses	PFU/100 mL[e]	10^1–10^4	10^1–10^3	10^1–10^3	10^0–<10^3

---

[a] From Chap. 3, Table 3–12 and 3–14.

[b] Conventional secondary is defined as activated sludge treatment with nitrification.

[c] BNR is defined as biological nutrient removal for the removal of nitrogen and phosphorus.

[d] With BNR process.

[e] Plaque forming units.

[f] For example, prescription and non-prescription drugs.

For constituents that are not modified significantly by biological treatment, such as inorganic TDS, it has been found that both arithmetic and log-normal distributions can be used to model process performance. Also, where the variability in performance is not great, both the arithmetic and log-normal distributions can be used to model the observed performance. The Weibull distribution (Kokoska and Zwillinger, 2000) has also proven useful in the analysis of the performance of advanced wastewater treatment processes (WCPH, 1996, 1997).

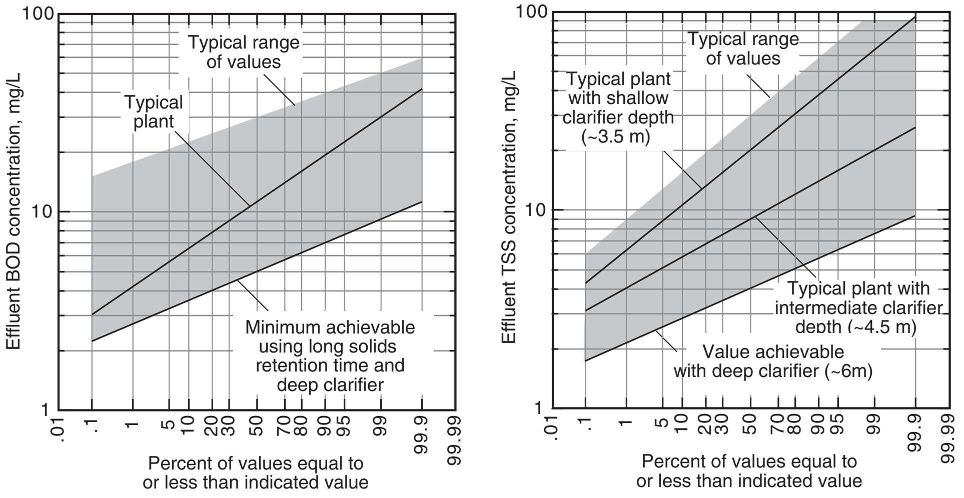


Figure 4–5

Variability of effluent constituents observed in the performance of the activated sludge process: (a) BOD and (b) TSS.

Table 4–6

Typical range of effluent quality variability observed from secondary treatment processes[a]

Biological treatment process	Unit	Range of effluent values	Geometric standard deviation, s_g[b]	
			Range	Typical
Conventional activated sludge				
BOD	mg/L	5–25	1.3–2.0	1.5
TSS	mg/L	5–25	1.2–1.8	1.4
Turbidity	NTU	5–15[c]	1.2–1.6	1.4
Activated sludge with BNR				
BOD	mg/L	5–15	1.3–2.0	1.5
TSS	mg/L	5–20	1.2–1.8	1.4
Turbidity	NTU	2–8	1.2–1.6	1.4
Membrane bioreactor				
BOD	mg/L	<3	1.3–1.6	1.4
TSS	mg/L	≤ 1	1.3–1.9	1.5
Turbidity	NTU	≤ 1	1.1–1.4	1.3

[a] All of the reported distributions are log normal, Mg = geometric mean, s_g = geometric standard deviation.

[b] $s_g = P_{84.1}/P_{50}$.

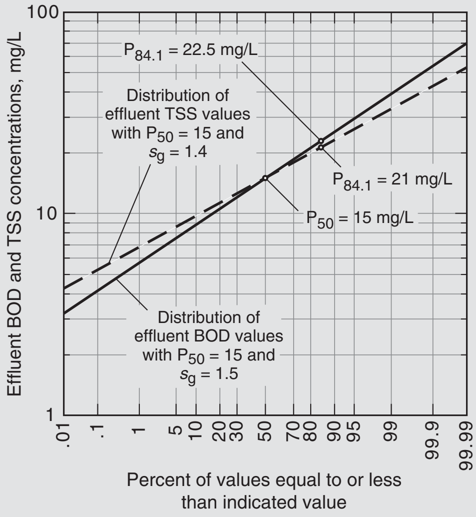
[c] Turbidity values of less than 2 NTU have been observed in plants with deep clarifiers (e.g., sidewater depths of 5.5 to 6 m). Corresponding BOD and TSS values are in the range from 3 to 6 mg/L.

EXAMPLE 4–1 **Evaluation of Activated Sludge Process Reliability** A conventional activated sludge process has been designed to have a mean effluent BOD and TSS value of 15 mg/L. Determine the maximum BOD and TSS values that are expected to occur with a frequency of (a) once per year and (b) once every three years. If the effluent limit for both BOD and TSS is 30 mg/L, estimate how often the effluent limits will be exceeded annually.

Solution

1. Select s_g values for BOD and TSS from Table 4–4 that correspond to the effluent BOD and TSS for a conventional activated sludge process. From Table 4–4, use the typical s_g values of 1.5 and 1.4 for BOD and TSS, respectively.
2. Determine the probability distribution of the effluent BOD and TSS values.
   a. Using the s_g values, compute the BOD and TSS values corresponding to the plotting position on $P_{84.1}$ (see footnote b from Table 4–6).
      i. For BOD
      $P_{84.1} = s_g \times P_{50} = 1.5 \times 15 \text{ mg/L} = 22.5 \text{ mg/L}$
      ii. For TSS
      $P_{84.1} = s_g \times P_{50} = 1.4 \times 15 \text{ mg/L} = 21 \text{ mg/L}$

   b. Estimate the distribution of effluent BOD and TSS values by plotting the $P_{84.1}$ and P_{50} values. As the effluent BOD and TSS values are expected to follow a log normal distribution, a straight line can be drawn through the $P_{84.1}$ and P_{50} values, as shown on the following plot.



3. Compute the effluent BOD and TSS values expected to occur with the frequency of interest.
   a. The probability of occurrence of a given event with a frequency of once per year is (1/365) × 100 = 0.3 %. Therefore, the percent of events occurring less than once per year is 100 − 0.3 = 99.7 %. Using the plot developed in step 2, the effluent BOD and TSS values corresponding to 99.7 % are
      i. For BOD
      $P_{99.7} = 45.8 \text{ mg/L}$
      ii. For TSS
      $P_{99.7} = 37.8 \text{ mg/L}$

b. Similarly, the probability of occurrence of a given event with a frequency of once in three years (i.e., 99.9%) is
   i. For BOD
      $P_{99.9} = 52.6$ mg/L
   ii. For TSS
      $P_{99.9} = 42.5$ mg/L

4. Estimate how often the annual effluent BOD and TSS values will exceed the effluent standard of 30 mg/L.
   a. From the plot presented in step 2, the effluent BOD will exceed 30 mg/L approximately 4.5% of the time (~16 d/y).
   b. From the plot presented in step 2, the effluent TSS will exceed 30 mg/L approximately 2.0% of the time (~7 d/y).

Comment As found in step 4, the effluent BOD and TSS values will exceed the discharge limit of 30 mg/L about 4.5 and 2.0 percent of the time, respectively. If the BOD and TSS are not to exceed the effluent limits, then either the process will have to be designed for a lower mean value or some form of effluent filtration must be added to meet the discharge limits reliably. The impact of adding some form of filtration is considered in Chap. 11.

Mechanical Process Reliability. In addition to the variability in the influent wastewater flowrate and characteristics and the inherent variability in the response of wastewater treatment processes, the variability associated with the mechanical equipment used at wastewater treatment facilities must also be considered in analyzing what design values and how much standby equipment must be available to meet stringent standards at some specified reliability value (e.g., 99 or 99.9 percent). A number of approaches are available for analyzing mechanical reliability of a treatment plant and include (WCPH, 1996):

1. Critical component analysis (CCA)
2. Failure modes and effects analysis
3. Event tree analysis
4. Fault tree analysis

All four of these approaches are cited frequently in the literature and are used by a variety of industries. The critical component analysis (CCA) approach was developed by the U.S. EPA to determine the in-service reliability, maintainability, and operational availability of selected critical wastewater treatment components (U.S. EPA, 1982). The objective of the CCA is to determine which mechanical components in the wastewater treatment plant will have the most immediate impact on effluent quality should failure occur. The statistical parameters used most commonly in applying the CCA method, as defined in Table 4–7, are *mean time before failure* (MTBF), *expected time before failure* (ETBF), *inherent availability* (AVI), and *operating availability* (AVO).

A complete process reliability analysis was performed for a treatment system designed to produce 3800 m^3/d (1.0 Mgal/d) of reclaimed water. The treatment facility included preliminary treatment (coarse screening and grit removal), primary treatment (rotary drum and disk screens), secondary treatment (water hyacinth ponds), and tertiary treatment (a package plant consisting of coagulation, softening, sedimentation, and filtration). Advanced water treatment consists of ultraviolet disinfection, reverse osmosis, air stripping, and granular activated carbon adsorption. Sodium hypochlorite is used for plant

Table 4–7

Statistical measures to assess equipment reliability[a]

Statistical measure	Description
Mean time before failure (MTBF)	A measure of the mechanical reliability of equipment, determined by the number of failures. The usual approach is to divide the operating hours by the number of failures
Expected time before failure (ETBF)	Similar to the MTBF, but the actual elapsed time is used as the total time in service
Inherent availability (AVI)	Fraction of calendar time that the component or unit was operating
Operating availability (AVO)	Fraction of time the component or unit can be expected to be operational excluding preventive maintenance

[a] Adapted from U.S. EPA (1982), WCPH (1996,1997).

effluent disinfection, with the required contact time taking place within the distribution system. The results of the process reliability analysis are presented in Table 4–8. As shown, the preliminary treatment process has the lowest MTBF. Typical problems experienced with the preliminary treatment facilities included: tripped breaker, packing leak, and gear box failure. With the exception of three treatment processes, the AVO for the remaining processes was greater than 0.99. The AVI was greater than 0.99 for all of the treatment process. Information such as presented in Table 4–8 can be used to determine maintenance schedules and the requirements for standby parts and backup components (WCPH, 1996, 1997).

Selection of Process Design Parameters to Meet Discharge Permit Limits

Because of the variations in effluent quality, treatment plants must now be designed to produce an average effluent concentration below the permit requirements. The question is what mean value should be used for process design to be assured that constituent concentrations in

Table 4–8

Summary statistics on the mechanical reliability for Aqua III[a,b]

	Statistical measure[c]			
Item	MTBF, y	90% CL MTBF, y	AVO	AVI
Preliminary (headworks)	0.35	0.57	0.9953	0.9998
Primary	0.82	0.65	0.9967	0.9981
Secondary	2.12	1 75	0.9757	0.9953
Package plant	2.24	1 78	0.9994	0.9995

[c] See Table 4–7 for definitions of statistical measures.

the effluent will be equal to or less than a specified limit with a specified degree of reliability? Two approaches can be used to estimate the design mean value needed to meet prescribed standards: (1) a statistical approach involving the coefficient of reliability and (2) a graphical approach. Both of these approaches are described and illustrated in the following discussion. Whether the mean value arrived at can be designed for is addressed subsequently.

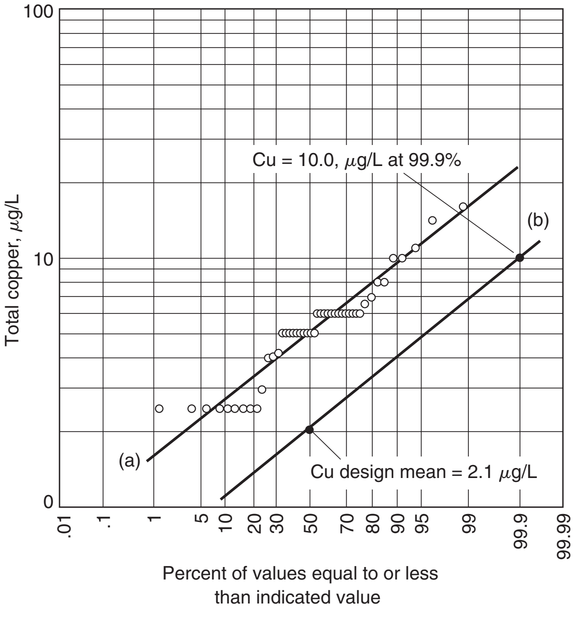
Statistical Approach to Selection of Mean Design Value. One approach that can be used to determine the mean design value involves the use of the coefficient of reliability (COR) approach developed by Niku et al. (1979, 1981). In the COR method, the mean constituent values (design values) are related to the standards that must be achieved on a probability basis. This method of analysis is documented in the 4th edition of this textbook.

Graphical Approach to Selection of Mean Design Value. Another method of determining appropriate mean design values to meet the specified effluent standards is the graphical probability method. If it is assumed that the geometric standard deviation can be used as a measure of reliability and that the value remains approximately constant at other design values, then the required effluent value can be set at the specified reliability level (e.g., 10 mg/L at 99 percent) and a line is passed through the value with the same geometric standard deviation as the measured data. The value at a probability value of 50 percent is the new mean design value.

The graphical approach is illustrated on Fig. 4–6. The plotted data correspond to the monthly total copper in the effluent from a wastewater treatment plant. If the permit limit is to be 10 μg/L at the 99.9 percent reliability value, that value is plotted and a line with the same geometric standard deviation is drawn through the point. The value at a probability of 50 percent on the line drawn through permit limit corresponds to the required mean design value, in this case 2.1 μg/L. For many constituents, it will be found that the required mean design value cannot be met with an existing process. Where the required mean value cannot be met with a single process, it may be necessary to use two or more treatment processes in series. The typical geometric standard deviation values given in Table 4–6 can also be used for the design of new treatment plants if the discharge permit limits are known.

Figure 4–6

Probability distributions:
(a) monthly efffluent total copper (Cu) samples collected over a period of two years and
(b) corresponding distribution to achieve 99.9 percent compliance with a copper limit of 10 mg/L, drawn with the same geometric standard deviation as the original distribution.



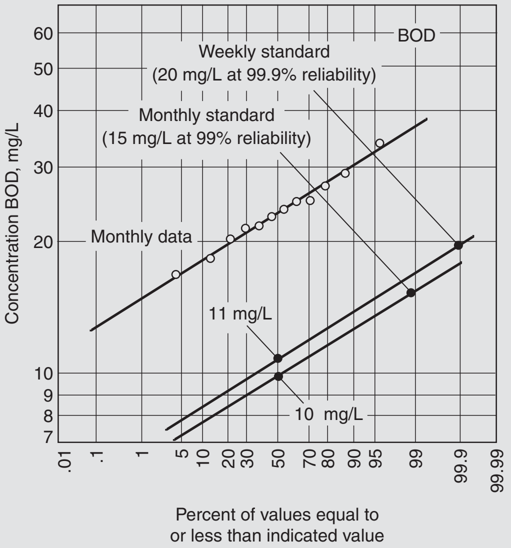
EXAMPLE 4–2 **Estimating Effluent Design BOD and TSS Concentrations Based on Reliability Considerations** An existing activated sludge plant is required to be expanded and upgraded to meet new permit requirements. The new effluent requirements are as given below. Determine the mean design effluent BOD and TSS concentrations required to meet the 99 percent reliability level for the monthly standard and the 99.9 percent reliability level for the weekly standard using the log-probability graphical method. Average monthly effluent BOD and TSS data for the existing facility for a period of one year are also given below.

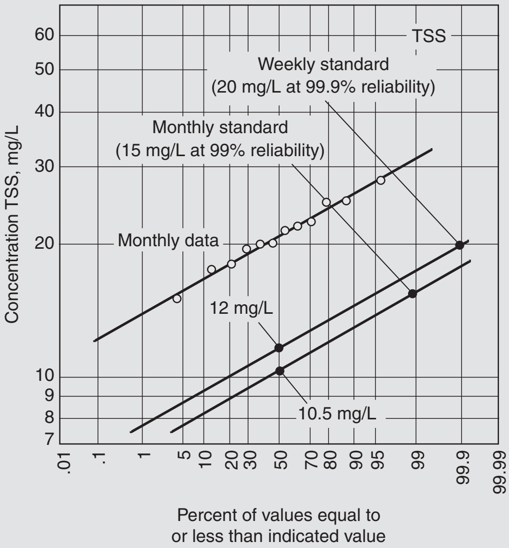
Constituent	Monthly mean	Weekly mean
BOD, mg/L	15	20
TSS, mg/L	15	20

Month	BOD, mg/L	TSS, mg/L
Jan	34.0	15.0
Feb	27.1	18.0
Mar	29.0	17.5
Apr	25.0	22.5
May	25.1	22.0
Jun	22.0	24.9
Jul	21.7	28.0
Aug	20.5	25.1
Sep	17.0	19.5
Oct	18.5	20.0
Nov	23.1	20.1
Dec	24.0	21.5

Solution

1. Plot the monthly data for BOD and TSS on log-probability paper. The required plots for BOD and TSS are shown below.





2. Estimate the design effluent concentrations for BOD and TSS for (a) 99 percent reliability for the monthly standard and (b) 99.9 percent reliability for the weekly standard.
   a. Determine the design effluent concentrations for BOD. The BOD concentrations are determined by passing lines with the same slope as the measured data through the points at 15 mg/L and 99% and 20 mg/L and 99.9% and noting the corresponding values at 50%. The values so determined are

$$\text{BOD}_{\text{design}} \text{ at } 15 \text{ mg/L and } 99\% = 10.0 \text{ mg/L}$$
$$\text{BOD}_{\text{design}} \text{ at } 20 \text{ mg/L and } 99.9\% = 11.0 \text{ mg/L}$$

b. Determine the design effluent concentrations for TSS. The TSS concentrations are determined by passing lines with the same slope as the measured data through the points at 15 mg/L and 99% and 20 mg/L and 99.9% and noting the corresponding values at 50%. The values so determined are
   $\text{TSS}_{\text{design}}$ at 15 mg/L and 99% = 10.5 mg/L
   $\text{TSS}_{\text{design}}$ at 20 mg/L and 99.9% = 12 mg/L

Comment When the concept of reliability is used, the mean effluent values selected for design will typically be significantly lower than permit requirements. Loge et al. (2001) demonstrated how the coefficient of variation was reduced (i.e. process variability) when processes are used in series with respect to the disinfection of treated effluent with ultraviolet radiation. Based on numerous past designs in England and Europe, it has been found that to achieve the prescribed limit at the 95 percent level the average design value should be about 50 percent of the prescribed limit.

Performance of Combined Processes

Applying either the statistical or the graphical procedures as illustrated in Example 4–2, it will often be found that the resulting mean design value for a given process is well below the range where any factual knowledge exists on how to design the process. For example, assume that to meet NPDES permit requirements, an activated sludge process must be designed to meet an average effluent suspended solids concentration of 4 mg/L. The fact is that it is difficult, if not impossible, to design a secondary clarifier to meet a specific design value. What is typically assumed is that with good design and effective operation of the secondary process, an average value of 4 or 5 mg/L can be achieved. Unfortunately, such assumptions are not acceptable when not-to-exceed permit limits must be met. In such a situation, it will usually be necessary to add an additional process, such as depth or surface filtration, to meet the permit requirements consistently. In the following example, the basis for determining the performance of the combined treatment processes is addressed.

EXAMPLE 4–3 **Estimating the Performance of Combined Treatment Processes Based on Reliability Considerations** Estimate the combined performance at the 98.3, 99.2, and 99.9 percent levels for an activated sludge process followed by a granular medium depth filter with respect to the removal of TSS and turbidity. Assume the following data apply to the activated sludge process. Also, assume that no chemicals are to be used with the depth filter.

1. Distribution for effluent TSS is log-normal
2. Geometric mean for effluent TSS, $M_g = 15$ mg/L
3. Geometric standard deviation for TSS, $s_g = 1.25$
4. $s_g = P_{84.1}/P_{50}$

Also assume the following relationship can be used to describe the performance of the filter.

Filter effluent turbidity, NTU = 0.5 NTU + 0.2 (filter influent turbidity, NTU)

Solution

1. To determine the TSS values after filtration, use the following relationships as given in Chap. 2.
   a. Secondary effluent TSS, mg/L = (2.3 mg/L/NTU) (effluent turbidity, NTU) [Eq. (2–18)]
   b. Filter effluent TSS = (1.4 mg/L/NTU) (filter effluent turbidity, NTU) [Eq. (2–18)]

2. Using the above relationships, determine the values corresponding to 50 percent and 84.1 percent (one standard deviation) after filtration
   a. At 50 percent
      i. Secondary effluent turbidity = (15 mg/L)/(2.3 mg/L/NTU) = 6.52 NTU
      ii. Filter effluent turbidity = 0.5 NTU + 0.2(6.52 NTU) = 1.8 NTU
      iii. Filter effluent TSS = (1.4 mg/L/NTU) (1.8 NTU) = 2.52 mg/L
   b. At 84.1 percent [use Eq. (D-9) from Appendix D]
      i. $P_{84.1} = P_{50} \times s_g = 15 \text{ mg/L} \times 1.25 = 18.75 \text{ mg/L}$
      ii. Secondary effluent turbidity = (18.75 mg/L)/(2.3 mg/L/NTU) = 8.15 NTU
      iii. Filter effluent turbidity = 0.5 NTU + 0.2(8.15 NTU) = 2.13 NTU
      iv. Filter effluent TSS = (1.4 mg/L/NTU) (2.13 NTU) = 2.98 mg/L
3. Plot the secondary effluent TSS and the filter effluent turbidity and TSS and prepare a summary compliance table.
   a. Log-probability plot

   b. Summary table

Item	Unit	Value at indicated probability		
		98.3%	99.2%	99.9%
TSS	mg/L	2.6	2.9	4.2
Turbidity	NTU	2.5	2.8	3.0

Comment As shown in the above summary table, for six-TSS exceedance events per year (which corresponds to 98.3 percent probability) the TSS concentration would be equal to or greater than 2.6 mg/L, for three TSS exceedance events per year (99.2 percent probability) the TSS concentration would be equal to or greater than 2.9 mg/L and for one-TSS exceedance event in three years (99.9 percent probability) the TSS concentration would be equal to or greater than 4.2 mg/L. If a turbidity level of 2 NTU had to be met for reuse applications, the 2-NTU limit would be exceeded 25 percent of the time, without the use of additional treatment.

4–4 ELEMENTS OF PROCESS DESIGN

Treatment process design is undertaken simultaneously with the selection of the treatment process and appropriate design coefficients based on the wastewater flowrate and characteristics and treatment objectives and goals. The principal elements of process design are (1) establishing the design period for facilities, (2) development of the process flow diagram, (3) establishing process design criteria, (4) preliminary sizing of treatment units, (5) preparation of solids balances, (6) site layout considerations, (7) evaluation of plant hydraulics (hydraulic profile), and (8) energy management. Each of these elements are introduced and discussed in this section.

Design Period

The design period corresponds to the target date when the design capacity of the facilities is reached. Design periods may vary for individual components, depending upon the ease or difficulty of expansion. Typical design periods for various types of facilities are given in Table 4–9. Longer periods are preferred for structures and hydraulic conduit systems, which cannot be expanded easily. The selection of the design period depends upon growth characteristics, environmental considerations, and the availability and source of construction funds.

Treatment Process Flow Diagrams

Treatment process flow diagrams are graphical representations of particular combinations of unit operations and processes. Depending on the constituents that must be removed, an almost limitless number of different flow diagrams can be developed by combining various unit processes. Apart from the analysis of the suitability of the types of individual treatment units, the exact configuration of process units selected will also depend on factors such as (1) the designer's past experience, (2) design and regulatory agency policies on the application of specific treatment methods, (3) the availability of suppliers of equipment for specific treatment methods, (4) the maximum use that can be made of existing facilities, (5) initial construction costs, and (6) future operation and maintenance costs. A typical process flow diagram for the treatment of wastewater to meet secondary treatment standards, as defined by the U.S. EPA is shown on Fig. 4–7(a).

Process Design Criteria

After one or more preliminary process flow diagrams have been developed, the next step is to determine the process design criteria for the selected treatment processes so that the size of the physical facilities can be determined. The hydraulic detention time would be an

Table 4–9

Typical design periods for wastewater treatment facilities

Facility	Planning period range, y
Collection Systems	20–40
Pump stations	
Structures	20–40
Pumping equipment	10–20
Treatment plants	
Process structures	20–40
Process equipment	10–20
Hydraulic conduits	20–40

Figure 4–7

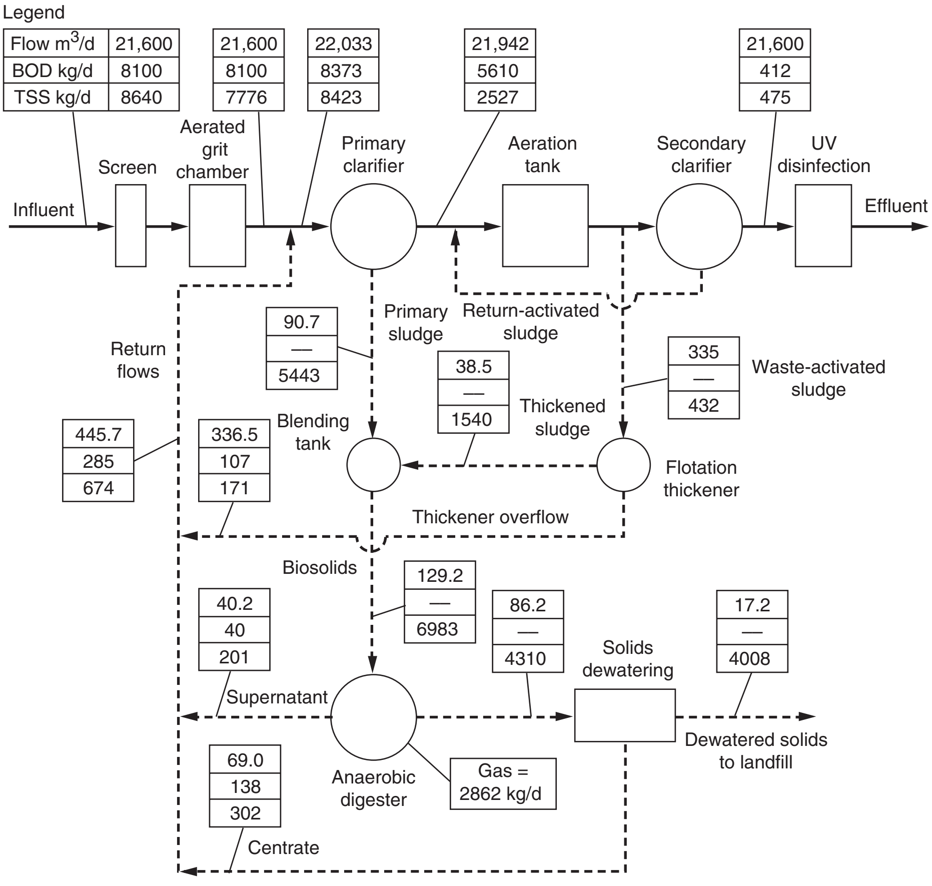
example of the process design criteria for the grit chamber. Similar procedures are followed for each unit process. All the key design criteria should be listed in a summary table. Because most treatment plants are designed to be effective for some time in the future (up to 40 y), design criteria are given generally for the time when the facilities will first be put into operation, and for the end of the design period. The latter will be influenced by projections of the population to be served and the economic studies of cost effectiveness for various design periods.

Preliminary Sizing

After the design criteria have been established, the next step is to determine the number and size of the physical facilities needed. For example, if the hydraulic detention time in the aerated grit chamber shown on Fig. 4–7(a) is to be 3.5 min at a peak flowrate, the corresponding grit chamber volume required would be calculated. In considering sizing, physical site constraints need to be considered: for example, will the site accommodate the use of round sedimentation tanks or will rectangular tanks have to be used? Operational considerations such as flow splitting and load balancing will have to be evaluated, particularly in process trains that combine different numbers of unit processes—for example, two primary clarifiers and three aeration tanks. Maintenance factors have to be considered in selecting the number of units so that provisions are included for taking a unit out of service for maintenance and repair. In small plants where a single unit is being considered, maintenance of that unit may be a particular problem unless special provisions, such as temporary storage, are included.

Solids Balance

After the design criteria are established and the preliminary sizing is completed, solids balances should be prepared for each process flow diagram. They should be prepared for the average load with appropriate peaking factors applied for maximum loads. Such information must be available to size (1) sludge thickening and storage facilities, (2) sludge digesters, (3) sludge dewatering facilities, (4) thermal reduction systems, (4) composting facilities, and (5) sludge piping and pumping equipment and other appurtenant facilities. The solids balance for the flow diagram shown on Fig. 4–7(a) is presented on Fig. 4–8. The details involved in the preparation of the solids balance are illustrated in Chap. 14.



Solids balance for second iteration

Figure 4–8

Results of solid mass balance for the treatment process flow diagram shown on Fig. 4–7. Computational details are presented in Sec. 14–7 in Chap. 14.

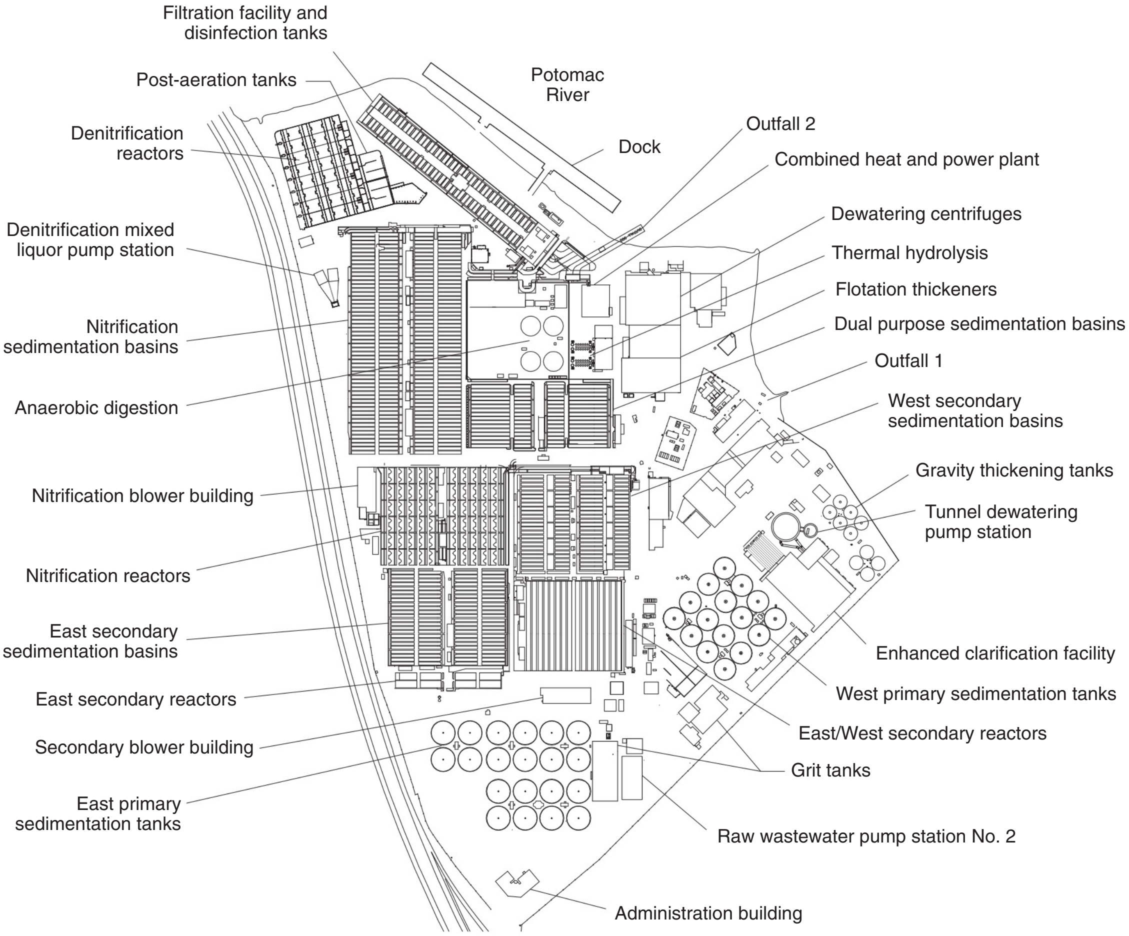


Figure 4–9

Layout of the Blue Plains Advanced Wastewater Treatment Plant with a capacity 16.2 m^3/s (370 Mgal/d) serving the Washington, DC area and environs. (Coordinates: 38.8178 N, 77.0220 W, view at altitude 4 km, also shown on the cover of this book.)

Plant Layout

Plant layout refers to the spatial arrangement of the physical facilities required to achieve a given treatment objective. The overall plant layout includes the location of the control and administrative buildings and any other necessary structures. Several different layouts, using computer generated overlays, are normally evaluated before a final selection is made. Among the factors that must be considered when laying out a treatment plant are the following: (1) geometry of the available treatment plant sites, (2) topography, (3) soil and foundation conditions, (4) location of the influent sewer, (5) location of the point of discharge, (6) plant hydraulics, preferably with straight flow paths between units to minimize headloss and provide symmetry for flow splits, (7) types of processes involved, (8) process performance and efficiency, (9) transportation access, (10) accessibility to operating personnel, (11) reliability and economy of operation, (12) aesthetics, (13) environmental control, and (14) provisions for future plant expansion including additional area. The physical layouts for a small and large wastewater treatment plant are shown on Figs. 4–7(b) and 4–9, respectively. The layout shown on Fig. 4–7(b) corresponds to the flow diagram shown on Fig. 4–7(a). The plant layout shown on Fig. 4–9 is of the large Blue Plains Wastewater Treatment Plant, Washington, DC, which includes a number of advanced treatment processes.

Plant Hydraulics

After the process flow diagram has been selected and the size of the corresponding physical facilities is determined, hydraulic computations and profiles are prepared for both average and peak flowrates. Hydraulic computations are made to size the interconnecting conduits and channels and to compute the headlosses through the plant. Typical ranges of headlosses through treatment units are given in Table 4–10. In designing the plant hydraulic system, consideration needs to be given to (1) equalizing the flow splitting between the treatment units, (2) making provisions for bypassing secondary treatment units at extreme peak flows to prevent loss of biomass, (3) provision for removing treatment facilities during periods of sustained low flow, and (4) minimizing the number of changes in direction of wastewater flow in conduits and channels.

Hydraulic profiles are prepared for three reasons: (1) to ensure that the hydraulic gradient is adequate for the wastewater to flow through the treatment facilities by gravity, (2) to establish the head requirement for the pumps where pumping will be needed, and (3) to ensure that the plant facilities will not be flooded or backed up during periods of peak flow. The hydraulic profile for the flow diagram given on Fig. 4–7 is shown on Fig. 4–10. In preparing a hydraulic profile, distorted vertical and horizontal scales are commonly used to depict the physical facilities.

Hydraulic profile computations involve the determination of the headloss as the wastewater flows through each of the physical facilities in the process flow diagram. Specific computational procedures may vary depending on local conditions. For example, if a downstream discharge condition is the control point, some designers prepare the hydraulic profile by working backward from the control point. Other designers prefer to

Table 4–10

Typical headlosses across various treatment units[a]

	Headloss range	
Treatment unit	**ft**	**m**
Bar Screen	0.5–1.0	0.2–0.3
Grit chambers		
Aerated	1.5–4.0	0.1–1.2
Velocity controlled	1.5–3.0	0.5–0.9
Primary sedimentation	1.5–3.0	0.5–0.9
Aeration tank	0.7–2.0	0.2–0.6
Trickling filter		
Low-rate	10.0–20.0	3.0–6.1
High-rate, rock media	6.0–16.0	1.8–4.9
High-rate, plastic media	16.0–40.0	4.9–12.2
Secondary sedimentation	1.5–3.0	0.5–0.9
Filtration	10.0–16.0	3.0–4.9
Carbon adsorption	10.0–20.0	3.0–6.1
Chlorine-contact tank	0.7–6.0	0.2–1.8

[a] The reported values do not reflect designs optimized for minimum energy usage.

work from the head end of the plant. Still others work from the center in each direction, adjusting the elevations at the end of the computations. The use of mathematical models and digital computers allow many possible hydraulic conditions to be analyzed.

Energy Management

Water and wastewater utilities in the United States consume about 2 to 4 percent of the total amount of electricity produced (WEF 2010a). Typically, 30 percent of the operating cost of a wastewater treatment plant is budgeted for energy use. During the next 20 to 30 y

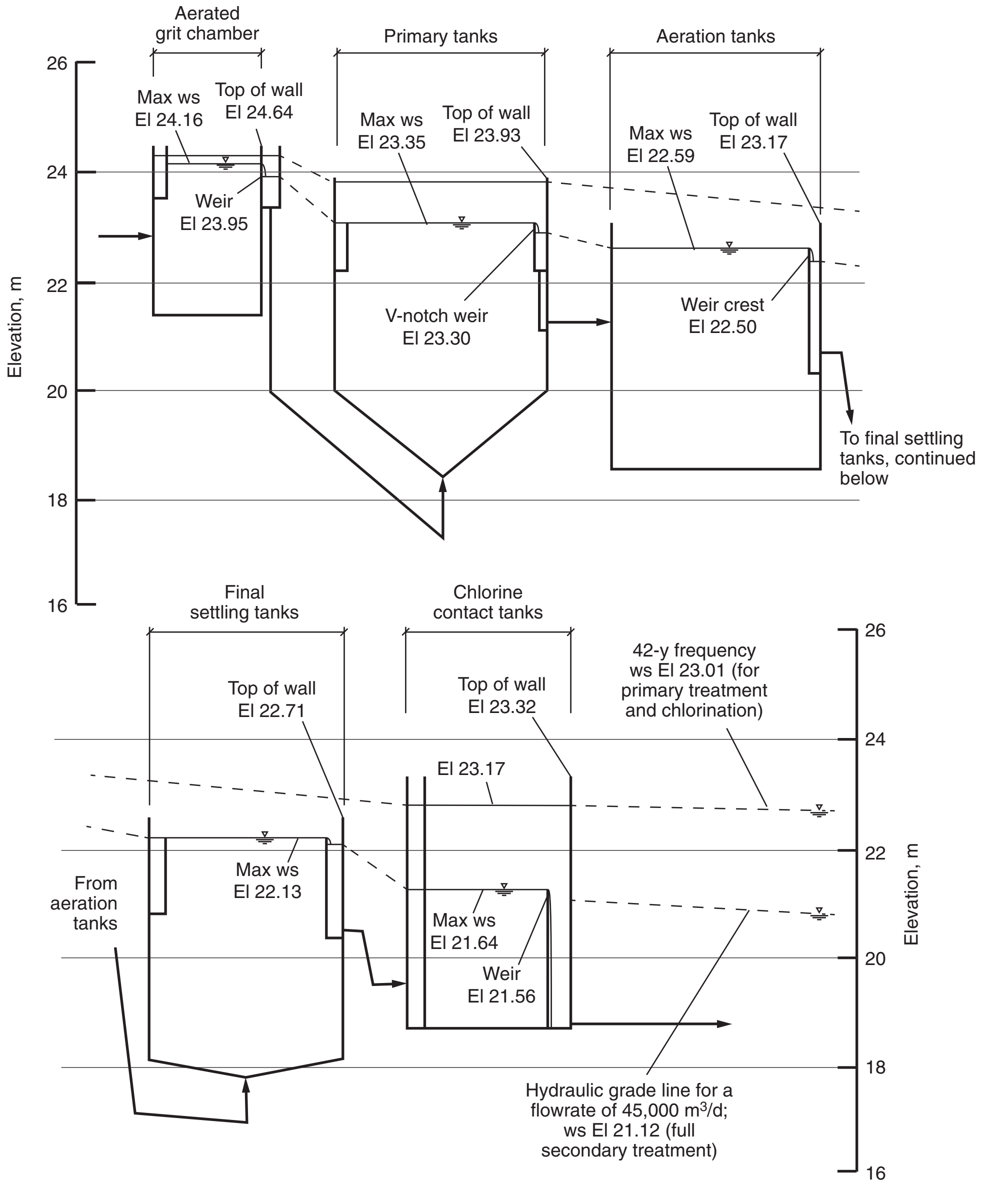

Figure 4–10

Hydraulic profile for wastewater treatment plant shown schematically on Fig. 4–7.
Note: ws = water surface, El = elevation.

the electricity requirements for wastewater treatment in the United States are expected to increase an additional 30 to 40 percent. In an era where there are concerns about the adequacy of fuel supplies, cost of energy, and the increasingly higher levels of treatment that result in increased energy consumption, the design and operation of wastewater treatment plants is focused increasingly on improving the efficiency of electric energy use and reducing the cost of treatment. Thus, the importance of energy usage and procurement in wastewater treatment cannot be overstated. Reference to energy usage and management is a constant theme throughout this book. A comprehensive analysis of the use of energy in wastewater treatment and the measures that can be employed to improve energy efficiency is presented in Chap. 17.

4–5 IMPLEMENTATION OF WASTEWATER MANAGEMENT PROGRAMS

Many of the major considerations in the overall design process and wastewater management programs are detailed in WEF (2010b). The principal elements of a wastewater management program, highlighted in this section, include (1) facilities planning, (2) design, (3) value engineering, (4) construction, and (5) startup and operation. Most major projects having a construction cost over \$10 to 20 million typically follow all steps. Smaller projects (less than \$10 million) may not include the value engineering step, although some simplified form of value engineering is highly desirable.

Facilities Planning

A facilities plan is a document established to analyze systematically the technical, economic, environmental, and financial factors necessary to select a cost-effective wastewater management plan. While the facilities plan itself may include an environmental impact assessment on major projects, the environmental assessment is usually a separate document. The scope of the facilities plan includes (1) defining the problem; (2) identifying life expectancies of major elements (usually 20–25 y for equipment and 50 y for structures); (3) defining, developing and analyzing alternative treatment and disposal systems; (4) selecting a plan; and (5) outlining an implementation plan including financial arrangements and a schedule for design and construction. The ultimate objective of a facilities plan is a well-defined, cost-effective, and environmentally sound project capable of being implemented and being acceptable to taxpayers and regulatory authorities. For more details about preparation of a facilities plan, U.S. EPA (1985) may be consulted.

Design

Following facilities planning, the approach used generally for designing a facility consists of conceptual design, preliminary design, special studies, and final design. The conceptual design is used to finalize the preliminary design criteria used in the facilities plan, to establish preliminary facilities layouts, and to define the necessary field investigations required such as surveys and geotechnical studies. The preliminary design is an expansion of the conceptual design and defines fully the facilities to be included in the project so that final design can proceed. Special studies may include field studies or testing necessary for the development of design criteria. The final design involves the production of the detailed contract plans and specifications used to bid and build the project. Mitigation measures may also be included in the design to reduce or lessen unavoidable environmental impacts. Because the design approach varies with the type and size of the project, only a general outline of the design process is provided in this text.

Value Engineering

Value engineering (VE) is an intensive review of a project to determine best value, or value improvement, which may or may not result in cost reduction. The purpose of the VE analysis is to obtain the best project at the least cost without sacrificing quality or reliability. Depending on the size and complexity of the project, the VE effort may vary from one team and one review session to multiple teams and multiple reviews. For large projects, two review sessions are usually held, each lasting about one week: one at approximately the 20 to 30 percent stage of design completion, and a second at the 65 to 75 percent stage. The VE team members are senior professionals who are not involved with the design of the project. For detailed information about the VE process, U.S. EPA (1985) may be consulted.

Construction

The quality of the design plans and specifications are often measured by (1) ease of integration of new facilities into existing sites, (2) clarity of presentation that allows contractors to submit bids with small allowances for undefined or unforeseen conditions, (3) specification of high quality materials of construction to ensure a long useful life of the facilities, (4) timely completion of the work, and (5) minimization of changes required during construction. Some of the construction considerations and management techniques for construction are discussed below.

Construction Considerations. In the preparation of the final plans and specifications, the design engineer must consider many of the details of construction. Some of the principal considerations are (1) how will the plant be built, (2) how will it interface with existing facilities, and (3) what will be the materials of construction. The buildability of a set of plans will be reflected in the bid price and the number of changes that must be made during construction. Numerous changes can result in costly change orders. Integrating a new facility with an existing one may present problems in (1) maintaining operations during construction, (2) continuing treatment at a level that will not violate discharge permit requirements, and (3) avoiding safety hazards to personnel. The construction contract must define clearly how these issues are addressed.

In selecting materials of construction, three principles are fundamental to the engineering design of process oriented facilities: (1) durability—the life of the equipment is expected to last at least 20 y, and up to 50 y for structures; (2) reliability—good quality materials and equipment to minimize maintenance and replacement; and (3) environmental suitability—realizing that wastewater and its attendant chemicals may be corrosive. For these reasons, most process structures are constructed of reinforced concrete and other materials of construction are selected based upon their corrosion-resistant properties. For information about materials of construction for wastewater treatment plants, WEF (2010a) may be consulted.

Construction and Program Management. Techniques used to ensure timely construction of the project in accordance with the plans and specifications include construction management and program management. Construction management usually provides review of the contract plans and specifications and management oversight of the construction contractor's operations. The purposes of construction management are to (1) verify the technical adequacy, operability, and constructability of the plans and specifications before construction begins; (2) establish construction schedules consistent with the program objectives and to optimize cash resources; (3) review the contractor's operation to ensure conformance with the plans and specifications; and (4) control change orders and possible construction claims. Program management differs from construction management in that it provides a single source of responsibility and authority (accountable to the owner) for the management, planning, engineering, permitting, financing, construction, and startup operations of the total wastewater management program. Program management is often used in very large projects or projects that are privatized (see Sec. 4–6).

Facilities Startup and Operation

Some of the principal concerns in wastewater engineering relate to the startup, operation, and maintenance of treatment plants. The challenges facing the design engineer and the treatment plant operator are (1) providing, operating, and maintaining a treatment plant that consistently meets its performance requirements; (2) managing operation and maintenance costs within the required performance levels required; (3) maintaining equipment to ensure proper operation and service; and (4) training operating personnel. Therefore, the design has to be done with the operations in mind, and the plant has to be operated in accordance with the design concept. One of the principal tools used for plant startup, operation, and maintenance is the operations and maintenance (O&M) manual. The purpose of an O&M manual is to provide treatment system personnel with the proper understanding, recommended operating techniques and procedures, and references necessary to efficiently operate and maintain their facilities. The design engineer usually has the lead responsibility in preparing the O&M manual.

4–6 FINANCING

As discussed earlier in this chapter, the traditional funding sources for wastewater treatment plants have changed. The U.S. government has provided grants for construction of treatment facilities for over 40 y. The 1987 Water Quality Act included a transition program that phased out the construction grants program and phased in a state revolving loan fund program. The revolving loan program pays only a portion of the costs; the wastewater agencies have to provide the balance. Therefore, cities, towns, and small communities have to investigate their funding options carefully to determine what is the most economical financing method for them. Alternative financing methods that are used commonly include (1) long-term municipal debt financing (with or without federal or state grants or loans), (2) non-debt financing, (3) leasing, and (4) private financing (privatization). Asset management, as described in Chap. 18, may be adopted to maximize the long-term benefits of the investment while maintaining the level of services provided. Because financing is becoming more integrally involved with wastewater treatment design, construction, and operation, a brief discussion of the financing methods is provided in this section.

Long-Term Municipal Debt Financing

For projects with major capital expenditures, public agencies often use long-term debt to spread the cost of the project over a number of years. Long-term financing mechanisms include general obligation bonds, limited or special obligation bonds, revenue bonds, special assessment bonds, industrial development bonds, locally issued bonds, and small denomination bonds called "mini-bonds." Of these options, general obligation and revenue bonds are used most frequently. General obligation bonds are debt instruments backed by the full faith and credit of the issuing agency. The bonds are secured by an unconditional pledge of the issuing agency to levy unlimited taxes to meet the bond obligations. Revenue bonds are used to finance projects that generate revenue and are expected to be self-sustaining. Principal and interest charges are paid from the revenues; no taxes are levied. Tax exempt bonds result in lower interest rates as the earnings are not subject to federal or local taxes. The 1984 and 1986 tax acts substantially limit the ability of agencies to issue debt that is fully tax exempt by restricting the use of bond proceeds. To increase the marketability of bonds and revenue, several features or variations may be added to the bond structure. Also, to reduce risk during periods of uncertain economic conditions, municipal bond insurance and letters of credit may be used to enhance the credit-worthiness of the bonds.

Non-Debt Financing

Non-debt financing is a method of generating revenues from system charges and is sometimes called "pay-as-you-go" financing. The funds generated annually by rates or charges that are not used for operations and maintenance or for debt payments can be used to finance new construction. Techniques used in non-debt financing may be connection charges, special assessments, system development charges, and increasing rates in advance of construction. This method of financing may be the limited to smaller projects depending upon the amount of funds that can be generated by these techniques.

Leasing

Leasing is an alternative form of facility financing that has limited application for wastewater treatment facilities. Leasing is complex, involving tax benefits to the lessor and tax implications to the lessee. The tax acts of 1984 and 1986 substantially reduced the benefits of tax-oriented leasing. Therefore, the legal and tax consequences have to be investigated carefully before undertaking a lease. In some cases, leases may be attractive for municipal agencies as a means of acquiring needed facilities and equipment where debt limitations restrict direct purchase and ownership. Many leases include an option to buy at the end of the contract period as an ultimate ownership feature.

Privatization

Privatization refers to private sector ownership and operation of facilities and services used by government entities in performing their public function (SERC, 2004). The term privatization came into vogue after the federal income tax amendments of 1981. The tax act focused attention on private sector tax benefits that could be shared with the public sector, thereby lowering the cost of facilities for the public sector and reducing user fees. In addition to cost savings, privatization may offer advantages in construction and operating efficiencies and in meeting effluent standards. Construction efficiencies may be realized by reduced construction time, greater flexibility in flow-matching the sizing to meet current needs, and the increased use of modular designs.

The overall result of privatization is, in most cases, a reduction in life cycle cost. Reductions as high as 20 to 30 percent have been achieved as compared to conventionally financed, constructed, and operated projects. Operating efficiencies may result under private operation by centralized administration, bulk ordering of chemicals and supplies, and sharing of key personnel among multiple facilities. Assurances in meeting effluent standards may be provided by the resources available from the private operator such as required management skills and trained operating personnel.

PROBLEMS AND DISCUSSION TOPICS

4–1 Prepare a brief summary of the history of wastewater treatment in your community. Identify major events that helped to bring about change, or improvements. If any of the events were related to crisis situations, try to assess whether the same result would have been achieved with proper planning.

4–2 If an EIR was prepared for the construction of your local wastewater treatment plant, obtain a copy and review it specifically with respect to the recommendations made concerning odor and energy management. Are the findings or recommendations made in light of today's concerns?

4–3 The current construction cost for a small wastewater treatment plant is estimated to be $\$5 \times 10^6$. If the construction of the plant is to be delayed 5 or 10 y (to be selected by instructor), estimate the cost when the plant will be constructed in the future. Use end-of-year ENRCCI values in making your projection.

4–4 Determine the year when your local wastewater treatment plant was constructed or expanded and its construction costs. What would the cost be to construct or expand the plant today? What has been the average rate of inflation from the time your plant was constructed to the present?

4–5 If the energy usage of an advanced secondary treatment plant, incorporating nutrient removal, is 2400 mJ/10^3 m^3 (2500 kWh/Mgal), estimate the annual cost for energy for a 4000 m^3/d wastewater treatment plant using your local electrical cost.

4–6 Search the literature and find 3 probability plots of effluent characteristics. How do the reported reliabilities compare with the values given in Table 4–6?

4–7 A superintendent of a wastewater treatment plant has requested that his staff collect and analyze 6 effluent samples of a specific constituent for submittal to the regulatory agency. If the regulatory agency, in turn, sets the not-to-be-exceeded value (i.e., 99.9 percent) in the effluent discharge permit at the maximum value measured in the 6 samples, has the superintendent potentially shot himself in the foot? Explain and illustrate your analysis.

4–8 Using the data in Table 4–5, estimate the total logs of removal for coliphage with a treatment process composed of activated sludge followed by microfiltration and reverse osmosis for influent coliphage concentrations of 20,000, 40,000, 28,000, 50,000 pfu (plaque forming units)/100 mL (value to be selected by instructor). Assume no removal of coliphage through the microfilter and that the logs of removal achieved with the particular reverse osmosis membrane used are 2, 3.2, 3.0, or 3.7 (log removal value to be selected by instructor). What is the removal achieved at 99 and 99.9 percent reliability?

4–9 The following monthly effluent constituent concentrations have been obtained from four different existing activated sludge treatment plants. Each of these plants is to be replaced with a new plant to meet new and more stringent discharge requirements. For one of these plants (to be selected by instructor), determine the mean design value assuming the following maximum monthly permit limits must be met: (a) BOD and TSS = 15 mg/L at 99 and 99.9 percent reliability, (b) BOD and TSS = 10 mg/L at 99 and 99.9 percent reliability, (c) BOD = 5 mg/L and TSS = 8 mg/L at 99 and 99.9 percent. On average, what percentage improvement would be required to meet the new discharge permit requirements. In your opinion, is the percentage improvement reasonable?

	Constituent concentration, mg/L							
	Treatment plant number							
	1		2		3		4	
Month	BOD	TSS	BOD	TSS	BOD	TSS	BOD	TSS
Jan	11.0	14.0	4.0	5.0	10.0	40.0	8.4	6.5

4–10 Average monthly performance data have been collected over a period of a year for an activated sludge process treating primary settled effluent followed by depth filters operated in parallel. Using these data, estimate what overall average monthly removal would be expected with the activated sludge process followed by one of the depth filters (to be selected by instructor) assuming the influent constituent concentration is 150, 200, 275, or 300 mg/L (to be selected by instructor).

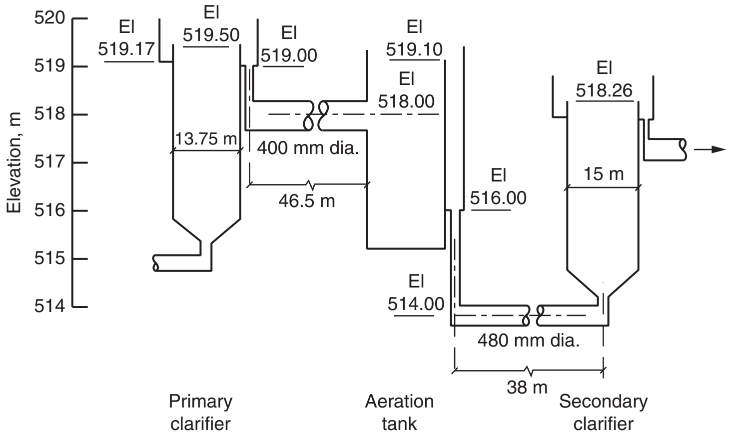
4–11 An existing conventional activated sludge wastewater treatment plant having a design capacity of 15,000 m^3/d is considering upgrading their existing solids processing facilities to include either aerobic digestion or anaerobic digestion. List the factors the design engineer will have to consider in selecting the process and comment on the energy implications associated with the process selection.

4–12 Develop the hydraulic profile for average and peak flow conditions for the schematic portion of the wastewater treatment plant shown below. Assume that the recycle sludge is returned directly to the aeration tank, that 90° v-notch weirs are used around the periphery of the primary and secondary clarifiers and that the overflow weir in the aeration tank is a Francis type with two end contractions. Other pertinent data and information are as follows:

Q_{avg} = 4000 m^3/d plus 100 percent sludge recycle
Q_{peak} = 8000 m^3/d plus 50 percent sludge recycle

Q_{low} = 2000 m^3/d plus 100 percent sludge recycle
Spacing of v-notch weirs = 600 mm
Width of aeration-tank effluent weir = 1400 mm



4–13 Referring to the portion of the wastewater treatment plant given in Problem 4–12, develop the hydraulic profile for peak and low flow conditions for the following conditions:

Q_{avg} = 7500 m^3/d plus 100 percent sludge recycle
Q_{peak} = 15,000 m^3/d plus 50 percent sludge recycle
Q_{low} = 2500 m^3/d plus 100 percent sludge recycle
Number of primary and secondary clarifiers = 2 each
Diameter of line from aeration tank to each clarifier = 400 mm
Spacing of v-notch weirs = 600 mm
Width of aeration-tank effluent weir = 1400 mm

4–14 Based on a tour of your local wastewater treatment plant, what consideration was given to energy conservation in the design of your local wastewater treatment plant? What, if anything, is being done currently to bring about a reduction in the use of energy?

5

Physical Unit Processes

WORKING TERMINOLOGY

Term	**Definition**
Absorption	The process by which atoms, ions, molecules, and other constituents are transferred from one phase and are distributed uniformly in another phase (see also adsorption).
Adsorption	The process by which atoms, ions, molecules, and other constituents are transferred from one phase and accumulate on the surface of another phase (see also absorption).
Air stripping	The removal of volatile and semi-volatile contaminants from a liquid by passing air and liquid counter-currently through a packed tower.
Ballasted flocculation	A process in which a flocculation aid and a ballasting agent, typically a silica microsand, are used to form dense microfloc particles, which settle rapidly.

Term	Definition
Blowers	Low-pressure air compressors that are used to deliver large quantities of air to aeration tanks to sustain biological activity.
Comminutors	In-stream grinders used for size reduction of coarse solids in wastewater.
Computational fluid dynamics (CFD)	A series of algorithms and computations used to predict or validate the behavior of liquids or gases flowing over or through constructed surfaces.
Desorption	The removal of gas from a liquid.
Diffusers	Devices used for dispersing air in a liquid.
Dissolved-air flotation (DAF)	The removal of particulate matter by attaching the particles to a blanket of rising air bubbles in a specially designed flotation tank.
Dispersed-air flotation (sometimes called induced air flotation)	The removal of oil and grease, principally in industrial wastewater, by inducing air into the wastewater by a downward pumping action; oil and solids attach to fine bubbles, which rise to the surface and are skimmed off.
Flocculation	A process by which small particles in a suspension increase in size resulting from particle collisions; flocculation is enhanced usually by gentle stirring.
Grinders	Devices used for the size reduction of coarse solids after the solids have been removed from the wastewater stream, usually by a bar screen.
Grit	Sand, gravel, cinders, other heavy inorganic materials and also organic matter such as eggshells, bone chips, seeds, and coffee grounds.
Grit chambers	Tanks designed for the removal of grit in wastewater by gravity sedimentation, helical flow, or centrifugal force.
Grit classifier (sometimes called a grit washer)	A mechanical device that uses an inclined screw or reciprocating rake to wash putrescible organics from grit.
Headloss	Energy loss for a fluid moving through a conduit, structure, or screening device caused by friction and/or turbulence.
High-rate clarification	A physical/chemical treatment process that employs special flocculation and sedimentation systems to achieve rapid settling; ballasted flocculation and tube or inclined-plate settlers are often used.
Lamella-plate clarification	A counter-current settling process in which a series of inclined plates enhance the separation of solids from clear liquid (supernatant).
Mass transfer	The transfer of material from one homogeneous phase to another; aeration, gas stripping, and adsorption are examples of mass transfer.
Mechanical aerators	Devices used to agitate water to promote mixing with atmospheric air or high purity oxygen in the head space of high purity oxygen activated sludge tank.
Mixing	The agitation of a liquid-solids suspension for the purpose of blending the mixture and keeping solids in suspension, entraining gases, or for accelerating a chemical reaction.
Preliminary treatment	Treatment steps (e.g., comminution, screening, grit removal, and preaeration) that prepare wastewater influent for further treatment.
Primary sedimentation	Customarily the first step in the wastewater treatment process in which significant amounts of suspended solids are removed by gravity sedimentation.
Screenings	Coarse material greater than 6 mm (0.25 in.) comprised of debris such as rocks, branches, pieces of lumber, leaves, paper, tree roots, plastics, bottles, cans, and rags.
Screens	Devices used to retain coarse materials (screenings) contained in wastewater; types of screens include coarse screens, fine screens, and microscreens.

Term	Definition
Sedimentation basins (also called clarifiers)	Circular or rectangular tanks that provide quiescent conditions to allow gravity settling of solid particles.
Short circuiting	Deviations from ideal flow patterns in tanks that results in shortened residence times and increased solids carryover.

Processes used for the treatment of wastewater in which change is brought about by means of or through the application of physical forces are known as *physical unit processes*. Because physical unit processes were derived originally from observations of the physical world, they were the first treatment methods to be used. Today, the physical unit processes shown on Fig. 5–1 are a major part of most wastewater-treatment systems. The physical unit processes most commonly used in preliminary and primary treatment of wastewater include some or all of the following (1) screening, (2) coarse solids reduction (comminution, maceration, and screenings grinding), (3) mixing and flocculation, (4) gravity separation, (5) grit removal, (6) primary sedimentation, (7) high-rate clarification, and (8) flotation. These topics are considered in the first 8 sections of this chapter.

New approaches for primary treatment involving physical unit processes are introduced in Sec. 5–9. The fundamentals of gas transfer discussed in Sec. 5–10 and aeration

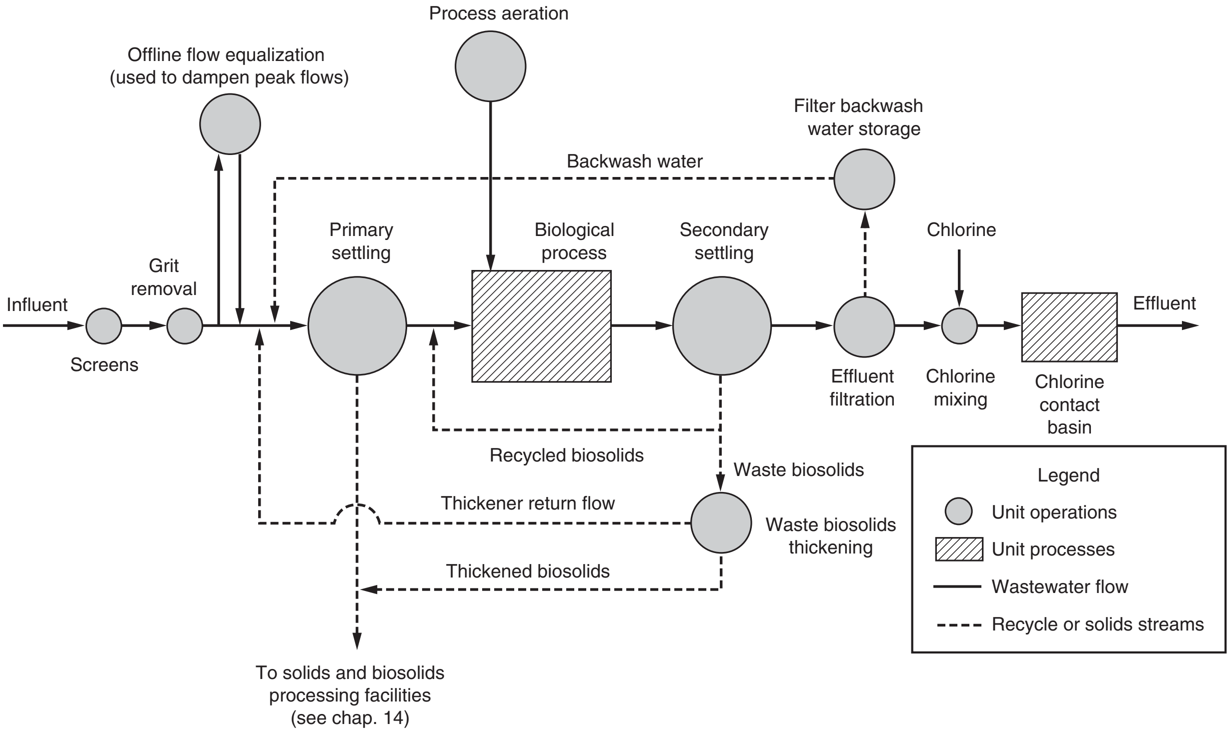

Figure 5–1

Location of physical unit operations in a conventional wastewater treatment plant flow diagram.

systems discussed in Sec. 5–11 are of critical importance in the biological treatment of wastewater discussed in Chaps. 7, 8 and 10, which follow. Physical unit processes that apply to advanced wastewater treatment systems such as depth and surface filtration, membrane separation systems, and ammonia stripping are discussed separately in Chap. 11. Unit processes associated with the processing of solids and biosolids (sludge) are covered in Chap. 13. The principal applications of these processes and treatment devices used in their implementation are summarized in Table 5–1.

Table 5–1

Typical physical unit processes used for wastewater treatment

Operation	Application	Device	See Section
Screening, coarse	Removal of coarse solids such as sticks, rags and other debris in untreated wastewater by interception (surface straining)	Bar Rack	5–1
Screening, fine	Removal of small particles	Fine Screen	5–1
Screening, micro	Removal of fine solids, floatable matter, and algae	Microscreen	5–1, 11–5
Comminution	In-stream grinding of coarse solids to reduce size	Comminutor	5–2
Grinding/ maceration	Grinding of solids removed by bar racks. Sidestream grinding of coarse solids	Screenings grinder Macerator	5–2 5–2
Mixing	Blending chemicals with wastewater and for homogenizing and maintaining solids in suspension	Rapid mixer	5–3
Flocculation	Promoting the aggregation of small particles into larger particles to enhance their removal by gravity sedimentation	Flocculator	5–3
Accelerated sedimentation	Removal of grit	Grit chamber	5–5
	Removal of grit and coarse solids	Vortex separator	5–5
Sedimentation	Removal of settleable solids	Primary clarifier	5–6
		High-rate clarifier	5–7
	Thickening of solids and biosolids	Gravity thickener	14–6
Flotation	Removal of finely divided suspended solids and particles with densities close to that of water; also thickens biosolids	Dissolved-air flotation (DAF)	5–8 14–6
	Removal of oil and grease	Induced-air flotation	5–8
Aeration	Addition of oxygen to biological process	Diffused-air aeration	5–11
		Mechanical aerator	5–11
	Post-aeration of treated effluent	Cascade aerator	5–11
VOC control	Removal of volatile and semi-volatile organic compounds from wastewaters	Gas stripper	16–4
Depth filtration	Suspended solids removal	Depth filters	11–4
Surface filtration	Suspended solids removal	Surface filters	11–5
Membrane filtration	Removal of suspended and colloidal solids and dissolved organic and inorganic matter	Reverse osmosis and other membrane systems	11–6
Air stripping	Removal of ammonia, hydrogen sulfide, and other gases from wastewater and digester supernatant	Packed tower	11–8

5–1 SCREENING

The first unit process generally encountered in wastewater treatment plants is screening. A screen is a device with openings, generally of uniform size, that is used to retain large solids found in the influent wastewater to the treatment plant or in combined wastewater collection systems subject to overflows, especially from stormwater. The principal role of screening is to remove coarse materials from the flow stream that could (1) damage or clog subsequent process equipment, (2) reduce overall treatment process reliability and effectiveness, or (3) contaminate waterways. Fine screens are sometimes used in place of or following coarse screens where greater removals of solids are required to (1) protect equipment which may be more sensitive to solids such as membrane bioreactors or (2) eliminate materials that may inhibit the beneficial reuse of biosolids.

All aspects of screenings removal, transport, and disposal must be considered in the application of screening devices, including (1) the degree of screenings removal required because of potential effects on downstream treatment processes and equipment, (2) health and safety of the operators as screenings contain pathogenic organisms and attract insects, (3) odor potential, and (4) requirements for handling, transport, prior to disposal (i.e., removal of organics by washing and reduced water content by pressing), and (5) disposal options. Thus, an integrated approach is required to achieve effective screenings management.

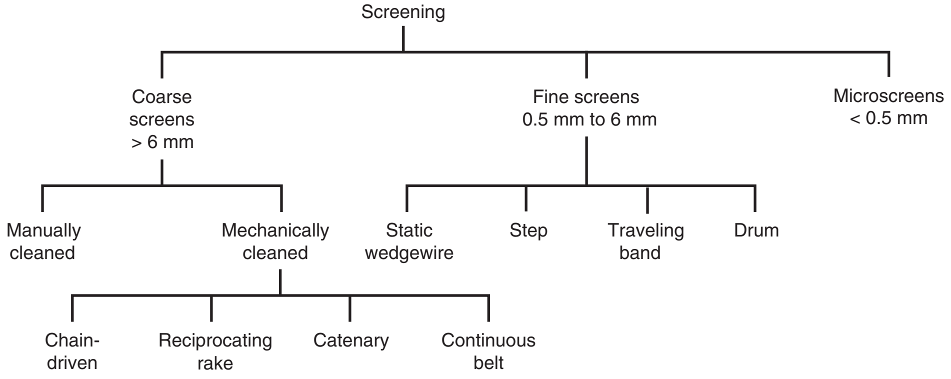
Classification of Screens

Types of screens commonly used in wastewater treatment are identified on Fig. 5–2. Two general types of screens, coarse and fine screens, are used in preliminary treatment. Fine screens may also be used as an alternative primary treatment process or for removal of additional organic solids from sludge streams prior to sludge processing. Microscreens are used principally for removing residual solids from treated effluents.

Screening elements may consist of parallel bars, rods or wires, grating, wire mesh, or perforated plate, and the openings may be of any shape, but generally are circular or rectangular slots. A screen composed of parallel bars or rods is often called a "bar rack" or a coarse screen and is used for the removal of coarse solids. Fine screens are devices consisting of perforated plates, wedge wire elements, and wire cloth that have smaller openings. The materials removed by these devices are known as screenings.

Figure 5–2

General classification for the types of screens used in wastewater treatment.



Screenings Characteristics and Quantities

Screenings are the material retained on bar racks and screens. The smaller the screen opening, the greater will be the quantity of collected screenings. While no precise definition of screenable material exists, and no recognized method of measuring quantities of screenings is available, screenings exhibit some common properties.

Screenings Retained on Coarse Screens. Coarse screenings greater than 6 mm (0.25 in.) consist of debris such as rocks, branches, pieces of lumber, leaves, paper, tree roots, plastics, bottles, cans, and rags. Organic matter associated with screenings are also removed with organic content increasing as the spacing decreases. The accumulation of oil and grease can be a serious problem, especially in cold climates. The quantity and characteristics of screenings collected for disposal vary, depending on the type of bar screen, the size of the bar screen opening, the type of sewer system, and the geographic location. Typical data on the characteristics and quantities of coarse screenings to be expected at wastewater treatment plants served by conventional gravity sewers are reported in Table 5–2.

The characteristics of the collection system will also impact the volume of screenings received. Where the collection system has many lift stations with their own screening equipment, the volume of screenings received at the treatment plant will be less. Combined sewer systems typically produce more screenings than separate sanitary sewers and may produce volumes of screenings at up to 20 times the average rate during the "first flush" of peak wet weather flow event (WEF, 2009).

Screenings Retained on Fine Screens. Fine screenings consist of materials retained on screens with openings of 0.5 mm (0.02 in.) to 6 mm (0.25 in.). The materials retained on fine screens include small rags, paper, plastic materials of various types, razor blades, grit, undecomposed food waste, feces, etc. Typical data on characteristics and quantities of screenings removed from various types of screens are reported in Table 5–3. Compared to coarse screenings, the specific weight of the fine screenings is lower and the moisture content is higher than for coarse screens. Fine screenings contain putrescible matter (including fecal material), substantial amounts of grease and scum and may be or become extremely odorous. Consequently, manual handling of collected fine screenings should be minimized and screening should be conveyed using enclosed conveyors and include grit washing and compacting equipment.

Table 5–2

Typical information on the characteristics and quantities of screenings removed from wastewater with coarse screens

Size of opening between bars, mm	Moisture content, %	Specific weight, kg/m³	Volume of screenings			
			ft³/Mgal		L/1000 m³	
			Range	Typical	Range	Typical

Coarse Screens (Bar Racks)

In wastewater treatment, coarse screens are used to protect pumps, valves, pipelines, and other appurtenances from damage or clogging by rags and large objects. Typically coarse screens precede fine screens to protect them from damage from large debris. Industrial waste treatment plants may not need coarse screens, depending on the character of the wastes. According to the method used to clean them, coarse screens are designated as either manually cleaned or mechanically cleaned. Screenings, handling, processing, and disposal are discussed following the discussion of the types of screens.

Manually Cleaned Coarse Screens. Manually cleaned coarse screens are used frequently ahead of pumps in small wastewater pumping stations and sometimes at the headworks of small- to medium-sized wastewater treatment plants. Often they are used for standby screening in bypass channels for service during high-flow periods, when mechanically cleaned screens are being repaired, or in the event of a power failure. Normally, mechanically cleaned screens are provided in lieu of manually cleaned screens to minimize labor required to clean the screens and to reduce flooding resulting from clogging of infrequently cleaned screens.

Where used, the length of the manually cleaned bar rack should not exceed the distance that can be conveniently raked, approximately 3 m (10 ft). The screen bars are welded to spacing bars located at the rear face, out of the way of the tines of the rake. A perforated drainage plate should be provided at the top of the rack where the rakings may be stored temporarily for drainage.

The screen channel should be designed to prevent the accumulation of grit and other heavy materials in the channel ahead of the screen and following it. The channel floor should be level or should slope downward through the screen without pockets to trap solids. Fillets may be desirable at the base of the sidewalls. The channel preferably should have a straight approach, perpendicular to the bar screen, to promote uniform distribution of screenable solids throughout the flow and on the screen. Typical design information for manually cleaned bar screens is provided in Table 5–4.

Mechanically Cleaned Bar Screens. The design of mechanically cleaned bar screens has evolved over the years to reduce the operating and maintenance problems and

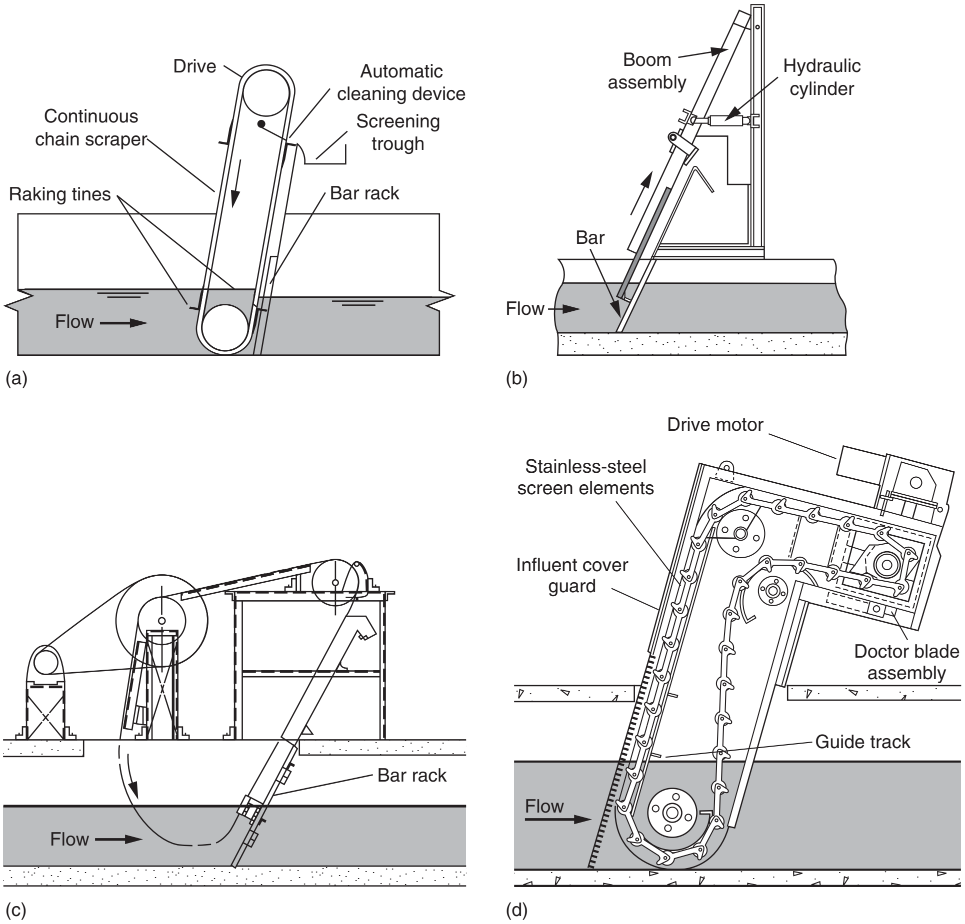
to improve the screenings removal capabilities. Many of the newer designs include extensive use of corrosion-resistant materials including stainless steel and plastics. Mechanically cleaned bar screens are divided into four principal types: (1) chain-driven, (2) reciprocating rake, (3) catenary, and (4) continuous belt. Cable-driven bar screens were used extensively in the past but have been replaced in most wastewater applications by the other types of screens. However, cable-driven raking mechanisms are still used in specific applications such as screens ahead of tunnel dewatering pump stations where deep tunnels are used for storage or conveyance of wet weather flow from combined sewer systems. Typical design information for mechanically cleaned screens is also included in Table 5–4. Examples of the different types of mechanically cleaned bar screens are shown on Fig. 5–3 and the advantages and disadvantages of each type are presented in Table 5–5.

Chain-Driven Screens. Chain-driven mechanically cleaned bar screens can be divided into categories based on whether the screen is raked to clean from the front (upstream) side or the back (downstream) side and whether the rakes return to the bottom of the bar screen from the front or back. Each type has its advantages and disadvantages, although the general mode of operation is similar. In general, front-cleaned, front-return screens [see Fig. 5–3(a)] are more efficient in terms of retaining captured solids, but they are less rugged and are susceptible to jamming by solids that collect at the base of the rake. In front-cleaned, back-return screens, the cleaning rakes return to the bottom of the bar screen on the downstream side of the screen, pass under the bottom of the screen, and clean the bar screen as the rake rises. The potential for jamming is minimized, but a hinged plate, which is also subject to jamming, is required to seal the pocket under the screen.

In back-cleaned screens, the bars protect the rake from damage by the debris. However, a back-cleaned screen is more susceptible to solids carryover to the downstream side, particularly as rake wipers wear out. The bar rack of the back-cleaned, back-return screens is less rugged than the other types because the top of the rack is unsupported so the rake

Figure 5–3

Typical mechanically-cleaned coarse screens: (a) front-cleaned, front-return chain-driven, (b) reciprocating rake, (c) catenary, and (d) continuous belt.



tines can pass through. Most of the chain-operated screens share the disadvantage of submerged sprockets that require frequent operator attention and are difficult to maintain. Additional disadvantages include the adjustment and repair of the heavy chains, and the need to dewater the channels for inspection and repair of submerged parts.

Reciprocating Rake (Climber) Screen. The reciprocating-rake-type bar screen [see Fig. 5–3(b)] imitates the movements of a person raking the screen. The rake moves to the base of the screen, engages the bars, and pulls the screenings to the top of the screen, where they are removed. Most screen designs utilize a cogwheel drive mechanism for the rake. The drive motors are either submersible electric or hydraulic type. A major advantage is that all parts requiring maintenance are above the waterline and can be easily inspected and maintained without dewatering the channel. The front-cleaned, front-return feature minimizes solids carryover. The screen uses only one rake instead of multiple rakes that are used with other types of screens. As a result, the reciprocating rake screen may have limited capacity in handling heavy screening loads, particularly in deep channels where a long "reach" is necessary. For example, heavy leaf loadings in the autumn on screens serving combined sewer systems can lead to clogging of the screens due to the long cycle time between raking. The high overhead clearance required to accommodate the rake mechanism can limit its use in retrofit applications.

Table 5–5

Advantages and disadvantages of various types of bar screens

Type of screen	Advantages	Disadvantages
Chain–driven screens		
Front clean/ back return	Multiple cleaning elements (short cleaning cycle)	Unit has submerged moving parts that require channel dewatering for maintenance
	Used for heavy duty applications	Less efficient screenings removal, i.e., carryover of residual screenings to screened wastewater channel
Front clean/ front return	Multiple cleaning elements (short cleaning cycle)	Unit has submerged moving parts that require channel dewatering for maintenance
	Very little screenings carryover	Submerged moving parts (chains, sprockets, and shafts) are subject to fouling
		Heavy objects may cause rake to jam
Back clean/ back return	Multiple cleaning elements (short cleaning cycle)	Unit has submerged moving parts that require channel dewatering for maintenance
	Submerged moving parts (chains, sprockets, and shafts) are protected by bar rack	Long rake teeth are susceptible to breakage
		Some susceptibility to screenings carryover
Reciprocating rake	No submerged moving parts; maintenance and repairs can be done above operating floor	Requires more headroom than other screens
	Can handle large objects (bricks, tires, etc.)	Long cycle time; raking capacity may be limiting
	Effective raking of screenings and efficient discharge of screenings	Grit accumulation in front of bar may impede rake movement
	Relatively low operating and maintenance costs	Relatively high cost due to stainless steel construction
	Stainless steel construction reduces corrosion	
Catenary	Sprockets are not submerged; most maintenance can be done above the operating floor	Because design relies on weight of chain for engagement of rakes with bars, chains are very heavy and difficult to handle
	Required headroom is relatively low	Because of the angle of inclination of the screen (45 to 75-deg), screen has a large footprint
	Multiple cleaning elements (short cleaning cycle)	Misalignment and warpage can occur when rakes are jammed
	Can handle large objects	May emit odors because of open design
	Very little screenings carryover	
Continuous belt	Most maintenance can be done above operating floor	Overhaul or replacement of the screening elements is a time-consuming and expensive operation
	Unit is difficult to jam	

Catenary Screen. A catenary screen is a type of front-cleaned, front-return, chain-driven screen, but it has no submerged sprockets. In the catenary screen [see Fig. 5–3(c)], the rake is held against the rack by the weight of the chain. If heavy objects become jammed in the bars, the rakes pass over them instead of jamming. The screen, however, has a relatively large "footprint" and requires greater space for installation.

Continuous Belt Screen. The continuous belt screen is a continuous, self-cleaning screening belt that can be used to remove both fine and coarse solids [see Fig. 5–3(d)]. A large number of screening elements (rakes) are attached to the drive chains; the number of screening elements depends on the depth of the screen channel. Because the screen openings can range from 0.5 to 30 mm (0.02 to 1.18 in.), it can be used as either a fine or a coarse screen. When used as a fine screen, this type of screen is better able to handle coarse solids and upstream protective devices may not be required. Hooks protruding from the belt elements are provided to capture large solids such as cans, sticks, and rags. The screen has no submerged sprocket. Newer designs of internally fed, continuous-belt, rotary screens using wedge wire instead of screen fabric are structurally more rugged.

Design of Coarse Screen Installations. Considerations in the design of screening installations include (1) location; (2) approach velocity; (3) clear openings between bars or mesh size; (4) headloss through the screens; (5) screenings handling, processing, and disposal; and (6) controls. Because the purpose of coarse screens is to remove large objects that may damage or clog downstream equipment, in nearly all cases, they should be installed ahead of the grit chambers. If grit chambers are placed before screens, rags and other stringy material could foul the grit chamber collector mechanisms, wrap around air piping, and settle with the grit. If grit is pumped, further fouling or clogging of the pumps will likely occur.

In manually cleaned installations, it is essential that the velocity of approach be limited to approximately 0.45 m/s (1.5 ft/s) at average flow to provide adequate screen area for accumulation of screenings between raking operations. Additional area to limit the velocity may be obtained by widening the channel at the screen and by placing the screen at a flatter angle to increase the submerged area. As screenings accumulate, partially plugging the screen, the upstream head will increase, submerging new areas for the flow to pass through. The structural design of the screen should be adequate to prevent collapse if it becomes plugged completely.

For most mechanically cleaned coarse screen installations, two or more units should be installed so that one unit may be taken out of service for maintenance. Slide gates or recesses in the channel walls for the insertion of stop logs should be provided ahead of, and behind, each screen so that the unit can be dewatered for screen maintenance and repair. If only one unit is installed, it is essential that a bypass channel with a manually cleaned bar screen be provided for emergency use. If the mechanically cleaned screen should become inoperative, especially during unattended hours, an overflow should be provided to direct flow to the manually cleaned bar screen. Flow through the bypass channel should be prevented by a closed slide or sluice gate. The screen channel should be designed to prevent the settling and accumulation of grit and other heavy materials. An approach velocity of at least 0.4 m/s (1.25 ft/s) is recommended to minimize solids deposition in the channel. To prevent the pass-through of debris at peak flowrates, the velocity through the bar screen should not exceed 0.9 m/s (3 ft/s).

The velocity through the bar screen can be controlled by installation of a down stream head control device such as a Parshall flume, or, for screens located upstream of a pumping station, by controlling the wetwell operating levels. If the channel velocities are controlled by wetwell levels, lower velocities can be tolerated provided flushing velocities occur during normal operating conditions.

Headloss through mechanically cleaned coarse screens is typically limited to about 150 mm (6 in.) by operational controls. The raking mechanisms are operated normally based on differential headloss through the screen or by a time clock. For time clock operation, a cycle length of approximately 15 min is recommended; however, either a high-water or high-differential contact should be provided that will place the screen in continuous operation when needed. Some mechanically cleaned screens are designed to operate at a higher speed at higher flowrates or higher differential flow conditions.

Hydraulic losses through bar screens are a function of approach velocity and the velocity through the bars. The headloss through coarse screens can be estimated using the following equation:

$$h_L = \frac{1}{C}\left(\frac{v_s^2 - v^2}{2g}\right) \tag{5–1}$$

where h_L = headloss, m (ft)
C = an empirical discharge coefficient to account for turbulence and eddy losses, typically 0.7 for a clean screen and 0.6 for a clogged screen
v_s = velocity of flow through the openings of the bar screen, m/s (ft/s)
v = approach velocity in upstream channel, m/s (ft/s)
g = acceleration due to gravity, 9.81 m/s^2 (32.2 ft/s^2)

The headloss calculated using Eq. (5–1) applies only when the bars are clean. Headloss increases with the degree of clogging. The buildup of headloss can be estimated by assuming that a part of the open space in the upper portion of the bars in the flow path is clogged. The use of Eq. (5–1) is illustrated in Example 5–1.

EXAMPLE 5–1 **Headloss Buildup in Coarse Screens** Determine the buildup of headloss through a bar screen when fifty percent of the flow area is blocked off due to the accumulation of coarse solids. Assume the following conditions apply:

Approach velocity = 0.6 m/s
Velocity through clean bar screen = 0.9 m/s
Open area for flow through clean bar screen = 0.19 m^2
Headloss coefficient for a clean bar screen = 0.7

Solution

1. Compute the clean water headloss through bar screen using Eq. (5–1).

$$h_L = \frac{1}{C}\left(\frac{v_s^2 - v^2}{2g}\right)$$

$$h_L = \frac{1}{0.7}\left[\frac{(0.9\,\text{m/s})^2 - (0.6\,\text{m/s})^2}{2(9.81\,\text{m/s}^2)}\right] = 0.033\,\text{m}$$

2. Estimate the headloss through the clogged bar screen (reducing the screen area by 50 percent results in a doubling of the velocity).

   The velocity through the clogged bar screen is

$$v_s = 0.9 \text{ m/s} \times 2 = 1.8 \text{ m/s}$$

Assuming the flow coefficient for the clogged bar screen is approximately 0.6, the estimated headloss is

$$h_L = \frac{1}{0.6}\left[\frac{(1.8\,\text{m/s})^2 - (0.6\,\text{m/s})^2}{2(9.81\,\text{m/s}^2)}\right] = 0.24\,\text{m}$$

Comment Where mechanically cleaned coarse screens are used, the cleaning mechanism typically is actuated by the buildup of headloss. Headloss is determined by measuring the water level before and after the screen. In some cases, the screen is cleaned at predetermined time intervals, as well as at a maximum head differential.

Although most screens use rectangular bars, optional shapes, i.e., "teardrop" and trapezoidal, are available. For the optional shapes, the wider width dimension is located on the upstream side of the bar rack to make it easier to dislodge materials trapped between the bars. The alternative shapes also reduce headloss through the rack.

Fine Screens

The applications for fine screens range over a broad spectrum and include preliminary treatment (following coarse bar screens), primary treatment (as a substitute for primary clarifiers), and treatment of combined sewer overflows. Fine screens can also be used to remove solids from primary effluent that could cause clogging problems in trickling filters or the membranes of membrane bioreactors. They may also be used for removal of solids from sludge flow streams prior to further treatment of the sludge (biosolids).

Screens for Preliminary and Primary Treatment. Fine screens used for preliminary treatment are (1) static wedgewire (fixed), (2) rotary drum (3) travelling belt, and (4) step type screens. Typically, the openings vary from 0.2 to 6 mm (0.01 to 0.25 in.). Examples of fine screens are illustrated on Fig. 5–4, descriptive information is provided in Table 5–6, and additional information is given below.

Fine screens may be used to replace primary treatment at small wastewater treatment plants, up to 0.13 to m^3/s (3 Mgal/d) in design capacity. Typical removal rates of BOD and TSS are reported in Table 5–7. Stainless-steel mesh or special wedge-shaped bars are used as the screening medium. Provision is made for the continuous removal of the collected solids, supplemented by water sprays to keep the screening medium clean. Headloss through the screens may range from about 0.8 to 1.4 m (2.5 to 4.5 ft).

Static Wedge Wire Screens. Static wedge wire screens [see Fig. 5–4(a)] customarily have 0.2 to 1.2 mm (0.01 to 0.06 in.) clear openings and are designed for flowrates of about 400 to 1200 $L/m^2 \cdot min$ (10 to 30 $gal/ft^2 \cdot min$) of screen area. Headloss ranges from 1.2 to 2 m (4 to 7 ft). The wedge wire medium consists of small, stainless steel, wedge-shaped bars with the flat part of the wedge facing the flow. Appreciable floor area is required for installation, and the screens must be cleaned once or twice daily with high-pressure hot water, steam, or degreaser to remove grease buildup. Static wedge wire screens are generally applicable to smaller plants or for industrial installations.

Drum Wedge Wire Screens. For the drum-type wedge wire screen [see Fig. 5–4(b)] and (c)), the screening or straining medium is mounted on a cylinder that rotates in a flow channel. The construction varies, principally with regard to the direction of flow through the screening medium. In the most common arrangements, wastewater flows either into

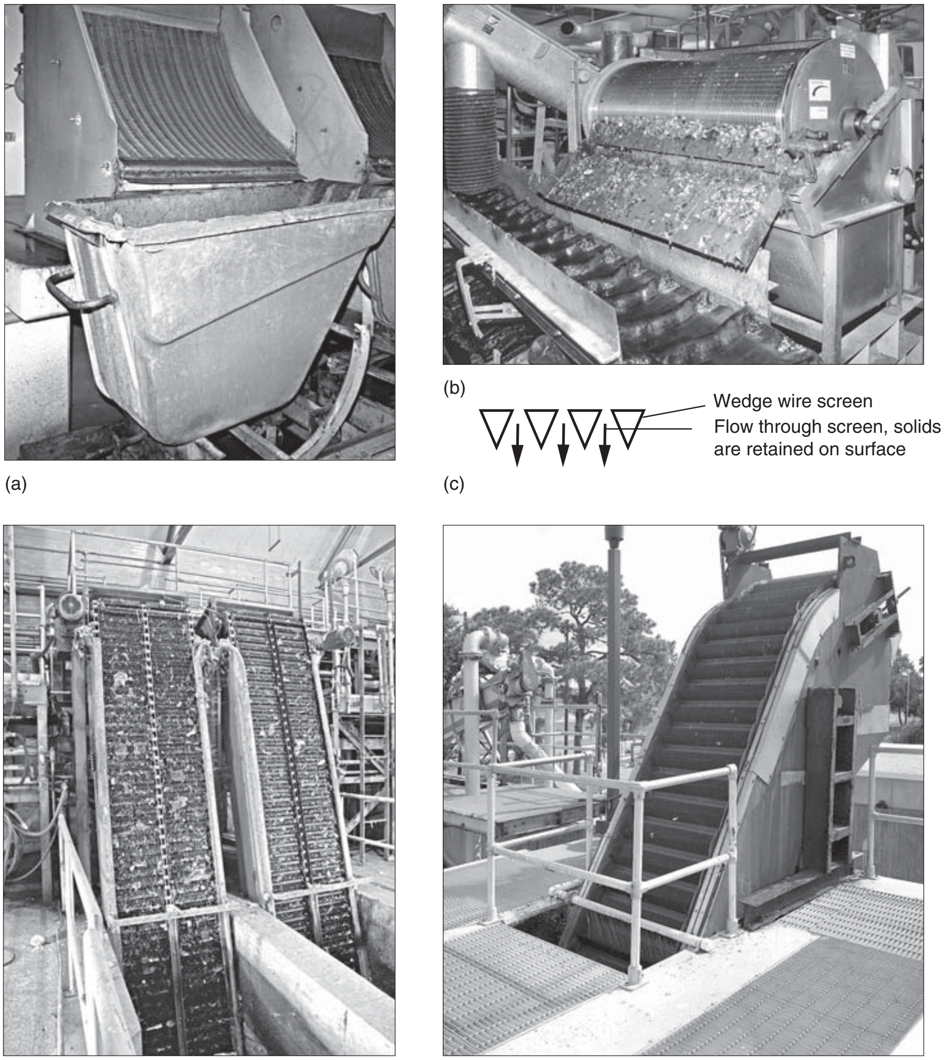


Figure 5–4

Typical fine screens: (a) static wedge wire, (b) wedge-wire drum screen, (c) section through wedge wire screen, (d) traveling band screen, and (e) step screen.

one end (single entry) of the drum and outward through the screen or from both sides (double entry) inward through the screens. In both cases, the screenings collect on the inner surface. As the screen rotates, the debris collected on the inside of the screen is lifted above the operating floor above debris hoppers located inside the screen structure and the debris is washed by a series of washwater jets. The collected debris and washwater then passes to the solids handling systems. In another arrangement, wastewater discharges into the top of the unit and passes through to the interior with solids collection on the exterior. However, this arrangement should only be used on low flowrates.

Traveling Band Screens. Traveling band screens [see Fig. 5–4(d)] are used for fine screening of influent wastewater at headworks or for secondary effluent ahead of tertiary membrane systems. In the typical application, the water being screened will pass through an opening in the front of the screen and then from the inside of the screen, through screen panels to the outside of the screen totally separating the influent and effluent. As the band of screen panels rotate, the debris collected on the inside of the screen is lifted above deck

Table 5–6

Description of screening devices used in wastewater treatment

Type of screening device	Screening surface				Application	See Fig.

Tangential	Fine	0.0475	1200 μm	Stainless steel mesh	Combined sewer overflows	5–5b

[a] Unless otherwise noted.

level by lifting elevators, where it is washed into a debris trough within the head section of the screen. The debris trough will discharge by gravity to the screenings handling equipment. The screens may be controlled either automatically or locally by hand.

Step Screens. Step screens consist of two step-shaped sets of thin vertical plates, one fixed and one movable [see Fig. 5–4(e)]. The fixed and movable step plates alternate across the width of an open channel and together form a single screen face. The movable plates rotate in a vertical motion. Through this motion, solids captured on the screen face are automatically lifted up to the next fixed step landing, and are eventually transported to the top of the screen where they are discharged to a collection hopper. The circular pattern of

Table 5–7

Typical data on the removal of BOD and TSS with fine screens used to replace primary sedimentation[a]

Type of screen	Size of openings		Percent removal	
	in.	mm	BOD	TSS
Fixed parabolic	0.0625	1.6	5–20	5–30
Rotary drum	0.01	0.25	25–50	25–45

[a] The actual removal achieved will depend on the nature of the wastewater collection system and the wastewater travel time.

the moving plates provides a self-cleaning feature for each step. Normal ranges of openings between the screen plates are 3 to 6 mm (0.12 or 0.24 in.); however, openings as small as 1 mm (0.04 in.) are available. Solids trapped on the screen also create a "filter mat" that enhances solids removal performance. In addition to wastewater screening, step screens can be used for removal of solids from septage, primary sludge, or digested biosolids.

Fine Screens for Combined Sewer Overflows. Screens have also been developed specifically for the removal of floatable and other solids from combined sewer overflows. Basic types include horizontal reciprocating screens, tangential flow screens, and drum screens. The horizontal reciprocating screen is a rigid, weir-mounted screen configured of narrow stainless-steel bars that run the length of the device [see Fig. 5–5(a)]. The screening bars are parallel to the normal direction of flow and are designed in continuous runs with no intermediate supports to collect solids. As the water in the screen channel rises, wastewater begins to pass through the openings in the screen bars. Solids are trapped on the screen, and as the level continues to rise in the channel due to the entrapped solids on the screen, a hydraulically driven rake assembly is automatically activated to remove the accumulated solids from the screen. The rake carriage travels back and forth across the screen, combing the entrapped solids. The combing tines of the rake assembly carry the solids to one end of the screen for disposal either into the wastewater channel that carries flow to the wastewater treatment plant or to a solids-collection pit.

In the tangential flow screen, the technology relies on the natural motion of water to screen and trap solids. The separation process is effected using a fine-mesh cylindrical screen and requires no moving parts [see Fig. 5–5(b)]. As the wastewater flows into the separation chamber, a circular motion is generated that is designed to allow water to pass through the cylindrical screen while forcing solids to swirl toward the center of the chamber. The swirling water is regulated so that the tangential flow around the chamber is greater than the radial force attempting to push the solids outward. Thus, the accumulation of solids on the screen is minimized. The solids settle into a central sump where they can be removed. Floatables are trapped in the separation chamber until the flow stops, when they can be removed.

More recently, drum screens as described above have also been developed for this service. Single entry drum screens with the capability of handling very high stormwater flowrates are now available.

Design of Fine Screen Installations. Fine screens are usually preceded by mechanically cleaned coarse screens. An installation should have a minimum of two parallel screens, each with the capability of handling peak flowrates. Flushing water should be provided nearby so that the buildup of grease and other solids on the screen can be removed periodically. In colder climates, hot water or steam is more effective for grease removal.

The calculation of headloss through fine screens differs from that of coarse screens. The clear water headloss through fine screens may be obtained from manufacturers' rating tables, or calculated using Eq. (5–2):

$$h_L = \frac{1}{2g}\left(\frac{Q}{CA}\right)^2 \tag{5–2}$$

where h_L = headloss, m (ft)

C = coefficient of discharge for the screen (a typical value for a clean screen is 0.60)

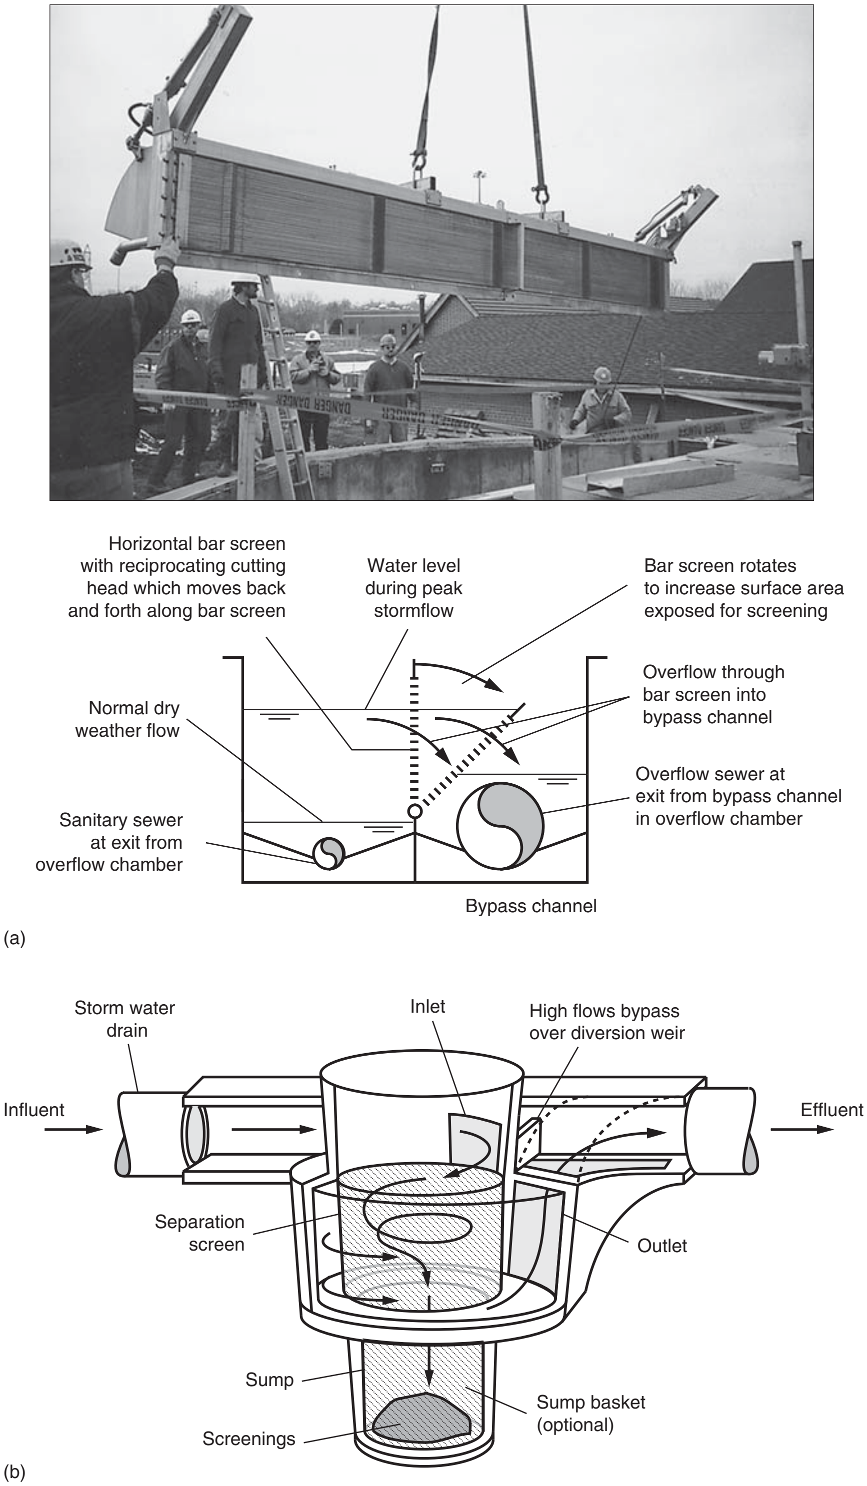
g = acceleration due to gravity, 9.81 m/s^2 (32.2 ft/s^2)

Q = discharge through screen, m^3/s (ft^3/s)

A = effective open area of submerged screen, m^2 (ft^2)

Figure 5–5

Devices used for the screening of combined sewer overflows: (a) view of horizontal screen during installation. The cutting mechanism travels back and forth horizontally along the bars. The screen can be rotated to increase the screening area exposed to the flow and (b) tangential flow device with separation screen.



Values of *C* and *A* depend on screen design factors, such as the size and milling of slots, the wire diameter and weave, and particularly the percent of open area, and must be obtained from the screen manufacturer or determined experimentally. The important determination is the headloss during operation; headloss depends on the size and amount of solids in the wastewater, the size of the apertures, and the method and frequency of cleaning.

Microscreens

Microscreening involves the use of variable low-speed (up to 4 rev/min), continuously backwashed, rotating drum screens operating under gravity-flow conditions (see Fig. 5–6). The filtering fabrics have openings of 10 to 35 microns (micrometers) and are fitted on the drum periphery. The wastewater enters the open end of the drum and flows outward through the rotating-drum screening cloth. The collected solids are backwashed by high-pressure jets into a trough located within the drum (see also Sec. 11–5 for cloth medium surface filters used in advanced wastewater treatment). The principal applications for microscreens are to remove suspended solids from secondary effluent and from stabilization pond effluent.

Typical suspended-solids removal achieved with microscreens ranges from 10 to 80 percent, with an average of 55 percent. Problems encountered with microscreens include incomplete solids removal and inability to handle solids fluctuations. Reducing the rotating speed of the drum and less frequent flushing of the screen have resulted in increased removal efficiencies but reduced capacity.

The functional design of a microscreen involves (1) characterizing the suspended solids with respect to the concentration and degree of flocculation, (2) selecting design parameters that will not only assure sufficient capacity to meet maximum hydraulic loadings rate with critical solids characteristics but also meet operating performance requirements over the expected range of hydraulic and solids loadings rates, and (3) providing backwash and cleaning facilities to maintain the capacity of the screen. Because of the variable performance of microscreens, pilot-plant studies are recommended, especially if the units are to be used to remove solids from stabilization-pond effluent, which may contain significant amounts of algae.

Figure 5–7

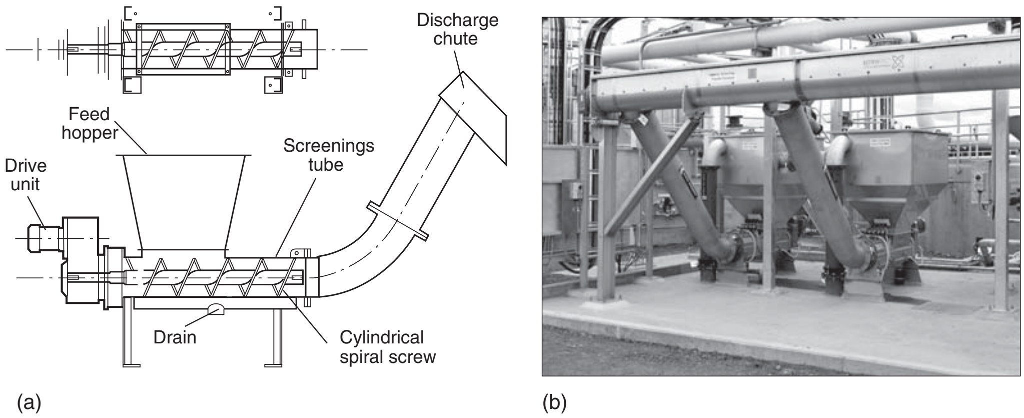
Conveyance system for coarse solids: (a) belt conveyor and (b) hydraulic transport.

Screenings Handling, Processing, and Disposal

In mechanically cleaned screen installations with multiple units, screenings are typically discharged from the screening unit onto a traveling belt conveyor or a hydraulic transport system (see Fig. 5–7) or pneumatic ejector system. Screenings can also be discharged directly into a screenings grinder, a pneumatic ejector, or a container for disposal. Belt conveyors and pneumatic ejectors are generally the primary means of mechanically transporting screenings. Belt conveyors offer the advantages of simplicity of operation, low maintenance, freedom from clogging, and low cost. Belt conveyors give off odors and may have to be provided with covers. Fluted conveyor belts can be problematic in operation due to screenings such as paper and latex products sticking to the flutes. Pneumatic ejectors are less odorous and typically require less space; however, they are subject to clogging if large objects are present in the screenings.

Screenings compactors can be used to dewater and reduce the volume of screenings (see Fig. 5–8). Such devices, including hydraulic ram and screw compactors, receive screenings directly from the bar screens and are capable of transporting the compacted screenings to a receiving hopper. Compactors can reduce the water content of the screenings by up to 50 percent and the volume by up to 75 percent. As with pneumatic ejectors, large objects can cause jamming, but automatic controls can sense jams, automatically reverse the mechanism, and actuate alarms and shut down equipment.

Macerators can be mounted above the pneumatic ejectors to grind up material and prevent clogging, however, these units must be designed to handle the characteristics of



(a) (b)

Figure 5–8

Typical device used for compacting screenings: (a) schematic and (b) view two screening compactors with overhead discharge trough.

the material to be collected to avoid bridging from excessive fats, oil, and grease (FOG) materials. The distance from screening units to the bin or truck loading area should be considered when determining height of screen and type of screening conveyance. In some cases it might be effective to confine the screening unit to the size required to remove the material from the flow path and use the conveying system to convey the material to upper levels where the storage bin or truck is located.

Means of disposal of screenings include (1) removal by hauling to disposal areas (landfill) including codisposal with municipal solid wastes, (2) disposal by burial on the plant site (small installations only), (3) incineration either alone or in combination with sludge and grit (large installations only), and (4) discharge to grinders or macerators where they are ground and returned to the wastewater. The first method of disposal is most commonly used. In some states, screenings are required to be lime stabilized for the control of pathogenic organisms before disposal in landfills. Grinding the screenings and returning them to the wastewater flow shares many of the disadvantages cited under comminution, as discussed in the following section.

5–2 COARSE SOLIDS REDUCTION

As an alternative to coarse bar screens or fine screens, comminutors and macerators can be used to intercept coarse solids and grind or shred them in the screen channel. High-speed grinders are used in conjunction with mechanically cleaned screens to grind and shred screenings that are removed from the wastewater. The solids are cut up into a smaller, more uniform size for return to the flow stream for subsequent removal by downstream treatment operations and processes. Comminutors, macerators, and grinders can theoretically eliminate the messy and offensive task of screenings handling and disposal. The use of comminutors and macerators is particularly advantageous in a pumping station to protect the pumps against clogging by rags and large objects and to eliminate the need to handle and dispose of screenings. They are particularly useful in cold climates where collected screenings are subject to freezing.

There is a wide divergence of views, however, on the suitability of using devices that grind and shred screenings at wastewater treatment plants. One school of thought maintains that once coarse solids have been removed from wastewater, they should not be returned, regardless of the form. The other school of thought maintains that once cut up, the solids are more easily handled in the downstream processes. Shredded solids often present downstream problems, particularly with rags and plastic bags, as they tend to form ropelike strands. Rag and plastic strands can have a number of adverse impacts, such as clogging pump impellers, sludge pipelines, and heat exchangers, and accumulating on air diffusers and clarifier mechanisms. Plastics and other nonbiodegradable material may also adversely affect the quality of biosolids that are to be beneficially reused.

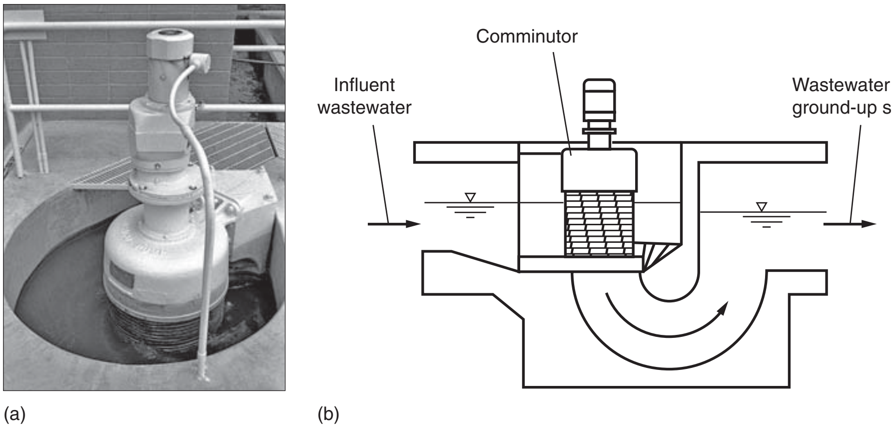
Approaches to using comminutors, macerators, and grinders are applicable in many retrofit situations. Examples of retrofit applications include plants where a spare channel has been provided for the future installation of a duplicate unit or in very deep influent pumping stations where the removal of screenings may be too difficult or costly to achieve. Alternative approaches may also be possible, such as using chopper pumps at pumping stations (see Sec. 13–4) or installing grinders ahead of sludge pumps.

Comminutors

Comminutors are used most commonly in small wastewater treatment plants, less than 0.2 m^3/s (5 Mgal/d). Comminutors are installed in a wastewater flow channel to screen and shred material to sizes from 6 to 20 mm (0.25 to 0.77 in.) without removing the shredded

Figure 5–9

Typical comminutor used for particle size reduction of solids in small plants: (a) view of installed unit and (b) schematic of typical installation.



solids from the flow stream. A typical comminutor uses a stationary horizontal screen to intercept the flow (see Fig. 5–9) and a rotating or oscillating arm that contains cutting teeth to mesh with the screen. The cutting teeth and the shear bars cut coarse material. The small sheared particles pass through the screen and into the down stream channel. Comminutors may create a string of material, namely rags, that can collect on downstream treatment equipment. Because of operating problems and high maintenance with comminutors, newer installations generally use a screen or a macerator described below.

Macerators

Macerators are slow-speed grinders that typically consist of two sets of counterrotating assemblies with blades [see Fig. 5–10(a) and (b)]. The assemblies are mounted vertically

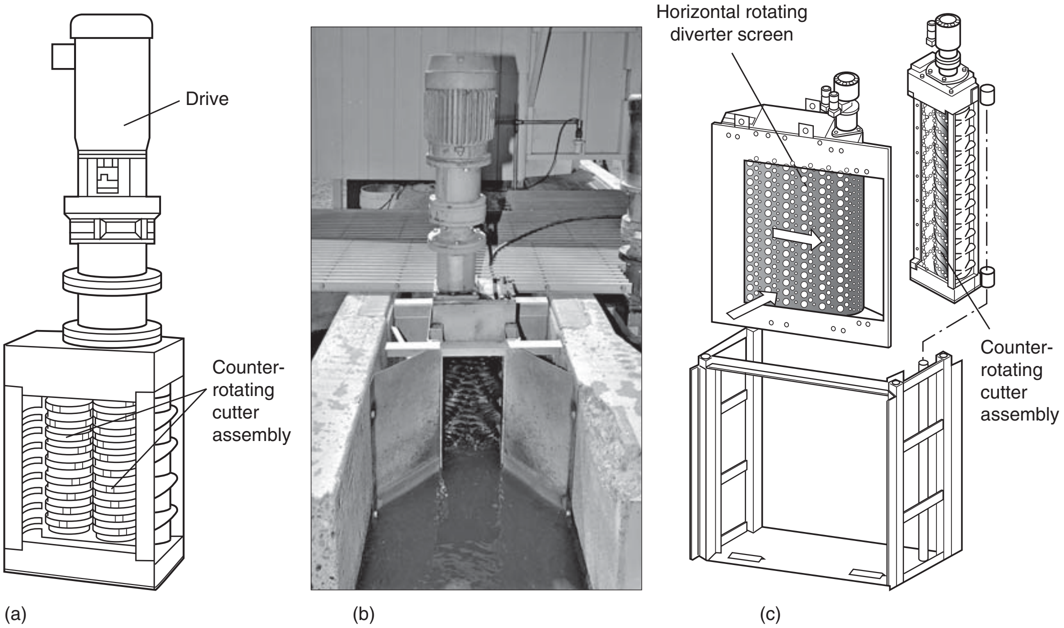


Figure 5–10

Typical macerators: (a) schematic of in-channel slow-speed grinder/macerator, (b) view of in-channel macerator, and (c) schematic of linked screen macerator.

in the flow channel. The blades or teeth on the rotating assemblies have a close tolerance that effectively chops material as it passes through the unit. The chopping action reduces the potential for producing ropes of rags or plastic that can collect on downstream equipment. Macerators can be used in pipeline installations to shred solids, particularly ahead of wastewater and sludge pumps, or in channels at smaller wastewater treatment plants. Sizes for pipeline applications typically range from 100 to 400 mm (4 to 16 in.) in diameter. Grinders for solids (sludge) applications are discussed in Chap. 13.

Another type of macerator used in channel applications is a moving, linked screen that allows wastewater to pass through the screen while diverting screenings to a grinder located at one side of the channel [see Fig. 5–10(c)]. Standard sizes of this device are available for use in large channels ranging from widths of 750 to 1800 mm (30 to 72 in.) and depths of 750 to 2500 mm (30 to 100 in.). The headloss is lower than that of the units with counterrotating blades shown on Fig. 5–10(a).

Grinders

High-speed grinders, typically referred to as hammermills, receive screened materials from bar screens. The materials are pulverized by a high-speed rotating assembly that cuts the materials passing through the unit. The cutting or knife blades force screenings through a stationary grid or louver that encloses the rotating assembly. Washwater is typically used to keep the unit clean and to help transport materials back to the wastewater stream. Discharge from the grinder can be located either upstream or downstream of the bar screen.

Design Considerations

Comminuting and macerating devices may be preceded by grit chambers to prolong the life of the equipment and to reduce the wear on the cutting surfaces. Comminutors should be constructed with a bypass arrangement so that a manual bar screen is used in case flowrates exceed the capacity of the comminutor or when there is a power or mechanical failure. Stop gates and provisions for dewatering the channel should also be included to facilitate maintenance. Headloss through a comminutor usually ranges from 0.1 to 0.3 m (4 to 12 in.) and can approach 0.9 m (3 ft) in large units at maximum flowrates. In cases where a comminutor or macerator precedes grit chambers, the cutting teeth are subject to high wear and require frequent sharpening or replacement. Units that use cutting mechanisms ahead of the screen grid should be provided with rock traps in the channel upstream of the comminutor to collect material that could jam the cutting blade.

Because these units are complete in themselves, no detailed design is necessary. Manufacturers' data and rating tables for these units should be consulted for recommended channel dimensions, capacity ranges, headloss, upstream and downstream submergence, and power requirements. Because manufacturers' capacity ratings are usually based on clean water, the ratings should be decreased by approximately 80 percent to account for partial clogging of the screen.

5–3 MIXING AND FLOCCULATION

Mixing is an important unit operation in many phases of wastewater treatment including (1) mixing of one substance completely with another, (2) blending of miscible liquids, (3) flocculation of wastewater particles, (4) continuous mixing of liquid suspensions, and (5) heat transfer. Most mixing operations in wastewater can be classified as continuous-rapid (less than 30 s) or continuous (i.e., ongoing). Continuous rapid mixing and continuous mixing are considered in this section. Each unit operation is described separately

Table 5–8

Typical mixing and flocculation devices, mixing times, and applications for mixing devices used in wastewater treatment facilities

Mixing device	Typical mixing times, s	Applications/remarks
Mixing and blending devices		
Static inline mixers	<1	Used for chemicals requiring instantaneous mixing such as alum (Al^{3+}), ferric chloride (Fe^{3+}), cationic polymer, chlorine (Cl_2)
Inline mixers	<1	Used for chemicals requiring instantaneous mixing such as alum (Al^{3+}), ferric chloride (Fe^{3+}), cationic polymer, chlorine (Cl_2)
High speed induction mixer	<1	Used for chemicals requiring instantaneous mixing such as alum (Al^{3+}), ferric chloride (Fe^{3+}), cationic polymer, chlorine (Cl_2)
Pressurized water jets	<1	Used in water treatment practice and for reclaimed water applications
Turbine and propeller mixers	2–20	Used in back mix reactors for the mixing of alum in sweep floc applications. Actual time depends on the configuration of the vessel in which mixing is taking place. Mixing of chemicals in solution feed tanks
Pumps	<1	Chemicals to be mixed are introduced in the suction intake of the pump
Other hydraulic mixing devices	1–10	Hydraulic jumps, weirs, Parshall flumes, etc.
Flocculation devices		
Static mixer	600–1800	Used for flocculation of coagulated colloidal particles
Paddle mixers	600–1800	Used for flocculation of coagulated colloidal particles
Turbine mixer	600–1800	Used for flocculation of coagulated colloidal particles
Continuous mixing		
Mechanical aerators	Continuous	Used to provide oxygen and to maintain mixed liquor suspended solids in suspension in suspended growth biological treatment processes
Hyperboloid mixers	Continuous	Used to maintain mixed liquor suspended solids in suspension in suspended-growth biological treatment processes
Pneumatic mixing	Continuous	Used to provide oxygen and to maintain mixed liquor suspended solids in suspension in suspended growth biological treatment processes

below followed by a description of the types of mixers and flocculation devices and an analysis of the energy requirements for these operations. Typical examples of the types of mixing devices used for mixing and blending, flocculation, and continuous mixing are given in Table 5–8.

Continuous Rapid Mixing in Wastewater Treatment

Continuous rapid mixing is used, most often, where one substance is to be mixed with another. The principal applications of continuous rapid mixing are in (1) the blending of chemicals with wastewater (e.g., the addition of alum or iron salts prior to flocculation and settling or for dispersing chlorine and hypochlorite into wastewater for disinfection), (2) the blending of miscible liquids, and (3) the addition of chemicals to sludge and biosolids to improve their dewatering characteristics.

Continuous Mixing in Wastewater Treatment

Continuous mixing is used where the contents of a reactor or holding tank or basin must be kept in suspension, such as in equalization basins, flocculation basins, suspended-growth biological treatment processes, aerated lagoons, and aerobic digesters. The two applications considered in the following discussion are flocculation and the maintenance of material in suspension.

Flocculation in Wastewater Treatment. The purpose of wastewater flocculation is to form aggregates or flocs from finely divided particles and from chemically destabilized particles. Flocculation is a transport step that brings about the collisions between the destabilized particles needed to form larger particles that can be removed readily by settling or filtration. Although not used routinely, flocculation of wastewater by mechanical or air agitation may be considered for (1) increasing removal of suspended solids and BOD in primary settling facilities, (2) conditioning wastewater containing certain industrial wastes, (3) improving performance of secondary settling tanks following the activated-sludge process, and (4) as a pretreatment step for the filtration of secondary effluent. When used, flocculation can be accomplished in separate tanks or basins specifically designed for the purpose, in inline facilities such as in the conduits and pipes connecting the treatment units, or in combination with flocculator-clarifiers.

Flocculation typically follows rapid mixing where chemicals have been added to destabilize the particles. The destabilization of particles resulting from the addition of chemicals is defined as "coagulation" and is considered in Chap. 6. There are two types of flocculation: (1) microflocculation and (2) macroflocculation. The distinction between these two types of flocculation is based on the particle sizes involved.

Microflocculation (also known as perikinetic flocculation) is the term used to refer to the aggregation of particles brought about by the random thermal motion of fluid molecules. The random thermal motion of fluid molecules is also known as *Brownian motion* or *movement* [see Fig. 5–11(a)]. Microflocculation is significant for particles that are in the size range from 0.001 to about 1 μm. *Macroflocculation* (also known as orthokinetic flocculation) is the term used to refer to the aggregation of particles greater than 1 or 2 μm. Macroflocculation can be brought about by (1) induced velocity gradients and (2) differential settling. Particles can be brought together (i.e., flocculated) by inducing velocity gradients in a fluid containing the particles to be flocculated. As illustrated on Fig. 5–11(b), faster-moving particles will overtake slower-moving particles in a velocity field. If the particles that collide stick together, a larger particle will be formed that will be easier to remove by gravity separation.

In macroflocculation by differential settling [see Fig. 5–11(b)], large particles overtake smaller particles during gravity settling. When the two particles collide and stick

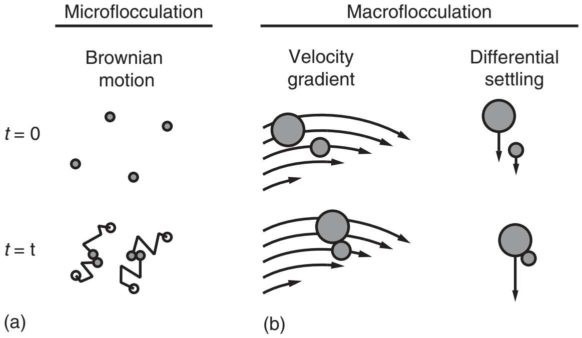

Figure 5–11

Schematic illustration of the two types of flocculation: (a) microflocculation (due to Brownian motion, also known as perikinetic flocculation) and (b) macroflocculation (also known as orthokinetic flocculation) due to (i) fluid shear and (ii) differential settling. (Adapted from Pankow, 1991; Logan, 2012.)

together, a larger particle is formed that settles at a rate that is greater than that of the larger particle before the two particles collided. Flocculent settling in the absence of induced velocity gradients is considered in the following section.

It should be noted that flocculation brought about by induced velocity gradients is ineffectual until the colloidal particles reach a size of 1 or 2 μm through contacts produced by Brownian motion. For example, macroflocculation cannot be used to aggregate viruses, which are 0.1 μm in size or smaller, until they are microflocculated or adsorbed or enmeshed in larger flocs or particles.

Maintaining Material in Suspension. Continuous mixing operations are used in biological treatment processes such as the activated-sludge process to maintain the mixed liquor suspended solids in suspension. In biological treatment systems the mixing device, in most cases, is also used to provide the oxygen transfer needed for the process. Thus, the aeration equipment must be able to provide the oxygen needed for the process and must be able to deliver the energy needed to maintain mixed conditions within the reactor. Both mechanical aerators and dissolved aeration devices are used. In both aerobic and anaerobic digestion, mixing is used to homogenize the contents of the digester to accelerate the biological conversion process, and to distribute uniformly the heat generated from biological conversion reactions or from external heating sources such as hot water circulation.

Energy Dissipation in Mixing and Flocculation

Mixing with an impeller in a reactor or mixing chamber causes two actions to occur: circulation and shearing of the fluid. The power input per unit volume of liquid can be used as a rough measure of mixing effectiveness, based on the reasoning that more input power creates greater turbulence, and greater turbulence leads to better mixing. Camp and Stein (1943) studied the establishment and effect of velocity gradients in coagulation tanks of various types and developed the following equations for use in the design and operation of systems with mechanical mixing devices (e.g., paddles).

$$G = \sqrt{\frac{P}{\mu V}} \tag{5–3}$$

where G = average velocity gradient, T^{-1}, 1/s
P = power requirement, W
μ = dynamic viscosity, $\mathrm{N{\cdot}s/m^2}$
V = flocculator volume, $\mathrm{m^3}$

In Eq. (5–3), it is important to note that the velocity gradient G is a measure of the average velocity gradient in the fluid. High G values will be observed near the blades of the mechanical mixing device, while significantly lower values will be observed at some distance from the blades of the mixing device.

As given by Eq. (5–3), the value of G depends on the power input, the viscosity of the fluid, and the volume of the basin. Multiplying both sides of Eq. (5–3) by the detention time $\tau = V/Q$ yields

$$G\tau = \frac{V}{Q}\sqrt{\frac{P}{\mu V}} = \frac{1}{Q}\sqrt{\frac{PV}{\mu}} \tag{5–4}$$

where τ = detention time, s
Q = flowrate, $\mathrm{m^3/s}$

Table 5–9

Typical detention time and velocity gradient, *G*, values for mixing and flocculation in wastewater[a]

Process	Range of values: Detention time	Range of values: *G* value, s^{-1}
Mixing		
Typical rapid mixing operations in wastewater treatment	5–30 s	500–1500
Rapid mixing for effective initial contact and dispersion of chemicals	<1 s	1500–6000
Rapid mixing of chemicals in contact filtration processes	<1 s	2500–7500
Flocculation		
Typical flocculation processes used in wastewater treatment	30–60 min	50–100
Flocculation in direct filtration processes	2–10 min	25–150
Flocculation in contact filtration processes	2–5 min	25–200

[a] The limitations associated with the use of the velocity gradient concept, as discussed in the text, must be considered in applying the *G* values given in this table.

Typical values that have been used for G for various mixing operations are reported in Table 5–9. The power required for various types of mixers is considered in the following discussion. The use of Eq. (5–3) is illustrated in Example 5–2.

EXAMPLE 5–2 **Power Requirement to Develop Velocity Gradients** Determine the theoretical power requirement to achieve a G value of 100/s in a tank with a volume of 2800 m^3 ($\sim 10^5$ ft^3). Assume that the water temperature is 15°C (59°F). What is the corresponding value when the water temperature is 5°C (41°F)?

Solution

1. Determine the theoretical power requirement at 15°C using Eq. (5–3) rearranged as follows.
   $P = G^2 \mu V$
   μ at 15°C $= 1.139 \times 10^{-3}$ N·s/m^2 (see Appendix C)
   $P = (100/s)^2(1.139 \times 10^{-3}\ \text{N·s/m}^2)(2800\ \text{m}^3)$
   $= 31{,}892$ W
   $= 31.9$ kW (23,524 ft·lb_f/s)

2. Determine the theoretical power requirement at 5°C
   μ at 5°C $= 1.518 \times 10^{-3}$ N·s/m^2 (see Appendix C)
   $P = (100/s)^2\ (1.518 \times 10^{-3}\ \text{N·s/m}^2)(2800\ \text{m}^3)$
   $= 42{,}504$ W
   $= 42.5$ kW (31,351 ft·lb_f/s)

While the use of the velocity gradient G has been popular in the water and wastewater field, it should be noted that use of the velocity gradient concept does not apply to microflocculation and, as will be discussed later, cannot be used as design parameter for some types of mixing devices. Insight into the reason that the velocity gradient G is not an effective measure for microflocculation can be gained by considering the following relationship developed by Kolmogoroff (1941) to describe the size of eddies formed as result of power input to a fluid (Davies, 1972).

$$l_K = \left(\frac{\nu^3}{P_M}\right)^{1/4} \tag{5–5}$$

where l_K = Kolmogoroff microscale length, m
ν = kinematic viscosity, m^2/s
P_M = Power per unit mass, W/kg, $[(kg{\cdot}m^2/s^3)/kg]$
$= G^2\nu$

Substituting $G^2\nu$ in Eq. (5–5) yields:

$$l_K = \left(\frac{\nu^2}{G^2}\right)^{1/4} \tag{5–6}$$

Equation (5–6) can now be used to estimate the smallest eddy that can be produced for a given average G value. For example, if $G = 1000/s$, and $\nu = 1.003 \times 10^{-6}\ m^2/s$ at 20°C, the corresponding value of the microscale length is 31.7 μm. Thus, particles smaller than 31.7 μm will not be affected. In fact, if the G value were increased to 10,000/s, the corresponding microscale length is 10.0 μm. Based on this analysis, it is clear that if particles smaller than 1 to 10 μm are to be removed they must first be destabilized and allowed to undergo microflocculation caused by Brownian motion. It can be argued that effective mixing is critical in keeping the particles in suspension so that collisions can occur by Brownian motion (Han and Lawler, 1992). Further, because the G value is an average value, the effectiveness of the mixing, which depends on the pumping characteristics of the mixer and the geometry of the mixing basin, must be evaluated carefully.

Time Scale in Mixing

The time scale for mixing is a consideration in the design of mixing facilities and operations. For example, if the reaction rate between the substance being mixed into a liquid and the liquid is rapid, the time of mixing is extremely important. For slowly reacting substances, the time of mixing is not as critical. The rationale for mixing times for various chemicals is considered in Chap. 6. Typical mixing times may be found in Table 6–24 in Chap. 6. As reported in Table 6–24, recommended mixing times for coagulants such as alum or iron salts and for dispersing chlorine and hypochlorite into solution are less than 1 s. Typical mixing times achievable for various mixing devices are reported in Table 5–8. It should be noted that achieving extremely short mixing times becomes increasingly difficult as the flowrate increases. In some applications, it may be preferable to use multiple mixing devices to achieve optimal mixing times.

Types of Mixers Used for Rapid Mixing in Wastewater Treatment

Many types of mixing devices are available, as summarized previously in Table 5–8, depending on the application and the time scale required for mixing. The principal devices used for rapid mixing in wastewater treatment applications include static inline mixers, inline mixers, high-speed induction mixers, pressurized water jets, and propeller and turbine mixers. Mixing can also be accomplished in pumps and with the aid of hydraulic devices such as hydraulic jumps, Parshall flumes, or weirs. Although hydraulic mixing can sometimes be highly efficient, the principal problem is that the energy input varies with the flowrate, and incomplete and ineffective mixing can occur at low flowrates.

Static Mixers. Static inline mixers contain internal vanes or orifice plates that bring about sudden changes in the velocity patterns as well as momentum reversals. Static mixers are principally identified by their lack of moving parts. Typical examples include inline static mixers that contain elements that bring about sudden changes in the velocity patterns as well as momentum reversals [see Fig. 5–12(a)] and mixers that contain orifice plates and nozzles [see Fig. 5–12(b)]. Static inline mixers are used most commonly for mixing of chemicals with wastewater. Inline mixers are available in sizes varying from

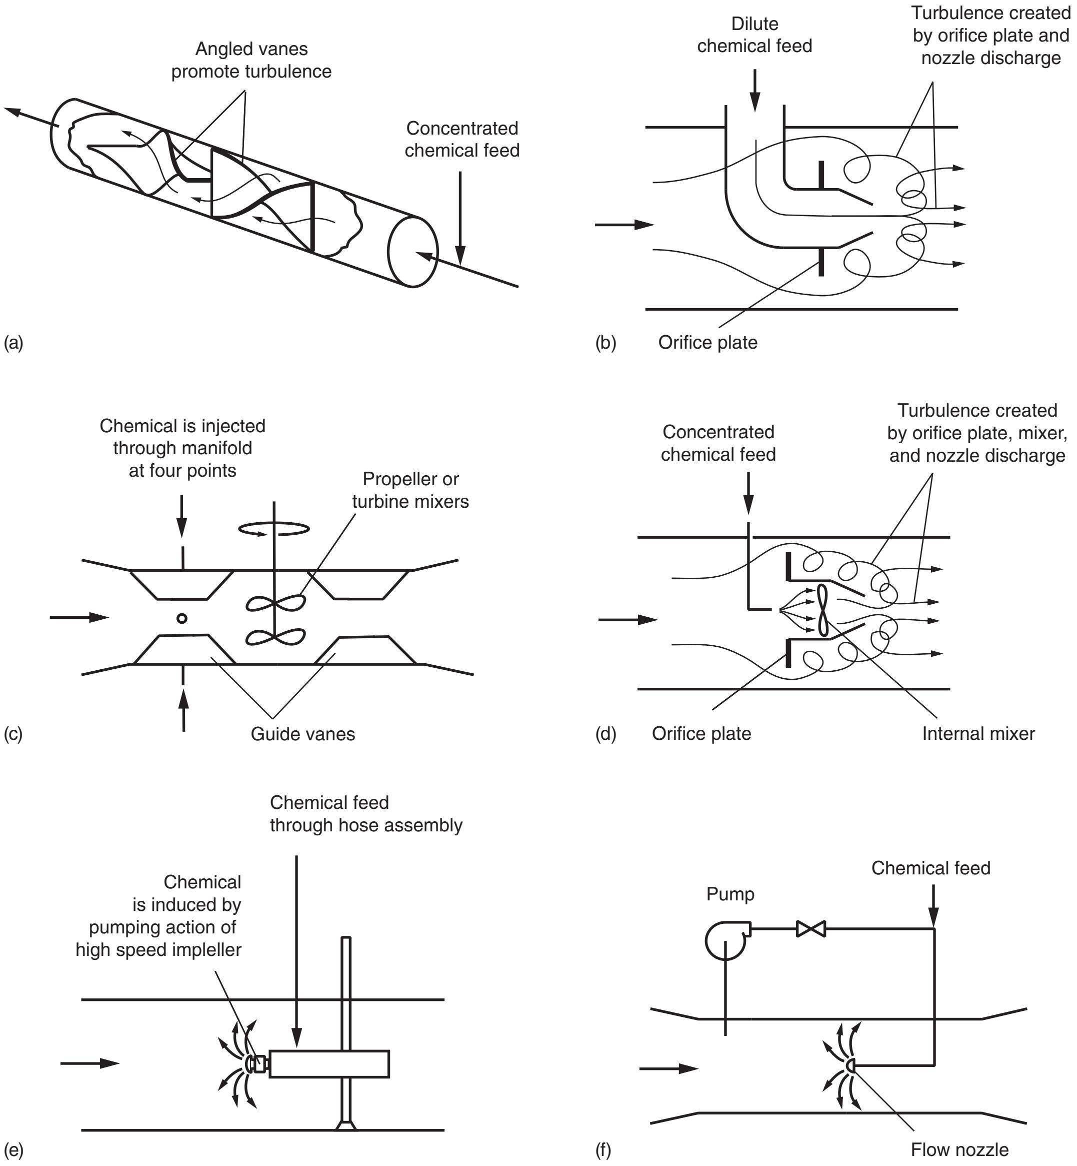

Figure 5–12

Typical mixers used in wastewater treatment for rapid mixing: (a) inline static mixer with internal vanes, (b) inline static mixer with orifice used to create internal turbulence for mixing dilute chemicals, (c) inline propeller or turbine mixer, (d) inline mixer with orifice and internal propeller mixer , (e) high speed induction mixer, and (f) pressurized water jet mixer.

about 12 mm to 3 m × 3 m open channels. Low-pressure-drop round, square, and rectangular inline static mixers have been developed for chlorine mixing in open channels and tunnels for flowrates varying from 0.22 to over 8.76 m^3/s (5 to over 200 Mgal/d) (Carlson, 2000).

For static inline mixers with vanes, the longer the mixing elements, the better the mixing; however, the pressure loss increases. It should also be noted that the shear rate and the scale (i.e., size) of the turbulent eddies formed in static mixers with vanes are more limited in range as compared to the wide range of values obtained with mechanical mixers. Mixing also occurs in a plug-flow regime in static inline mixers. Mixing times in static mixers are quite short, typically less than 1 s. The actual mixing time will vary with the length of the mixer, which depends on the number of mixing elements used, and the internal volume occupied by the mixing element. Thus, because the nature of the mixing that occurs in static mixers is quite different from that of mechanical mixers, use of the velocity gradient concept [see Eq. (5–3)] is inappropriate for static mixers.

For static mixers, the degree of mixing is related to the headloss (i.e., pressure drop) through the mixer. The headloss through the mixer can be estimated using the following expression:

$$h \approx k\left(\frac{v^2}{2g}\right) \approx K_{SM}v^2 \tag{5–7}$$

where h = headloss dissipated as liquid passes through mixing device, m
k = empirical coefficient characteristic of the mixing
v = approach velocity, m/s
K_{SM} = overall coefficient for mixing device, s^2/m
g = acceleration due to gravity, 9.81 m/s^2

Typical values for K_{SM} vary from about 1.0 to 4.0, with a value of 2.5 being typical for the mixers used in wastewater. However, because the specific geometry of the internal mixing vanes used in such mixers varies with each manufacturer, the headloss or pressure-drop curves provided by the manufacturer must be used for estimation purposes. The power dissipated by static mixing devices can be computed using the following equation:

$$P = \gamma Qh \tag{5–8}$$

where P = power dissipated, kW
γ = specific weight of water, kN/m^3
Q = flowrate, m^3/s

Inline Mixers. Inline mixers are similar to static mixers but contain a rotating mixing element to enhance the mixing process. Typical examples of inline mixers are illustrated on Fig. 5–12(c) and (d). In the inline mixer shown on Fig. 5–12(c), the power required for mixing is supplied by an external source. For the mixer shown on Fig. 5–12(d), the power for mixing is supplied by the energy dissipation caused by the orifice plate and by the power input to the propeller mixer.

High-Speed Induction Mixer. The high-speed induction mixer is an efficient mixing device for a variety of chemicals. A proprietary device, shown on Fig. 5–12(e) for chlorine mixing, consists of a motor-driven open propeller that creates a vacuum in the chamber directly above the propeller. The vacuum created by the impeller induces the chemical to be mixed directly from the storage container without the need for dilution water. The high operating speed of the impeller (3450 rev/min) provides a thorough mixing of the chemical that is being added to the water by the high velocity of the fluid leaving the impeller of the mixing device.

Pressurized Water Jets. Pressurized water jet mixers, such as illustrated on Fig. 5–12(f), can also be used to mix chemicals. An important design feature of pressurized water jet mixers is that the velocity of the jet containing the chemical to be mixed must be sufficient to achieve mixing in all parts of the pipeline (Chao and Stone, 1979; Pratte and Baines, 1967). As shown on Fig. 5–12(f), a reactor tube has been added to achieve effective mixing. With pressurized water jet mixers, the power for mixing is provided by an external source (i.e., the solution feed pump).

Types of Mixers Used for Maintaining Solids in Suspension in Wastewater Treatment and Chemical Mixing

A variety of different impeller types are used for maintaining solids in suspension and mixing chemicals. Information on the types of mixing impellers used in wastewater treatment is presented in Table 5–10. Turbine and propeller and hyperboloid mixers are discussed further below.

Turbine and Propeller Mixers. Turbine and propeller mixers are used commonly in wastewater treatment processes for mixing and blending of chemicals, for keeping material in suspension, and for aeration. Turbine or propeller mixers are usually constructed with a vertical shaft driven by a speed reducer and electric motor. Two types of impellers are used for mixing: (1) radial-flow impellers and (2) axial-flow impellers (see Fig. 5–13). Radial-flow impellers generally have flat or curved blades located parallel to the axis of the shaft. The vertical flat-blade turbine impeller is a typical example of a radial-flow impeller. Axial-flow impellers make an angle of less than 90° with the drive shaft. Axial-flow impellers are further classified as variable pitch–constant angle of attack

Table 5–10

Typical types of mixing impellers used in wastewater treatment[a]

Type of impeller	Flow	Shear	Pumping capacity	Applications
Vertical flat blade turbine (VFBT)	Radial	High	Low	Vertical flow flash mixing, suspension of solids, gas dispersion
Disk turbine	Radial	High	Low	Mixing, gas dispersion
Hyperboloid	Radial	Very low	High	Suspension of solids, flocculation, mixing, gas dispersion
Surface impeller	Radial	High	Moderate	Gas transfer
Pitched blade turbine (45 or 32° PBT)	Axial	Moderate	Moderate	Horizontal flash mixing, suspension of solids
Low shear hydrofoil (LS)	Axial	Low	High	Horizontal flow flash mixing, suspension of solids, blending, flocculation
Propeller	Axial	Very low	High	Horizontal flow flash mixing, suspension of solids, blending, flocculation

[a] Adapted, in part, from Philadelphia Mixer Catalog.

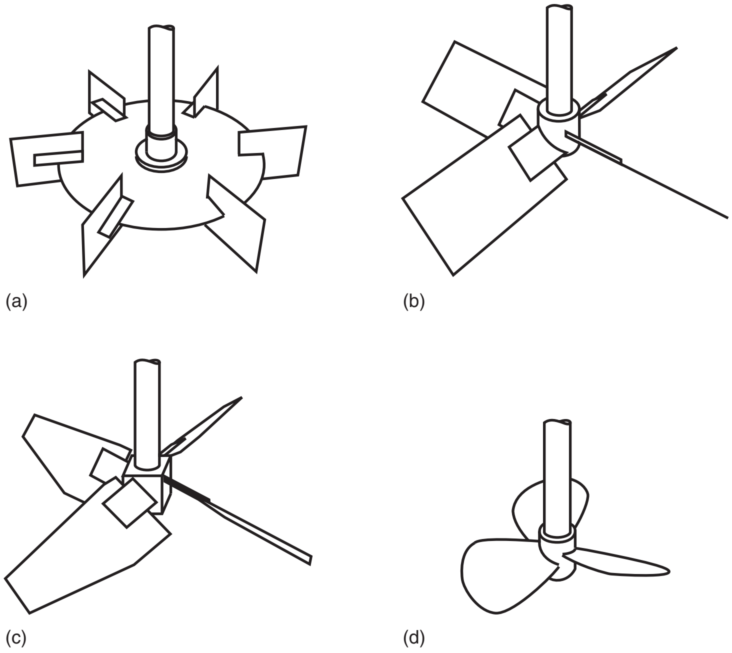

Figure 5–13

and constant pitch-variable angle of attack. Propellers and hydrofoils are typical examples. Propeller mixers may be provided with more than one set of propeller blades on a shaft.

Rapid mixing in wastewater-treatment processes usually occurs in the regime of turbulent flow in which inertial forces predominate. As a general rule, the higher the velocity and the greater the turbulence, the more efficient the mixing. On the basis of inertial and viscous forces, the following mathematical relationships can be used to estimate the power requirements for mixing and the pumping capacity of the mixer.

Power for mixing

$$P = N_P \rho n^3 D^5 \tag{5–9}$$

Pumping capacity

$$Q_i = N_Q n D^3 \tag{5–10}$$

where P = power input, W, (kg·m^2/s^3)
N_P = power number for impeller, unitless
ρ = density, kg/m^3
n = revolutions per second, r/s
D = diameter of impeller, m
Q_i = pump discharge, m^3/s
N_Q = flow number for impeller, unitless

Typical values for N_P and N_Q are presented in Table 5–11 for various types of impellers. It is important to consult manufacturers' catalogs for the appropriate values for N_P and N_Q for a specific piece of equipment. The values of N_P and N_Q must be adjusted for viscosity, blade characteristics, and the number of impellers on a single shaft.

Based on Eqs. (5–9) and (5–10), for a constant input of power as the impeller size is increased, more power is expended on flow and less on turbulence or shear. Thus, a small impeller operating at a high rotational speed will produce greater fluid shear and less pumping, whereas a large impeller operating at a slow speed will result in a high pumping

Table 5–11

Typical power and flow numbers for various impellers

Type of impeller	Power number, N_P	Flow number, N_Q	Pumping capacity
Vertical flat blade turbine(VFBT)	3.5–4.0	0.84–0.86	Low
Disk turbine			Low
Pitched blade turbine (45° PBT)	1.6	0.84–0.86	
Pitched blade turbine (32° PBT)	1.1	0.84–0.86	Moderate
Low shear hydrofoil (LS, 3-blade)	0.30	0.50	High
Low shear hydrofoil (LS, 4-blade)	0.60	0.55	High
Propeller			High

[a] Adapted, in part, from Philadelphia Mixer Catalog.

capacity and low fluid shear. Mixers with small impellers operating at high speeds are best for dispersing gases or small amounts of chemicals in wastewater. Mixers with slow-moving impellers are best for blending two fluid streams, or for flocculation.

Typically, Eq. (5–9) applies if the Reynolds number is in the turbulent range (greater than 10,000). For intermediate values of the Reynolds number, manufacturers' catalogs should be consulted. The Reynolds number is given by

$$N_R = \frac{D^2 n \rho}{\mu} \tag{5–11}$$

where D = diameter of impeller, m
n = rotational speed, rev/s
ρ = mass density of fluid, kg/m^3
μ = dynamic viscosity of fluid, N·s/m^2
Note: N = kg·m/s^2

Mixers are selected on the basis of laboratory or pilot-plant tests or similar data provided by manufacturers. No satisfactory method exists for scaling up from an agitator of one design to a unit of a different design. Geometrical similarity should be preserved, and the power input per unit volume should be kept the same.

Where propeller or turbine mixers are used, it is imperative that vortexing or mass swirling of the liquid be eliminated. Vortexing, in which the liquid to be mixed rotates with the impeller, causes a reduction in the difference between the fluid velocity and the impeller velocity and thus decreases the effectiveness of mixing. If the mixing vessel is fairly small, vortexing can be prevented by mounting the impellers off-center or at an angle with the vertical, or by having them enter the side of the basin at an angle. In circular and rectangular tanks the usual method used to limit vortexing is to install four or more vertical baffles extending approximately one-tenth the diameter out from the wall [see Fig. 5–14, see also Fig. 6–33(b)]. These baffles effectively break up the mass rotary motion and promote vertical mixing.

Typical design parameters for mixing operations, as given in Table 5–12, include (1) the velocity gradient G, subject to the caveats discussed previously, (2) the rotational

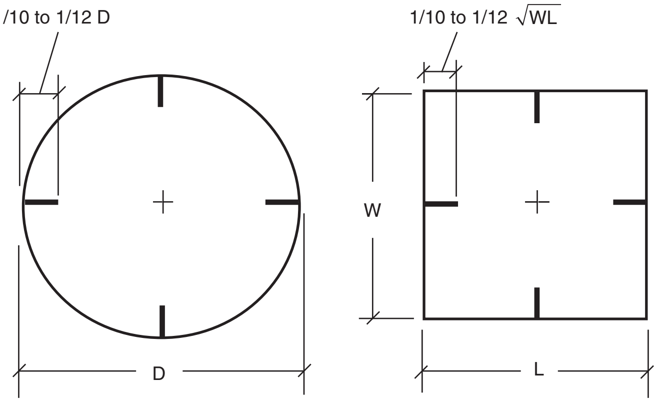

Figure 5–14

Definition sketch for the placement of baffles to limit vortexing in mixing tanks and reactors.

speed, and (3) the ratio of the impeller diameter to the equivalent tank diameter. The rotation speed will vary considerably, depending on whether the flow through the mixer is horizontal or vertical (see Fig. 5–15).

Hyperboloid Mixers. Hyperboloid mixers are used in water and wastewater treatment processes in a variety of applications including mixing and blending of chemicals, for flocculation, suspension of biosolids in anaerobic and anoxic basins, and for aeration in activated sludge and in sludge basins (see Fig. 5–16). Typically hyperboloid mixers are designed with a vertical shaft driven by a speed reducer and electric motor. The size of the hyperboloid impeller and the rotational speed depends on the basin size and geometry. The hyperboloid mixers have the advantage of being mounted close to the bottom of the tank which allows for the energy introduction where it is needed to suspend sludge floc.

Types of Mixers Used for Flocculation in Wastewater Treatment

The principal types of mixers used for flocculation can be classified as (1) static mixers, (2) paddle mixers, and (3) turbine, propeller, and hyperboloid mixers. Each of these types of mixers is considered briefly in the following discussion.

Table 5–12

Typical design parameters for mixing operations[a]

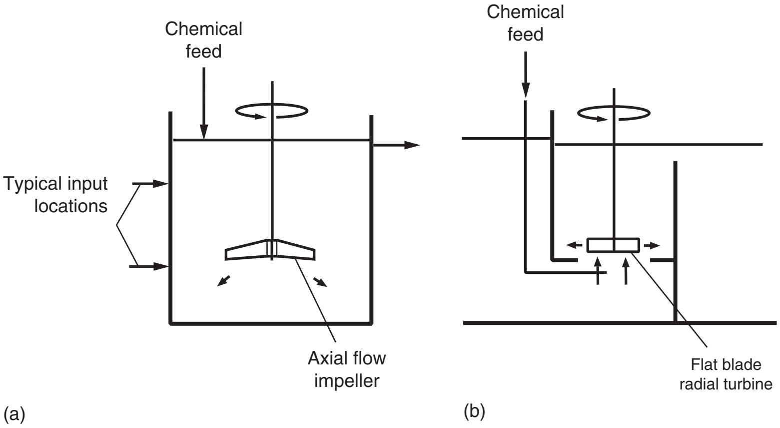
Parameter	Symbol	Unit	Value
Horizontal flow mixing			
Velocity gradient	G	1/s	500–2500
Rotational speed	n	rev/min	40–125
Ratio impeller diameter to equivalent tank diameter[b]	D/T_e	unitless	0.25–0.40
Vertical flow mixing			
Velocity gradient	G	1/s	500–2500
Rotational speed	n	rev/min	25–45
Ratio impeller diameter to equivalent tank diameter	D/T_e	unitless	0.40–0.60

[a] Adapted, in part, from Philadelphia Mixer Catalog.

[b] $T_e \approx 1.13\sqrt{L \times W}$ where L = length and W = width.

Figure 5–15

Definition sketch for rapid mixing in a tank or channel (typically mixing times are 10 to 30 s): (a) horizontal flow through a mixing tank equipped with an axial flow impeller and (b) vertical flow through a mixing basin equipped with radial flow impeller.



Baffled Static Mixers. In the most common type of baffled static mixer, the liquid to be treated is subjected to a series of flow reversals in which the direction of flow is changed. Baffled static mixers can be composed of over and under narrow flow channels, such as shown on Fig. 5–17(a), or the narrow flow channels can be laid out horizontally. The headloss caused by frictional resistance offered by the flow channels and the flow reversals provides the energy for flocculation. In some designs, the channel spacing is varied to provide a decreasing energy gradient so that the large floc particles formed toward the end of the flocculation basin will not be broken apart.

Paddle Mixers. Paddle mixers are used as flocculation devices when coagulants, such as aluminum or ferric sulfate, and coagulant aids, such as polyelectrolytes and lime, are added to wastewater or solids (sludge). Paddle flocculators consist of a series of appropriately spaced paddles mounted on either a horizontal or vertical shaft. Flocculation is promoted by gentle mixing brought about by the slow-moving paddles, which, as shown on Fig. 5–17(b), rotate the liquid and promote mixing. Increased particle contact promotes floc growth, but, if the mixing is too vigorous, the increased shear forces will break up the floc into smaller particles. Agitation should be controlled carefully so that the floc particles will be of suitable size and will settle readily. Variable-speed drives are often used to regulate the paddle speed. There has been a movement away from paddle flocculators to the

Figure 5–16

Hyperboloid mixer: (a) schematic and (b) view of mixer (air diffusers below the mixer have been blanketed off for the mixer to work properly).

Typical mixers used for flocculation in wastewater treatment facilities: (a) over and under baffled reactor, (b) paddle mixer in baffled tank, and (c) turbine mixer in a baffled tank.

use of turbine flocculators because of the maintenance problems associated with paddle flocculators.

Power in a mechanical paddle system can be related to the drag force on the paddles as follows.

$$F_D = \frac{C_D A \rho v_p^2}{2} \tag{5–12}$$

$$P = F_D v_p = \frac{C_D A \rho v_p^3}{2} \tag{5–13}$$

where F_D = drag force, N
C_D = coefficient of drag of paddle moving perpendicular to fluid
A = cross-sectional area of paddles, m^2
ρ = mass density of fluid, kg/m^3
v_p = relative velocity of paddles with respect to the fluid, m/s, usually assumed to be 0.6 to 0.75 times the paddle-tip speed
P = power requirement, W ($kg \cdot m^2/s^3$)

The application of Eq. (5–13) is illustrated in Example 5–3.

EXAMPLE 5–3 **Power Requirements and Paddle Area for a Wastewater Flocculator**

Determine the theoretical power requirement and the paddle area required to achieve a G value of 50/s in a tank with a volume of 3000 m^3. Assume that the water temperature is 15°C, the coefficient of drag C_D for rectangular paddles is 1.8, the paddle-tip velocity υ is 0.6 m/s, and the relative velocity of the paddles υ_p is 0.75 υ.

Solution

1. Determine the theoretical power requirement using Eq. (5–3), rearranged as shown below.

$$\mu \text{ at } 15^\circ\text{C} = 1.139 \times 10^{-3} \text{ N·s/m}^2 \text{ (see Appendix C)}$$

$$\begin{aligned} P &= G^2 \mu V \\ &= (50/\text{s})^2 (1.139 \times 10^{-3} \text{ N·s/m}^2)(3000 \text{ m}^3) \\ &= 8543 \text{ (kg·m}^2/\text{s}^3) = 8543 \text{ W} \\ &= 8.54 \text{ kW} \end{aligned}$$

2. Determine the required paddle area using Eq. (5–13).

$$\rho = 999.1 \text{ kg/m}^3 \text{ (see Appendix C)}$$

$$\begin{aligned} A &= \frac{2P}{C_D \rho \upsilon_p^3} \\ &= \frac{2(8543 \text{ kg/m}^2 \cdot \text{s}^3)}{1.8(999.1 \text{ kg/m}^3)(0.75 \times 0.6 \text{ m/s})^3} \\ &= 104.3 \text{ m}^2 \end{aligned}$$

Turbine, Propeller, and Hyperboloid Flocculators. The rotating element of turbine- and propeller-type flocculators consists of three or four blades attached to a vertical shaft [see Fig. 5–17(c)]. The hyperboloid-type flocculator consists of a hyperboloid shaped mixer body that has 8 integrated so-called motion fins. Hyperboloid-type mixer was shown previously in Fig. 5–16. The flocculator is driven with an external gear reduction system powered with a variable-speed drive. The blades of the propeller may be rectangular in shape or have the shape of a hydrofoil. Blades shaped as hydrofoils or hyperboloid impellers are used to limit the amount of floc shearing while at the same time providing the velocity gradients and pumping capacity needed for mixing. Typical design parameters for flocculation facilities are presented in Table 5–13. In sizing turbine, propeller, or hyperboloid flocculators, both the power and the pumping requirements must be considered. In addition, the tip speed and the superficial velocity must also be considered. The required power and the pumping capacity can be estimated using Eqs. (5–9) and (5–10), presented previously. In wastewater flocculation, if variable-speed drives are provided for the flocculators (considering the minimum G required to keep particles in suspension), the mixer speed can be adjusted to optimize flocculation and energy use.

Types of Mixers Used for Continuous Mixing in Wastewater Treatment

Continuous mixing operations are used in biological treatment processes such as the activated-sludge process to maintain the mixed liquor suspended solids uniformly mixed state. In biological treatment systems the mixing device is also used to provide the oxygen needed for the process. Thus, the aeration equipment must be able to provide the oxygen needed for the process and the energy needed to maintain mixed conditions within the reactor.

Table 5–13

Typical design parameters for flocculation facilities[a]

Parameter	Symbol	Unit	Value
Velocity gradient	G	1/s	100–500
Rotational speed	n	rev/min	10–30
Ratio length to width	L/W	unitless	$1 \leq L/W \leq 1.25$
Ratio impeller diameter to equivalent tank diameter[b]	D/T_e	unitless	0.35–0.45
Ratio height to equivalent tank diameter[b]	H/T_e	unitless	0.9–1.1
Tip speed			
Flat blade turbine	TS	m/s	0.6–1.5
Pitch blade turbine (45 or 32°)	TS	m/s	1.8–2.4
Low shear propeller (3 or 4 blade)	TS	m/s	2–2.7
Superficial velocity[c]	SV	m/min	1–2
Hyperboloid impeller (8 motion fins)	TS	m/s	1.8–3.0

[a] Adapted, in part, from Philadelphia Mixer Catalog.

[b] $T_e = 1.13\sqrt{L \times W}$ where L = length and W = width in m.

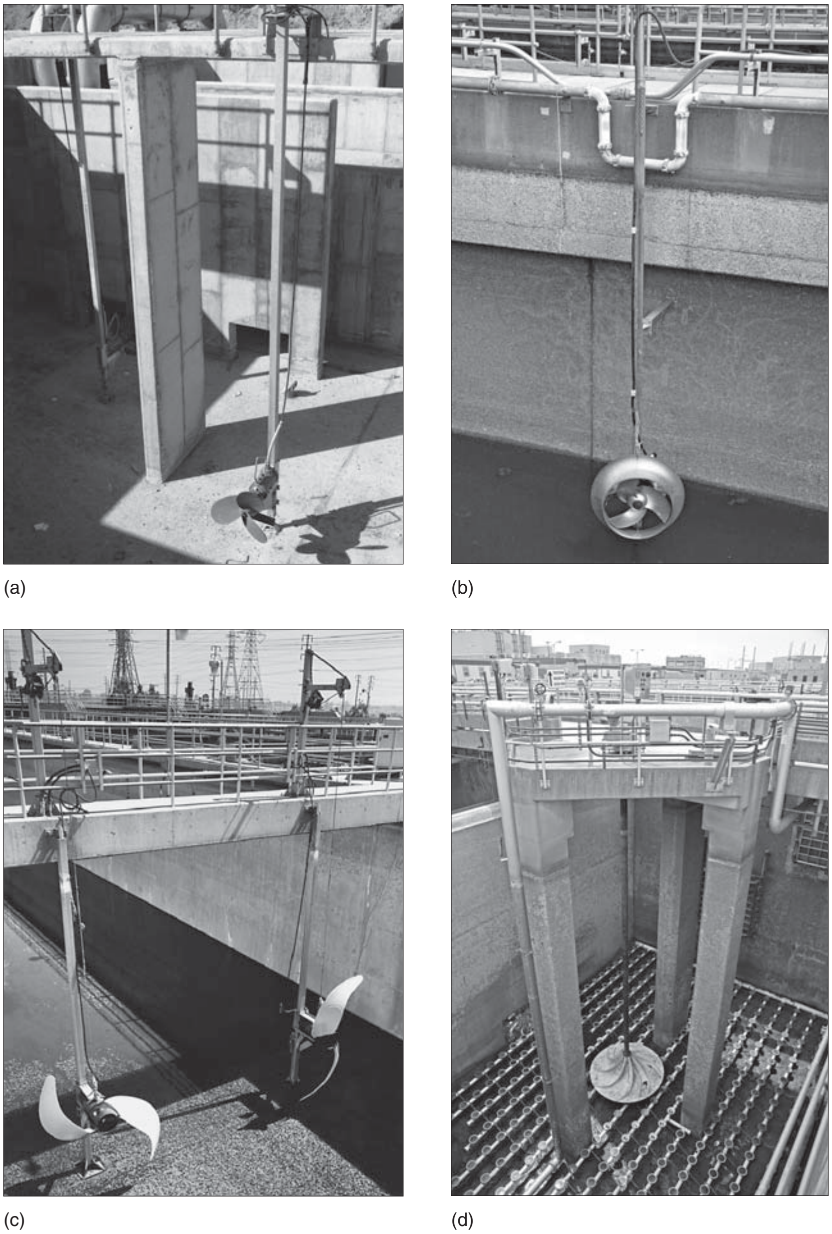
[c] $SV = Q/A$ where Q is the pumping rate and A is the basin cross-sectional area.

Both mechanical aerators and dissolved aeration devices are used. Diffused air is often used to fulfill both the mixing and oxygen requirements for aeration tanks and for maintaining solids in suspension in distribution channels with low velocities carrying raw, unsettled wastewater or mixed liquor. Alternatively, mechanical turbine-aerator mixers may be used. Hyperboloid mixer/aerators can be used in situations where a large variety in oxygen levels can be expected.

Where biological bioreactors are being used for biological nutrient removal, it is essential that the feed channels to the bioreactors and the anaerobic or anoxic zones within the bioreactor be non-aerated. Horizontal, submersible propeller mixers provide directional mixing and can be used to maintain channel velocities in oxidation ditches operating at low dissolved oxygen levels or to mix the contents of anoxic or anaerobic reactor zones, (see Fig. 5–18). Hyperboloid mixers can be used for non-aerated mixing of influent feed channels and are particularly applicable for non-directional mixing of anaerobic or anoxic zones with low depth to width ratios [see Fig. 5–16(b)]. In general, hyperboloid mixers will be more efficient than other types of mixing equipment.

Pneumatic Mixing. In pneumatic mixing, a gas (usually air or oxygen) is injected into the bottom of mixing or activated-sludge tanks, and the turbulence caused by the rising gas bubbles serves to mix the fluid contents of the tank. In aeration, soft bubbles are formed with an average diameter of 5 mm while the air flow is about 10 percent of the liquid flow. The velocity gradients due to bubble formation range from a $G_{\text{avg}} < 200\ \text{s}^{-1}$ to $G_{\max} = 8200\ \text{s}^{-1}$ (Masschelein, 1992).

Where air flocculation is employed, the air supply system should be adjustable so that the flocculation energy level can be varied throughout the tank. When air is injected in



(a) (b) (c) (d)

Figure 5–18

Mixers used to mix the contents of an anoxic biological reactor: (a) horizontal, submersible propeller, (b) submersible propeller with shroud, (c) airfoil mixer, and (d) hyperbolic mixer. (Air diffusers below the mixer have been blanked off. This tank has been designed to either operate with mixing or with diffused air.)

mixing or flocculation tanks or channels, the power dissipated by the rising air bubbles can be estimated with the following equation:

$$P = p_a V_a \ln \frac{p_c}{p_a} \tag{5–14}$$

where P = power dissipated, kW
p_a = atmospheric pressure, kN/m^2
V_a = volume of air at atmospheric pressure, m^3/s
p_c = air pressure at the point of discharge, kN/m^2

Equation (5–14) is derived from a consideration of the work done when the volume of air released under compressed conditions expands isothermally. If the flow of air at atmospheric pressure is expressed in terms of m^3/min (ft^3/min) and the pressure is expressed in term of meters (feet) of water, Eq. (5–14) can be written as follows:

$$P = KQ_a \ln\left(\frac{h + 10.33}{10.33}\right) \qquad \text{S.I. units} \tag{5–15a}$$

$$P = KQ_a \ln\left(\frac{h + 33.9}{33.9}\right) \qquad \text{U.S. customary units} \tag{5–15b}$$

where K = constant 1.689 (35.28 in U.S. customary units)
Q_a = air flowrate at atmospheric pressure, m^3/min (ft^3/min)
h = air pressure at the point of discharge expressed in meters of water, m (ft)

The velocity gradient G achieved in pneumatic mixing is obtained by substituting P from Eq. (5–15) into Eq. (5–3).

Mechanical Aerators and Mixers. The principal types of mechanical aerators used for continuous mixing are high- or low-speed surface aerators and hyperboloid mixer/aerators. These devices are discussed in Sec. 5–11, which deals with aeration, and in Chap 8. Typical power requirements for mixing with surface aerators range from 20 to 40 kW/10^3 m^3 (0.75 to 1.50 hp/10^3 ft^3), depending on the type of mixer and the geometry of the tank, lagoon, or basin. For hyperboloid mixer/aerators the power requirements for mixing are significantly lower because the mixing and the aeration functions are separated. The typical range depending on geometry of the tank, lagoon, or basin is 2 to 4 kW/10^3 m^3 (0.08 to 0.15 hp/10^3 ft^3).

New Developments in Mixing Technology

New analytical tools that are now being applied to the analysis of and design of mixing devices include (1) computational fluid dynamics (CFD), (2) digital particle image velocimetry (DPIV), (3) laser doppler anemometry (LDA), and (4) laser-induced fluorescence (LIF). Computational fluid dynamics is used to model the fluid flow patterns in mixing devices and for scale-up analysis. In respect to fluid flow, both two- and three-dimensional models are now available. Digital particle image velocimetry is used to understand fluid movement in mixing devices. The movement of neutrally buoyant fluorescent particles is photographed using laser beam illumination. Laser doppler anemometry is used to study turbulence and to obtain data on the mean velocity at a given location in the mixing chamber. To evaluate the mean velocity, two laser beams are focused so that the beams intersect. As a particle passes through the intersection of the beams, light is reflected. The wavelength of the reflected light is a function of the particle velocity. Laser-induced fluorescence is used to measure the degree of mixing of solutions. Dyes such as rhodimine and other materials will fluoresce when struck by laser light of a given wavelength. The scattering of light is measured to assess the degree of mixing. This technique is being used to study the diffusion and mixing of a substance by assessing the coefficient of variation of the mixed solution and to evaluate blending times.

5–4 GRAVITY SEPARATION THEORY

The removal of suspended and colloidal materials from wastewater by gravity separation is one of the most widely used physical unit processes in wastewater treatment. A summary of gravitational phenomena utilized in wastewater treatment is presented in Table 5–14.

Table 5–14

Types of gravitational phenomena utilized in wastewater treatment

Type of separation phenomenon	Description	Application/occurrence
Discrete particle settling	Refers to the settling of particles in a suspension of low solids concentration by gravity in a constant acceleration field. Particles settle as individual entities, and there is no significant interaction with neighboring particles	Removal of grit and sand particles from wastewater
Flocculant settling	Refers to a rather dilute suspension of particles that coalesce, or flocculate, during the settling operation. By coalescing, the particles increase in mass and settle at a faster rate	Removal of a portion of the TSS in untreated wastewater in primary settling facilities, and in upper portions of secondary settling facilities. Also removes chemical floc in settling tanks
Ballasted flocculant settling	Refers to the addition of an inert ballasting agent and a polymer to a partially flocculated suspension to promote rapid settling and improved solids reduction. A portion of the recovered ballasting agent is recycled to the process	Removal of a portion of the TSS in untreated wastewater, wastewater from combined systems, and industrial wastewater. Also reduces BOD and phosphorus
Hindered settling (also called zone settling)	Refers to suspensions of intermediate concentration, in which interparticle forces are sufficient to hinder the settling of neighboring particles. The particles tend to remain in fixed positions with respect to each other, and the mass of particles settles as a unit. A solids-liquid interface develops at the top of the settling mass	Occurs in secondary settling facilities used in conjunction with biological treatment facilities
Compression settling	Refers to settling in which the particles are of such concentration that a structure is formed, and further settling can occur only by compression of the structure. Compression takes place from the weight of the particles, which are constantly being added to the structure by sedimentation from the supernatant liquid	Usually occurs in the lower layers of a deep solids or biosolids mass, such as in the bottom of deep secondary settling facilities and in solids-thickening facilities
Accelerated gravity settling	Removal of particles in suspension by gravity settling in an acceleration field	Removal of grit and sand particles from wastewater
Flotation	Removal of particles in suspension that are lighter than water by air or gas flotation	Removal of greases and oils, light material that floats, thickening of solids suspensions

Sedimentation is the term applied to the separation of suspended particles that are heavier than water, by gravitational settling. The terms sedimentation and settling are used interchangeably. A sedimentation basin may also be referred to as a sedimentation tank, clarifier, settling basin, or settling tank. Accelerated gravity settling involves the removal of particles in suspension by gravity settling in an accelerated flow field. The fundamentals of gravity separation are introduced in this section. The design of facilities for the removal of grit and TSS are considered in Secs. 5–6 and 5–7, respectively.

Description

Sedimentation is used for the removal of grit, TSS in primary settling basins, biological floc removal in the activated-sludge settling basin, and chemical floc removal when the chemical coagulation process is used. Sedimentation is also used for solids concentration in sludge thickeners. In most cases, the primary purpose is to produce a clarified effluent, but it is also necessary to produce sludge with a solids concentration that can be handled and treated easily.

On the basis of the concentration and the tendency of particles to interact, four types of gravitational settling can occur: (1) discrete particle, (2) flocculent, (3) hindered (also called zone), and (4) compression. Because of the fundamental importance of the separation processes in the treatment of wastewater, the analysis of each type of separation process is discussed separately. In addition, tube settlers, used to enhance the performance of sedimentation facilities, are also described. Other gravitational separation processes include high-rate clarification, accelerated gravity settling, and flotation and are discussed subsequently.

Particle Settling Theory

The settling of discrete, nonflocculating particles can be analyzed by means of the classic laws of sedimentation formed by Newton and Stokes. Newton's law yields the terminal particle velocity by equating the gravitational force of the particle to the frictional resistance, or drag. The gravitational force is given by

$$F_G = (\rho_p - \rho_w) g V_p \tag{5–16}$$

where F_G = gravitational force, MLT^{-2} ($kg{\cdot}m/s^2$)
ρ_p = density of particle, ML^{-3} (kg/m^3)
ρ_w = density of water, ML^{-3} (kg/m^3)
g = acceleration due to gravity, LT^{-2} (9.81 m/s^2)
V_p = volume of particle, L^3 (m^3)

The frictional drag force depends on the particle velocity, fluid density, fluid viscosity, particle diameter, and the drag coefficient C_d (dimensionless), and is given by Eq. (5–17).

$$F_d = \frac{C_d A_p \rho_w \upsilon_p^2}{2} \tag{5–17}$$

where F_d = frictional drag force, MLT^{-2} ($kg{\cdot}m/s^2$)
C_d = drag coefficient (unitless)
A_p = cross-sectional or projected area of particles in direction of flow, L^2 (m^2)
υ_p = particle settling velocity, LT^{-1} (m/s)

Equating the gravitational force to the frictional drag force for spherical particles yields Newton's law:

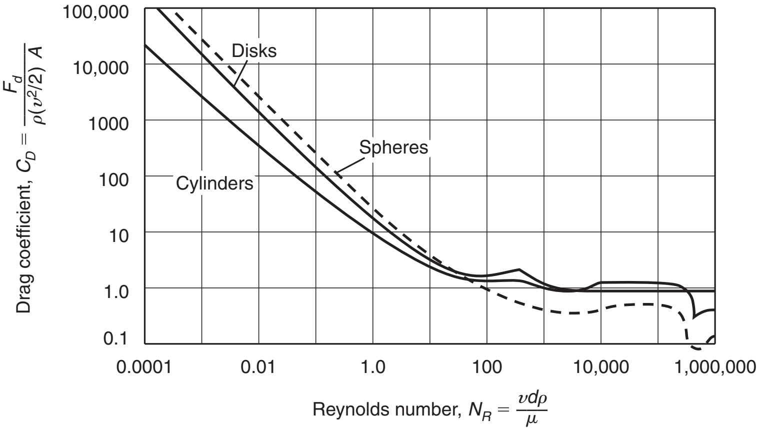
$$\upsilon_{p(t)} = \sqrt{\frac{4g}{3C_d}\left(\frac{\rho_p - \rho_w}{\rho_w}\right) d_p} \approx \sqrt{\frac{4g}{3C_d}(sg_p - 1) d_p} \tag{5–18}$$

where $\upsilon_{p(t)}$ = terminal velocity of particle, LT^{-1} (m/s)
d_p = diameter of particle, L (m)
sg_p = specific gravity of the particle

The coefficient of drag C_d takes on different values depending on whether the flow regime surrounding the particle is laminar or turbulent. The drag coefficient for various particles is shown on Fig. 5–19 as a function of the Reynolds number. As shown on Fig. 5–19, there are three more or less distinct regions, depending on the Reynolds number: laminar ($N_R < 1$), transitional (N_R = 1 to 2000), and turbulent ($N_R > 2000$).

Figure 5–19

Coefficient of drag as a function of Reynolds number.



Although particle shape affects the value of the drag coefficient, for particles that are approximately spherical, the curve on Fig. 5–19 is approximated by the following equation (upper limit of $N_R = 10^4$):

$$C_d = \frac{24}{N_R} + \frac{3}{\sqrt{N_R}} + 0.34 \tag{5–19}$$

The Reynolds number, N_R, for the settling of spherical particles is defined as

$$N_R = \frac{v_p d_p \rho_w}{\mu} = \frac{v_p d_p}{\nu} \tag{5–20}$$

where ν = kinematic viscosity, L^2T^{-1} (m^2/s)
μ = dynamic viscosity, MTL^{-2} ($N{\cdot}s/m^2$)

Other terms are as defined above.

Non Spherical Particles. Because most of the particles in wastewater are nonspherical, a sphericity factor, ψ, is introduced in the Reynolds number as shown in Eq. (5–21).

$$N_R = \frac{v_p d_p \rho_w \psi}{\mu} = \frac{v_p d_p \psi}{\nu} \tag{5–21}$$

where ψ = sphericity, dimensionless
Other terms are as defined above.

The sphericity factor is the ratio of the surface area of a sphere with the same volume as a given particle to the surface area of the particle [see Eq. (11–11) in Chap.11]. Sphericity factors vary from 1.0 for spheres to about 0.70 for crushed sand. An alternative approach to account for non spherical particles is to multiply the coefficient of drag by a shape factor, ϕ (Degremont, 2007). Typical values of ϕ for sand and anthracite are 2 and 2.25, respectively. Values for flocculent particles can range as high as 15 to 25 and higher. Because ψ, as defined above, is essentially equal to $1/\phi$, this latter approach is more conservative than the use of Eq. (5–21), and is used mostly for flocculent particles (see Example 5–10).

Settling in the Laminar Region. For Reynolds numbers less than about 1.0, viscosity is the predominant force governing the settling process, and the first term in

Eq. (5–19) predominates. Assuming spherical particles, substitution of the first term of the drag coefficient equation [Eq. (5–19)] into Eq. (5–18) yields Stokes' law:

$$v_p = \frac{g(\rho_p - \rho_w)d_p^2}{18\mu} \approx \frac{g(sg_p - 1)d_p^2}{18\nu} \tag{5–22}$$

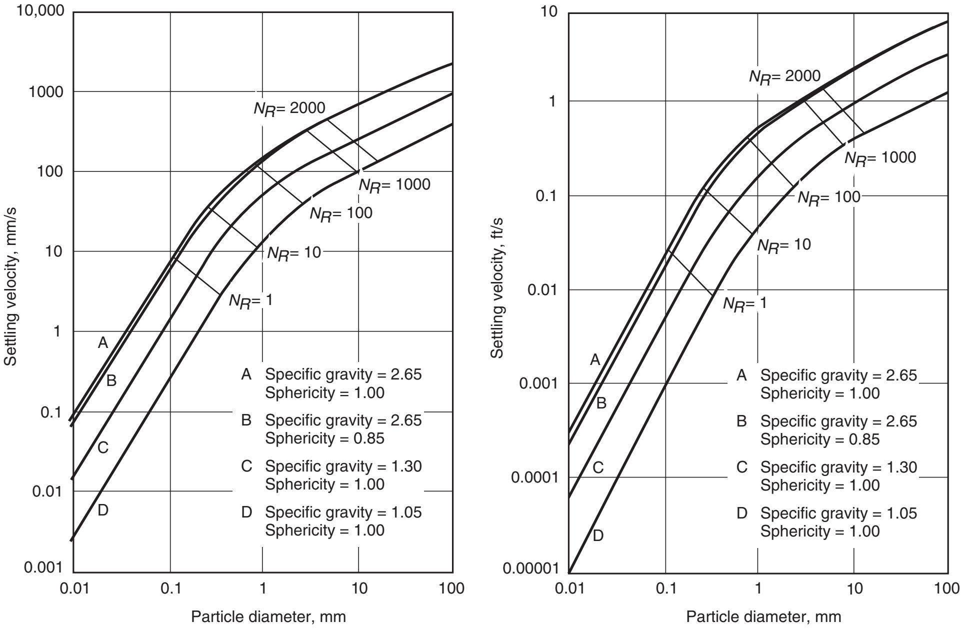
Terms are as defined previously. For laminar-flow conditions, Stokes found the drag force to be

$$F_D = 3\pi\mu v_p d_p \tag{5–23}$$

Stokes' law [Eq. (5–22)] can also be derived by equating the drag force found by Stokes to the effective weight of the particle [Eq. (5–16)].

Settling in the Transition Region. In the transition region, the complete form of the drag equation [Eq. (5–19)] must be used to determine the settling velocity, as illustrated in Example 5–4. Because of the nature of the drag equation, finding the settling velocity is an iterative process. As an aid in visualizing settling in the transition region, Fig. 5–20 has been prepared, which covers the laminar and the transition region for particle sizes of interest in environmental engineering.

Settling in the Turbulent Region. In the turbulent region, inertial forces are predominant, and the effect of the first two terms in the drag coefficient equation [Eq. (5–19)] is reduced. For settling in the turbulent region, a value of 0.4 is used for the



(a) (b)

Figure 5–20

Settling velocities for various particle sizes under varying conditions: (a) settling velocity in mm/s versus particle size in mm, and (b) settling velocity in ft/s versus particle size in mm (Crites and Tchobanoglous, 1998).

coefficient of drag. If a value of 0.4 is substituted into Eq. (5–21) for C_d, the resulting equation is

$$v_p = \sqrt{3.33\,g\left(\frac{\rho_p - \rho_w}{\rho_w}\right)d_p} \approx \sqrt{3.33\,g(sg_p - 1)\,d_p} \tag{5–24}$$

The use of Eqs. (5–18) through (5–22) is illustrated in Example 5–4.

EXAMPLE 5–4 **Determination of Particle Terminal Settling Velocity** Determine the terminal settling velocity for a sand particle with an average diameter of 0.5 mm (0.00164 ft), a sphericity factor of 0.85, and a specific gravity of 2.65, settling in water at 20°C (68°F). At this temperature, the kinematic viscosity value given in Appendix C is 1.003×10^{-6} m²/s (1.091×10^{-5} ft²/s).

Solution

1. Determine the terminal settling velocity for the particle using Stokes' Law (Eq. 5–22).

$$\begin{aligned} v_p &= \frac{g(sg_p - 1)d_p^2}{18\nu} \\ &= \frac{(9.81\ \text{m/s}^2)(2.65 - 1)(0.5 \times 10^{-3}\ \text{m})^2}{18(1.003 \times 10^{-6}\ \text{m}^2/\text{s})} = 0.224\ \text{m/s} \end{aligned}$$

2. Check the Reynolds number with Eq. (5–21) which includes the sphericity factor, ψ.

$$N_R = \frac{v_p d_p \psi}{\nu} = \frac{(0.224\ \text{m/s})(0.5 \times 10^{-3}\ \text{m})(0.85)}{(1.003 \times 10^{-6}\ \text{m}^2/\text{s})} = 94.9$$

The use of Stokes' Law is not appropriate for Reynolds number > 1.0. Therefore, Newton's Law (Eq. 5–18) must be used to determine the settling velocity in the transition region (see Fig. 5–20). The drag coefficient term in Newton's equation is dependent on the Reynolds number, which is a function of the settling velocity. Because the settling velocity is not known, an initial settling velocity must be assumed. The assumed velocity is used to compute the Reynolds number, which is used to determine the drag coefficient, which is used in the Newton equation to calculate the settling velocity. A solution is achieved when the initial assumed settling velocity is approximately equal to the settling velocity resulting from Newton's equation. The solution process is iterative, as illustrated below.

3. For the first assumed settling velocity, use the Stokes' Law settling velocity calculated above. Using the resulting Reynolds number, also determined previously, compute the drag coefficient.

$$C_d = \frac{24}{N_R} + \frac{3}{\sqrt{N_R}} + 0.34 = \frac{24}{94.9} + \frac{3}{\sqrt{94.9}} + 0.34 = 0.901$$

4. Use the drag coefficient in Newton's equation to determine the particle settling velocity.

$$v_p = \sqrt{\frac{4g(sg - 1)d}{3C_d}} = \sqrt{\frac{4(9.81\ \text{m/s}^2)(2.65 - 1)(0.5 \times 10^{-3}\ \text{m})}{3 \times 0.901}} = 0.109\ \text{m/s}$$

Because the initial assumed settling velocity (0.224 m/s) does not equal the settling velocity calculated by Newton's equation (0.109 m/s), a second iteration is necessary.

5. For the second iteration, assume a settling velocity value of 0.09 m/s, and calculate the Reynolds number. Use the Reynolds number to determine the drag coefficient, and use the drag coefficient in Newton's equation to find the settling velocity.

$$N_R = \frac{(0.09\text{ m/s})(0.5 \times 10^{-3}\text{ m})(0.85)}{(1.003 \times 10^{-6}\text{ m}^2\text{/s})} = 38.1$$

$$C_d = \frac{24}{38.1} + \frac{3}{\sqrt{38.1}} + 0.34 = 1.456$$

$$v_p = \sqrt{\frac{4(9.81\text{ m/s}^2)(2.65 - 1)(0.5 \times 10^{-3}\text{ m})}{3 \times 1.456}} = 0.086\text{ m/s}$$

Although the assumed settling velocity (0.09 m/s) and the calculated settling velocity (0.086 m/s) still do not agree, they are approaching closure. Successive iterations to calculate the actual settling velocity will be done as a homework problem.

Because the settling velocity used to compute the Reynolds number agrees with the settling velocity value from Newton's equation, the solution approach has been confirmed.

Discrete Particle Settling

In the design of sedimentation basins, the usual procedure is to select a particle with a terminal velocity v_c and to design the basin so that all particles that have a terminal velocity equal to or greater than v_c will be removed. The rate at which clarified water is produced is equal to

$$Q = Av_c \tag{5–25}$$

where Q = flowrate, L^3T^{-1} (m^3/s)
A = surface of the sedimentation basin, L^2 (m^2)
v_c = particle settling velocity, LT^{-1} (m/s)

Rearranging Eq. (5–25) yields

$$v_c = \frac{Q}{A} = \text{overflow rate}, LT^{-1}(\text{m}^3/\text{m}^2 \cdot \text{d})$$

Thus, the critical velocity is equivalent to the overflow rate or surface loading rate. A common basis of design for discrete particle settling recognizes that the flow capacity is independent of the depth.

For continuous-flow sedimentation, the length of the basin and the time a unit volume of water is in the basin (detention time) should be such that all particles with the design velocity v_c will settle to the bottom of the tank. The design velocity, detention time, and basin depth are related as follows:

$$v_c = \frac{\text{depth}}{\text{detention time}} \tag{5–26}$$

In actual practice, design factors must be adjusted to allow for the effects of inlet and outlet turbulence, short circuiting, sludge storage, and velocity gradients due to the operation of sludge-removal equipment. These design factors are discussed in Sec. 5–6. In the above discussion ideal settling conditions have been assumed.

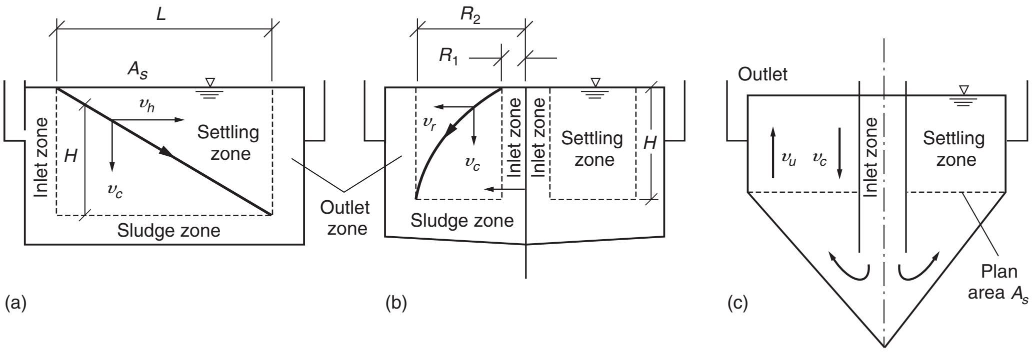


Figure 5–21

Definition sketch for the idealized settling of discrete particles in three different types of settling basins: (a) rectangular, (b) circular, and (c) upflow (Crites and Tchobanoglous, 1998).

Idealized discrete particle settling in three different types of settling basins is illustrated on Fig. 5–21. Particles that have a velocity of fall less than v_c will not all be removed during the time provided for settling. Assuming that the particles of various sizes are uniformly distributed over the entire depth of the basin at the inlet, it can be seen from an analysis of the particle trajectory on Fig. 5–22 that particles with a settling velocity less than v_c will be removed in the ratio

$$X_r = \frac{v_p}{v_c} \tag{5–27}$$

where X_r is the fraction of the particles with settling velocity v_p that are removed.

In most suspensions encountered in wastewater treatment, a large gradation of particle sizes will be found. To determine the efficiency of removal for a given settling time, it is necessary to consider the entire range of settling velocities present in the system. The settling velocities of the particles can be obtained by use of a settling column test. The particle settling data are used to construct a velocity settling curve as shown on Fig. 5–23.

For a given clarification rate Q where

$$Q = v_c A \tag{5–28}$$

Figure 5–22

Definition sketch for the analysis of ideal discrete particle settling.

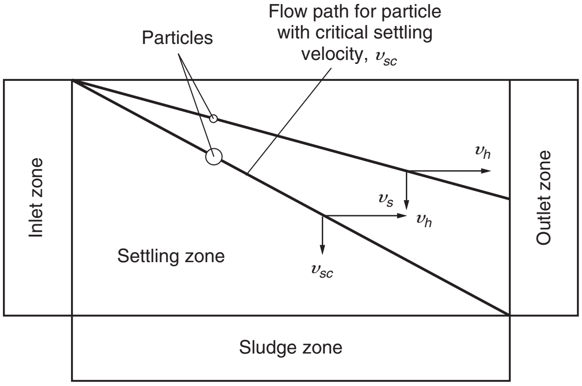

Figure 5–23

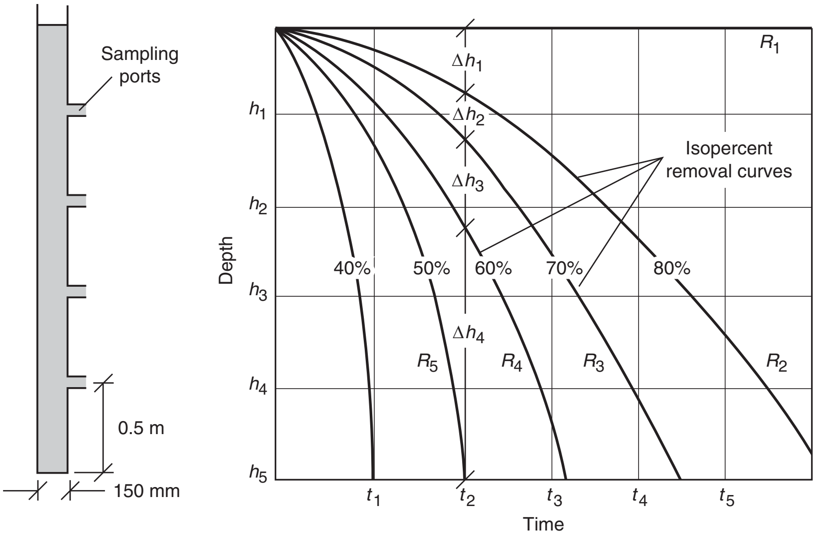
Definition sketch for the analysis of flocculent settling.



only those particles with a velocity greater than v_c will be removed completely. The remaining particles will be removed in the ratio v_p/v_c. The total fraction of particles removed for a continuous distribution is given by Eq. (5–29).

$$\text{Fraction removed} = (1 - X_c) + \int_0^{X_c} \frac{v_p}{v_c} dx \tag{5–29}$$

where $1 - X$ = fraction of particles with velocity v_p greater than v_c

$\int_0^{X_c} \frac{v_p}{v_c} dx$ = fraction of particles removed with v_p less than v_c

For discrete particles within a given settling velocity range, the following expression may be used

$$\text{Total fraction removed} = \frac{\sum_{i=1}^{n} \frac{v_{n_i}}{v_c}(n_i)}{\sum_{i=1}^{n} n_i} \tag{5–30}$$

where v_{n_i} = average velocity of particles in the ith velocity range

n_i = number of particles in the ith velocity range

The use of Eq. (5–30) is illustrated in Example 5–5.

EXAMPLE 5–5 Calculation of Removal Efficiency for a Primary Sedimentation Basin

Determine the removal efficiency for a sedimentation basin with a critical overflow velocity of 2 $m^3/m^2 \cdot h$ in treating a wastewater containing particles whose settling velocities are distributed as given in the table below. Plot the particle histogram for the influent and effluent wastewater.

Settling velocity, m/h	Number of particles per liter × 10^{-5}
0.0–0.5	30
0.5–1.0	50
1.0–1.5	90
1.5–2.0	110
2.0–2.5	100
2.5–3.0	70
3.0–3.5	30
3.5–4.0	20
Total	500

Solution

1. Create a table for calculating the percentage removal for each particle size. Enter the particle settling velocity ranges in column (1).

Settling velocity range, m/h (1)	Average settling velocity, m/h (2)	Number of particles in influent, × 10^{-5} (3)	Fraction of particles removed (4)	Number of particles removed, × 10^{-5} (5)	Particles remaining in effluent, × 10^{-5} (6)
0.0–0.5	0.25	30	0.125	3.75	26.25
0.5–1.0	0.75	50	0.375	18.75	31.25
1.0–1.5	1.25	90	0.625	56.25	33.75
1.5–2.0	1.75	110	0.875	96.25	13.75
2.0–2.5	2.25	100	1.000	100.0	0.0
2.5–3.0	2.75	70	1.000	70.0	0.0
3.0–3.5	3.25	30	1.000	30.0	0.0
3.5–4.0	3.75	20	1.000	20.0	0.0
Total		500		395.00	105.00

2. Calculate the average particle settling velocity for each velocity range by taking the average of the range limits, and enter the values in column (2). For the first velocity range, the average settling velocity is (0.0 + 0.5)/2 = 0.25 m/h.
3. Enter the number of influent particles for each velocity range in column (3).
4. Calculate the removal fraction for each velocity range by dividing the average settling velocity by the critical overflow velocity (2.0 m/h), and enter the result in column (4). For the first velocity range

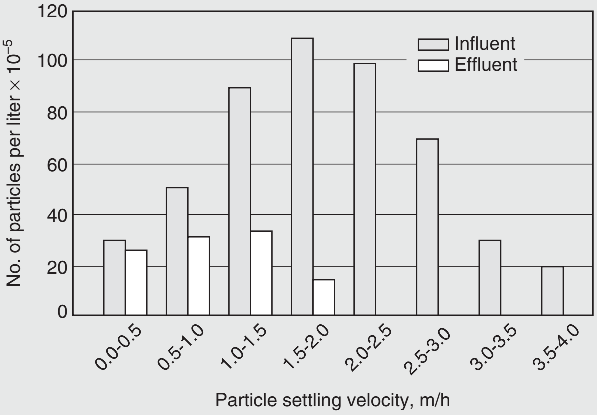
$$\text{Fraction removed} = \frac{v_{n_i}}{v_c} = \frac{0.25}{2.0} = 0.125$$

Where the result is greater than 1.0, enter a value of 1.0, because all of the particles are removed.

5. Determine the number of particles removed by multiplying the number of influent particles by the percent removal [column (3) × column (4)]. Enter the values in column (5).
6. Calculate the particles remaining by subtracting the particles removed from the number of influent particles [column (3) − column (5)]. Enter the result in column (6).
7. Compute the removal efficiency by calculating the sum of particles removed and dividing the sum by the total number of particles in the influent.

$$\text{Total fraction removed} = \frac{\sum_{i=1}^{n} \frac{v_{n_i}}{v_c}(n_i)}{\sum_{i=1}^{n} n_i} = \frac{395 \times 10^{-5}}{500 \times 10^{-5}} \times 100\% = 79\%$$

8. Plot the particle histogram for the influent and effluent wastewater.



Flocculent Particle Settling

Particles in relatively dilute solutions will not act as discrete particles but will coalesce during sedimentation. As coalescence or flocculation occurs, the mass of the particle increases, and it settles faster. The extent to which flocculation occurs is dependent on the opportunity for contact, which varies with overflow rate, depth of the basin, velocity gradients in the system, concentration of particles, and range of particle sizes. The effects of these variables can be determined only by sedimentation tests.

The settling characteristics of a suspension of flocculent particles can be obtained by using a settling column test. Such a column can be of any diameter but should be equal in height to the depth of the proposed tank. The solution containing the suspended matter should be introduced into the column in such a way that a uniform distribution of particle sizes occurs from top to bottom. Care should be taken to ensure that a uniform temperature is maintained throughout the test to eliminate convection currents. Settling should take place under quiescent conditions. The duration of the test should be equivalent to the settling time in the proposed tank.

At the conclusion of the settling time, the settled matter that has accumulated at the bottom of the column is drawn off, the remaining liquid is mixed, and the TSS of the liquid is measured. The TSS of the liquid is then compared to the sample TSS before settling to obtain the percent removal.

The more traditional method of determining settling characteristics of a suspension is to use a column similar to the one described above but with sampling ports inserted at approximately 0.5 m (1.5 ft) intervals. At various time intervals, samples are withdrawn from the ports and analyzed for suspended solids. The percent removal is computed for each sample analyzed and is plotted as a number against time and depth, as elevations are plotted on a survey grid. Curves of equal percent removal are drawn as shown on Fig. 5–23. From the curves shown on Fig. 5–23, the overflow rate for various settling is determined by noting the value where the curve intersects the x axis. The settling velocity v_c is

$$v_c = \frac{H}{t_c} \tag{5–31}$$

where H = height of the settling column, L (m)
t_c = time required for a given degree of removal to be achieved, T (min)

The fraction of particles removed is given by

$$R, \% = \sum_{h=1}^{n} \left(\frac{\Delta h_n}{H}\right)\left(\frac{R_n + R_{n+1}}{2}\right) \tag{5–32}$$

where R = TSS removal, %
n = number of equal percent removal curve
h_n = distance between curves of equal percent removal, L (m)
H = total height of settling column, L (m)
R_n = equal percent removal curve number n
R_{n+1} = equal percent removal curve number $n + 1$

The advantage of the more traditional method is that it is possible to obtain removal data at various depths of settling. The removal percentage obtained using the curve given on Fig. 5–23 is illustrated in Example 5–6.

EXAMPLE 5–6 **Removal of Flocculent Suspended Solids** Using the results of the settling test shown on Fig. 5–23, determine the overall removal of solids if the detention time is t_2 and the depth is h_5. Also demonstrate that the same result is obtained when the solids are measured after settling has occurred.

Solution

1. Determine the percent removal.

   Percent removal

$$= \frac{\Delta h_1}{h_5} \times \frac{R_1 + R_2}{2} + \frac{\Delta h_2}{h_5} \times \frac{R_2 + R_3}{2} + \frac{\Delta h_3}{h_5} \times \frac{R_3 + R_4}{2} + \frac{\Delta h_4}{h_5} \times \frac{R_4 + R_5}{2}$$

2. For the curves shown on Fig. 5–23, a total removal for quiescent settling is 65.7 percent. The computations follow.

$\dfrac{\Delta h_n}{h_5} \times \dfrac{R_n + R_{n+1}}{2}$	Percent removal
$0.20 \times \dfrac{100 + 80}{2} =$	18.00
$0.11 \times \dfrac{80 + 70}{2} =$	8.25
$0.15 \times \dfrac{70 + 60}{2} =$	9.75
$0.54 \times \dfrac{60 + 50}{2} =$	29.70
1.00	65.70

3. Determine the percent removal if the liquid had been mixed and the solids were measured.
   a. Assume the initial solids concentration is equal to 100 and that at the end of the settling period the concentration of the solids at the top of the column is equal to zero.
   b. Set up a computation table and determine the remaining solids after settling.

$\Delta h \times \dfrac{\text{TSS}_n + \text{TSS}_{n+1}}{2}$	Average TSS
$0.20 \times \dfrac{0 + 20}{2} =$	2.00
$0.11 \times \dfrac{20 + 20}{2} =$	2.75
$0.15 \times \dfrac{30 + 40}{2} =$	5.25
$0.54 \times \dfrac{40 + 50}{2} =$	24.30
	34.30

The percent removal is $R_t = 100 - 34.30 = 65.70$.

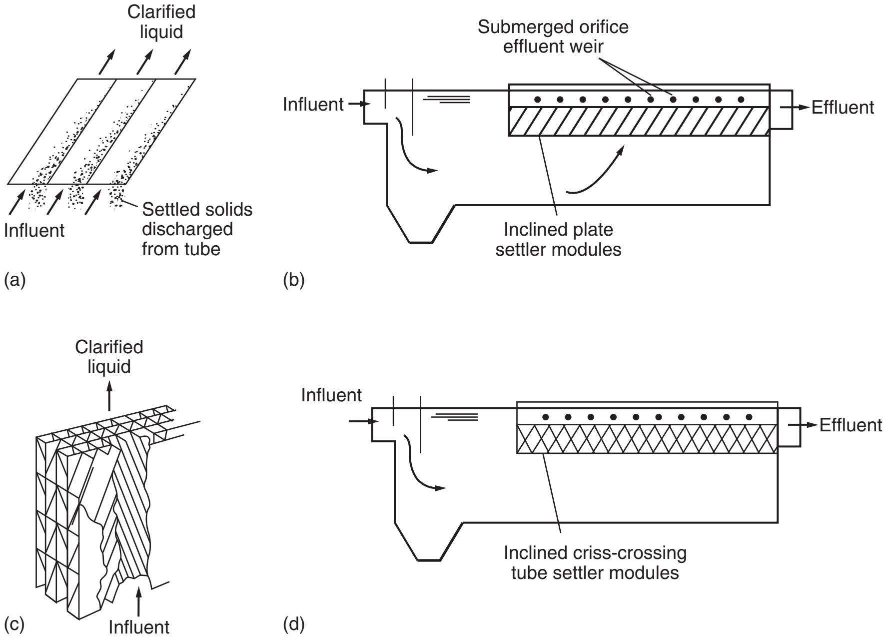
Comment To account for the less than optimum conditions encountered in the field, the design settling velocity or overflow rate obtained from column studies often is multiplied by a factor of 0.65 to 0.85, and the detention times are multiplied by a factor of 1.25 to 1.5.

Inclined Plate and Tube Settling

Inclined plate and tube settlers are shallow settling devices consisting of stacked offset trays or bundles of small plastic tubes of various geometries [see Figs. 5–24(a) and (c)] that are used to enhance the settling characteristics of sedimentation basins [see Figs. 5–24(b) and (d)]. Application of these devices are based on the theory that settling depends on the settling area rather than detention time. Although they are used predominantly in water-treatment applications, plate and tube settlers are used in wastewater treatment for primary, secondary, and tertiary sedimentation. In primary sedimentation applications, however, fine screening should be provided ahead of the settling operation to prevent plugging of the plates or tubes.

Figure 5–24

Plate and tube settlers: (a) module of inclined plates, (b) plates installed in a rectangular sedimentation tank, (c) module of criss-crossing tubes, and (d) criss-crossing tubes installed in a rectangular sedimentation tank.



To be self-cleaning, plate or tube settlers are usually set at an angle between 45 and 60° above the horizontal. When the angle is increased above 60°, the efficiency decreases. If the plates and tubes are inclined at angles less than 45°, solids will tend to accumulate within the plates or tubes. Nominal spacing between plates is 50 mm (2 in.), with an inclined length of 1 to 2 m (3 to 6 ft). To control biological growths and the production of odors (the principal problems encountered with their use), the accumulated solids must be flushed out periodically (usually with high-pressure water). The need for flushing poses a problem with the use of plate and tube settlers when the characteristics of the solids to be removed vary from day to day.

The main objective in inclined settler development has been to obtain settling efficiencies close to theoretical limits. Attention must be given to providing equal flow distribution to each settler, producing good flow distribution within each settler, and collecting settled solids while preventing resuspension. Inclined settling systems are generally constructed for use in one of three ways with respect to the direction of liquid flow relative to the direction of particle settlement: (1) countercurrent, (2) cocurrent, and (3) cross-flow. These three flow patterns are shown schematically on Fig. 5–25 along with definition sketches for their analysis.

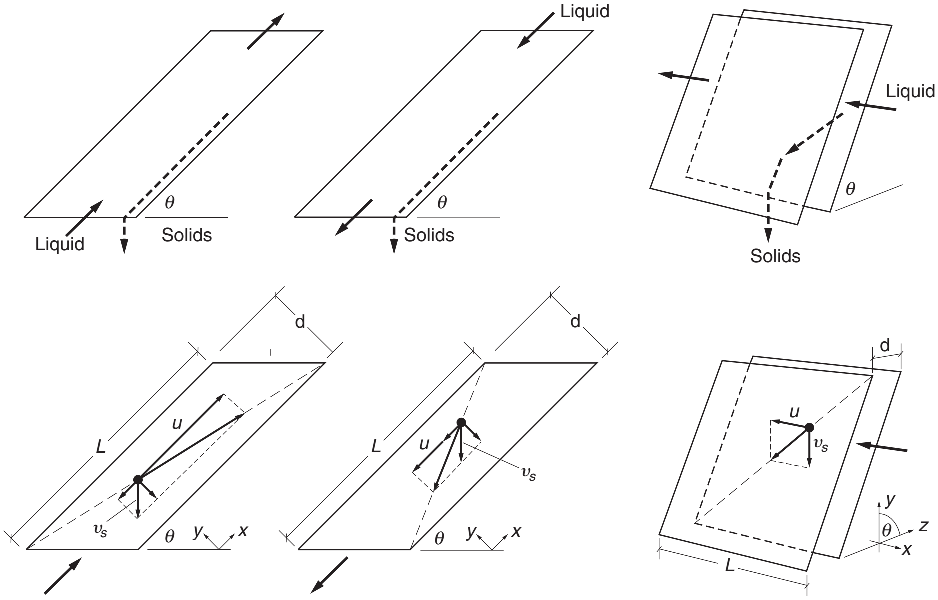
Countercurrent Settling. With countercurrent flow, wastewater suspension in the basin passes upward through the plate or tube modules and exits from the basin above the modules [see Fig. 5–25(a)]. The solids that settle out within the plates or tubes move by gravity countercurrently downward and out of the modules to the basin bottom. Tube settlers are mostly used in the countercurrent mode.

In countercurrent settling, the time, t, for a particle to settle the vertical distance between two parallel inclined surfaces is:

$$t = \frac{d}{v_s \cos\theta} \tag{5–33}$$

Figure 5–25

Alternative flow patterns and corresponding definition sketches for the analysis of plate and tube settlers: (a) countercurrent flow with respect to the movement of solids, (b) cocurrent flow with respect to the movement of solids, and (c) cross-flow.



(a) Countercurrent (b) Cocurrent (c) Cross-flow

where d = perpendicular distance between surfaces, L (m)
v_s = settling velocity, LT^{-1} (m/s)
θ = angle of the surface inclination from the horizontal

The length of surface, L, needed to provide this time, if the fluid velocity between the surfaces is u, is calculated as:

$$L = \frac{d(u - v_s \sin\theta)}{v_s \cos\theta} \tag{5–34}$$

By rearranging this equation, all particles with a settling velocity v_s and greater are removed if

$$v_s \geq \frac{u \cdot d}{L\cos\theta + d\sin\theta} \tag{5–35}$$

When many plates or tubes are used

$$u = \frac{Q}{Ndw} \tag{5–36}$$

where u = fluid velocity, LT^{-1} (m/s)
Q = flowrate, L^3T^{-1} (m^3/s)
N = number of channels made by N+1 plates
d = perpendicular distance between surfaces, L (m)
w = width of the channel, L (m)

A proprietary settler, the Lamella® Gravity Settler, manufactured by the Parkson Corporation, is based on countercurrent settling with modifications (see Fig. 5–26). The feed stream is introduced into the settler by means of a feed duct to the feed box, which is a bottomless channel between plate sections. The flow is directed downward toward individual side-entry plate slots. The feed is distributed across the width of the plates and flows upward under laminar flow conditions. The plates are inclined 55° from the horizontal. The solids settle on the plates and the clean supernatant exits the plates through orifice holes. The orifice holes are placed immediately above each plate and are sized to induce a

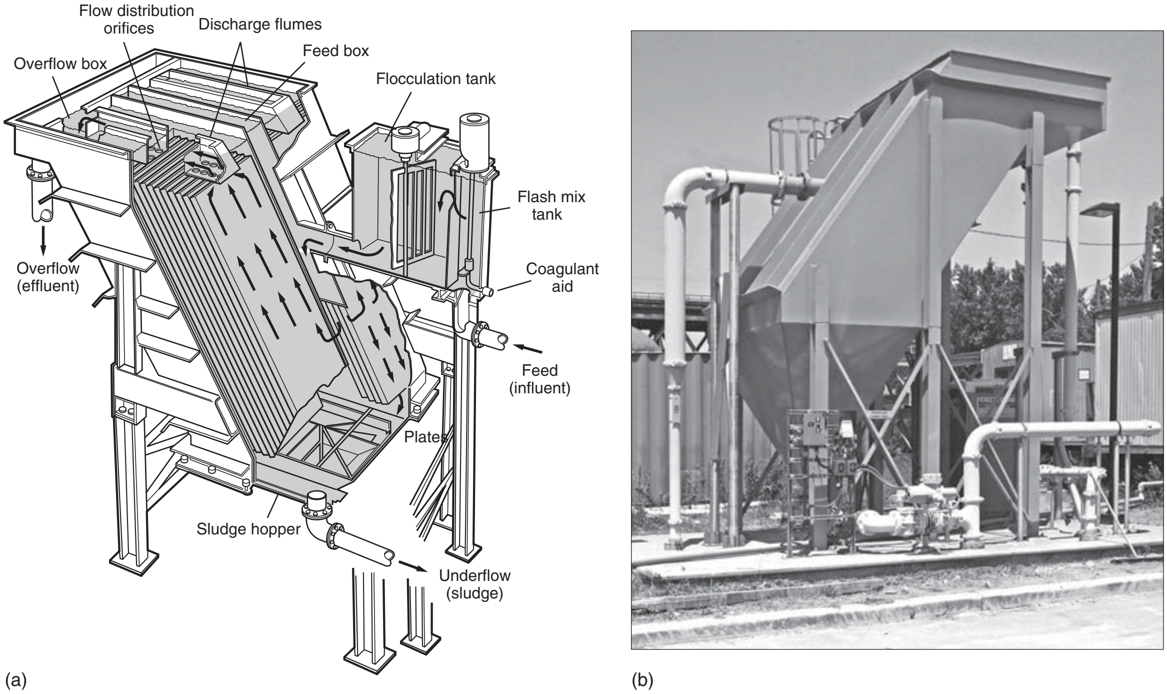


Figure 5–26

Example of a Lamella plate settler: (a) schematic (courtesy of Parkson Corporation) and (b) typical unit for pilot testing.

calculated pressure drop to ensure the feed is hydraulically distributed equally among the plates. The solids slide down the plates into a collection hopper. Further thickening of the solids occurs in the hopper due to compression in the quiescent zone made possible by feeding the plates from the side rather than from the bottom. Plate packs can also be retrofitted into existing clarifiers to improve performance.

Cocurrent Settling. In cocurrent settling, the solids suspension is introduced above the inclined surfaces and the flow is down through the tubes or plates [see Fig. 5–25(b)]. The time for a particle to settle the vertical distance between two surfaces is the same as for countercurrent settling. The length of surface needed, L_p, however, has to be based on downward and not upward liquid flow, as follows:

$$L = d\frac{(u - v_s \sin\theta)}{v_s \cos\theta} \tag{5–37}$$

Consequently, the condition for removal of particles is given by

$$v_s \geq \frac{u \cdot d}{L\cos\theta - d\sin\theta} \tag{5–38}$$

Cross-Flow Settling. In cross-flow settling, the liquid flow is horizontal and does not interact with the vertical settling velocity [see Fig. 5–25(c)]. The length of the surface L_p is determined by

$$L = \frac{u \cdot d}{v_s \cos\theta} \tag{5–39}$$

and

$$v_s \geq \frac{u \cdot d}{L \cos \theta} \tag{5–40}$$

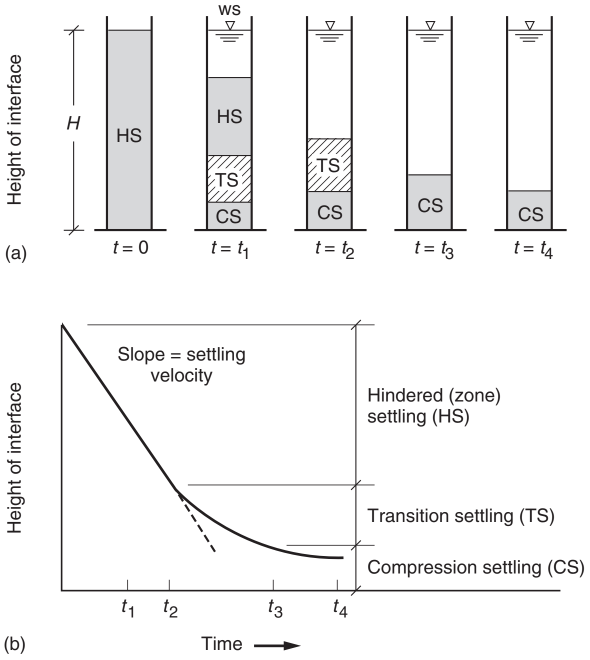
Hindered (Zone) Settling

In addition to discrete (free) and flocculent settling discussed previously, other forms of settling known as hindered or zone and compression settling usually occur in systems that contain a high concentration of suspended solids. The settling phenomenon that occurs when a concentrated suspension, initially of uniform concentration throughout, is placed in a graduated cylinder, is illustrated on Fig. 5–27. Because of the high concentration of particles, the liquid tends to move up through the interstices of the contacting particles. As a result, the contacting particles tend to settle as a zone or "blanket," maintaining the same relative position with respect to each other. The phenomenon is known as hindered settling. As the particles settle, a relatively clear layer of water is produced above the particles in the settling region. The scattered, relatively light particles remaining usually settle as discrete or flocculent particles, as discussed previously. In most cases, an identifiable interface develops between the upper region and the hindered settling region as shown on Fig. 5–27(a). The rate of settling in the hindered settling region is a function of the concentration of solids and their characteristics.

As settling continues, a compressed layer of particles begins to form on the bottom of the cylinder in the compression settling region. The particles apparently form a structure in which there is close physical contact between the particles. As the compression layer forms, regions containing successively lower concentrations of solids than those in the compression region extend upward in the cylinder. Thus, in actuality the hindered settling

Figure 5–27

Definition sketch for hindered (zone) settling: (a) settling column and (b) settling curve.



region contains a gradation in solids concentration from that found at the interface of the settling region to that found in the compression settling region.

Because of the variability encountered, settling tests are usually required to determine the settling characteristics of suspensions where hindered and compression settling are important considerations. On the basis of data derived from column settling tests, two different design approaches can be used to obtain the required area for the settling/thickening facilities. In the first approach, the data derived from one or more batch settling tests are used. In the second approach, known as the solids flux method, data from a series of settling tests conducted at different solids concentrations are used. Both methods are described in the following discussion. The solids flux method is considered further in Sec. 8–10 in Chap. 8. It should be noted that both methods have been used where existing plants are to be expanded or modified. These methods are, however, seldom used in the design of small treatment plants.

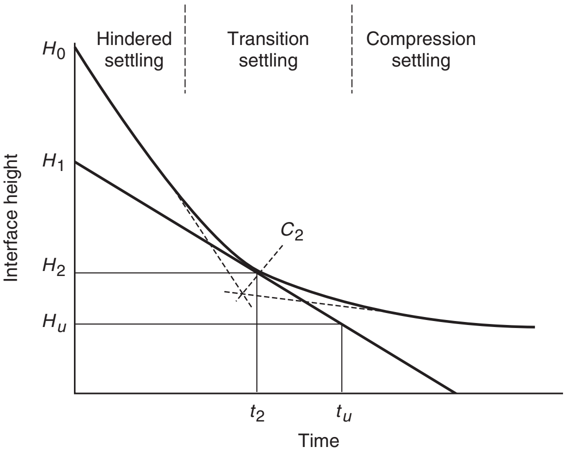
Area Requirement Based on Single-Batch Test Results. For purposes of design, the final overflow rate selected should be based on a consideration of the following factors: (1) the area needed for clarification, (2) the area needed for thickening, and (3) the rate of sludge withdrawal. Column settling tests, as previously described, can be used to determine the area needed for the free settling region directly. However, because the area required for thickening is usually greater than the area required for the settling, the rate of free settling rarely is the controlling factor. In the case of the activated-sludge process where stray, light, fluffy floc particles may be present, it is conceivable that the free flocculent settling velocity of these particles could control the design.

The area requirement for thickening is determined according to a method developed by Talmadge and Fitch (1955). A column of height H_o is filled with a suspension of solids of uniform concentration C_o. The position of the interface as time elapses and the suspension settles is given on Fig. 5–28. The rate at which the interface subsides is then equal to the slope of the curve at that point in time. According to the procedure, the area required for thickening is given by Eq. (5–41):

$$A = \frac{Qt_u}{H_o} \tag{5–41}$$

Figure 5–28

Graphical analysis of hindered (zone) interface settling curves.



where A = area required for sludge thickening, L^2 (m^2)
Q = flowrate into tank, L^3T^{-1} (m^3/s)
H_o = initial height of interface in column, L (m)
t_u = time to reach desired underflow concentration, T (s)

The critical concentration controlling the solids handling capability of the tank occurs at a height H_2 where the concentration is C_2. This point is determined by extending the tangents to the hindered settling and compression regions of the subsidence curve to the point of intersection and bisecting the angle thus formed, as shown on Fig. 5–28. The time t_u can be determined as follows:

1. Construct a horizontal line at the depth H_u that corresponds to the depth at which the solids are at the desired underflow concentration C_u. The value of H_u is determined using the following expression:

$$H_u = \frac{C_o H_o}{C_u} \tag{5–42}$$

2. Construct a tangent to the settling curve at the point indicated by C_2.
3. Construct a vertical line from the point of intersection of the two lines drawn in steps 1 and 2 to the time axis to determine the value of t_u.

With this value of t_u, the area required for the thickening is computed using Eq. (5–41). The area required for clarification is then determined. The larger of the two areas is the controlling value. Application of this procedure is illustrated in Example 5–7.

EXAMPLE 5–7 **Sizing an Activated-Sludge Settling Tank** The settling curve shown in the following diagram was obtained for an activated sludge with an initial solids concentration C_o of 3000 mg/L. The initial height of the interface in the settling column was at 0.75 m (2.5 ft). Determine the area required to yield a thickened solids concentration, C_u, of 12,000 mg/L with a total flow of 3800 m^3/d (1 Mgal/d). Determine also the solids loading rate (kg/m^2·d) and the overflow rate (m^3/m^2·d).

Solution

1. Determine the area required for thickening using Eq. (5–42).
   a. Determine the value of H_u

$$H = \frac{C_o H_o}{C_u}$$

$$= \frac{(3000 \text{ mg/L})(0.75 \text{ m})}{(12{,}000 \text{ mg/L})} = 0.188 \text{ m}$$

On the following settling curve, a horizontal line is constructed at H_u = 0.188 m. A tangent is constructed to the settling curve at C_2, the midpoint of the region between hindered and compression settling. Bisecting the angle formed where the two tangents meet determines point C_2. The intersection of the tangent at C_2 and the line H_u = 0.188 m determines t_u. Thus t_u = 47 min, and the required area is

$$A = \frac{Qt_u}{H_o} = \left[\frac{(3800 \text{ m}^3\text{/d})}{(24 \text{ h/d})(60 \text{ min/h})}\right]\left(\frac{47 \text{ min}}{0.75 \text{ m}}\right) = 165 \text{ m}^2$$

2. Determine the area required for clarification.

   a. Determine the interface subsidence velocity *v*. The subsidence velocity is determined by computing the slope of the tangent drawn from the initial portion of the interface settling curve. The computed velocity represents the unhindered settling rate of the sludge.

$$v = \left(\frac{0.75\text{ m} - 0.3\text{ m}}{29.5\text{ min}}\right)\left(\frac{60\text{ min}}{\text{h}}\right) = 0.92\text{ m/h}$$

   b. Determine the clarification rate. Because the clarification rate is proportional to the liquid volume above the critical sludge zone, it may be computed as follows:

$$Q = 3800\text{ m}^3\text{/d}\left(\frac{0.75\text{ m} - 0.188\text{ m}}{0.75\text{ m}}\right) = 2847\text{ m}^3\text{/d}$$

   c. Determine the area required for clarification. The required area is obtained by dividing the clarification rate by the settling velocity.

$$A = \frac{Q_c}{v} = \frac{(2847\text{ m}^3\text{/d})}{(24\text{ h/d})(0.92\text{ m/h})} = 129\text{ m}^2$$

3. The controlling area is the thickening area (165 m^2) because it exceeds the area required for clarification (129 m^2).
4. Determine the solids loading rate. The solids loading rate is computed as follows:

$$\text{Daily solids mass, kg/d} = \frac{(3800\text{ m}^3\text{/d})(3000\text{ g/m}^3)}{(10^3\text{ g/1 kg})} = 11{,}400\text{ kg/d}$$

$$\text{Solids loading rate} = \frac{(11{,}400\text{ kg/d})}{165\text{ m}^2} = 69.1\text{ kg/m}^2\text{·d}$$

5. Determine the hydraulic loading rate.

$$\text{Hydraulic loading rate} = \frac{(3800\text{ m}^3\text{/d})}{165\text{ m}^2} = 23.0\text{ m}^3\text{/m}^2\cdot\text{d}$$

Comment An alternative approach for sizing the secondary clarifiers using the initial settling velocity of the sludge is given in Sec. 8–10 in Chap. 8.

Area Requirements Based on Solids Flux Analysis. An alternative method of determining the area required for hindered settling is based on an analysis of the solids (mass) flux (Coe and Clevenger, 1916). In the solids flux method of analysis it is assumed that a settling basin is operating at steady state. Within the tank, the downward flux of solids is brought about by gravity (hindered) settling and by bulk transport due to the underflow that is being pumped out and recycled. The solids flux method of analysis is used to assess the performance of existing facilities and to obtain information for the design of new facilities to treat the same wastewater. Application of the solids flux method of analysis is illustrated in Sec. 8–7 in Chap. 8, and additional information may be found in the following references: Dick and Ewing (1967), Dick and Young (1972), Keinath (1985), Wahlberg and Keinath (1988), and Yoshika et al. (1957).

Compression Settling

The volume required for sludge in the compression region can also be determined by settling tests. The rate of consolidation has been found to be proportional to the difference in the depth at time *t* and the depth to which the sludge will settle after a long period of time. The long-term consolidation can be modeled as a first-order decay function, as given by Eq. (5–43).

$$H_t - H_\infty = (H_2 - H_\infty)e^{-i(t-t_2)} \tag{5–43}$$

where H_t = sludge height at time t, L
H_∞ = sludge depth after long settling period, on the order of 24 h, L
H_2 = sludge height at time t_2, L
i = constant for a given suspension

Stirring serves to compact solids in the compression region by breaking up the floc and permitting water to escape. Rakes are often used on sedimentation equipment to manipulate the solids and thus produce better compaction.

Gravity Separation in an Accelerated Flow Field

Sedimentation, as described previously, occurs under the force of gravity in a constant acceleration field. The removal of settleable particles can also be accomplished by taking advantage of a changing acceleration field. A number of devices that take advantage of both gravitational and centrifugal forces and induced velocities have been developed for the removal of grit from wastewater. The principles involved are illustrated on Fig. 5–29. In appearance, the separator looks like a large diameter cylinder with a conical bottom. Wastewater, from which grit is to be separated, is introduced tangentially near the top and exits through the opening in the top of the unit. The liquid is removed at the top. Grit is removed through an opening in the bottom of the unit.

Because the top of the separator is enclosed, the rotating flow creates a free vortex within the separator. The most important characteristic of a free vortex is that the product of the tangential velocity times the radius is a constant:

$$Vr = \text{constant} \tag{5–44}$$

where V = tangential velocity, LT^{-1} (m/s)
r = radius, L (m)

The significance of Eq. (5–44) can be illustrated by the following example. Assume the tangential velocity in a separator with a 1.5 m (5 ft) radius is 0.9 m/s (3 ft/s). The product of the velocity times the radius at the outer edge of the separator is equal to 1.35 m^2/s (15 ft^2/s). If the discharge port has a radius of 0.9 m (3 ft), then the tangential velocity at

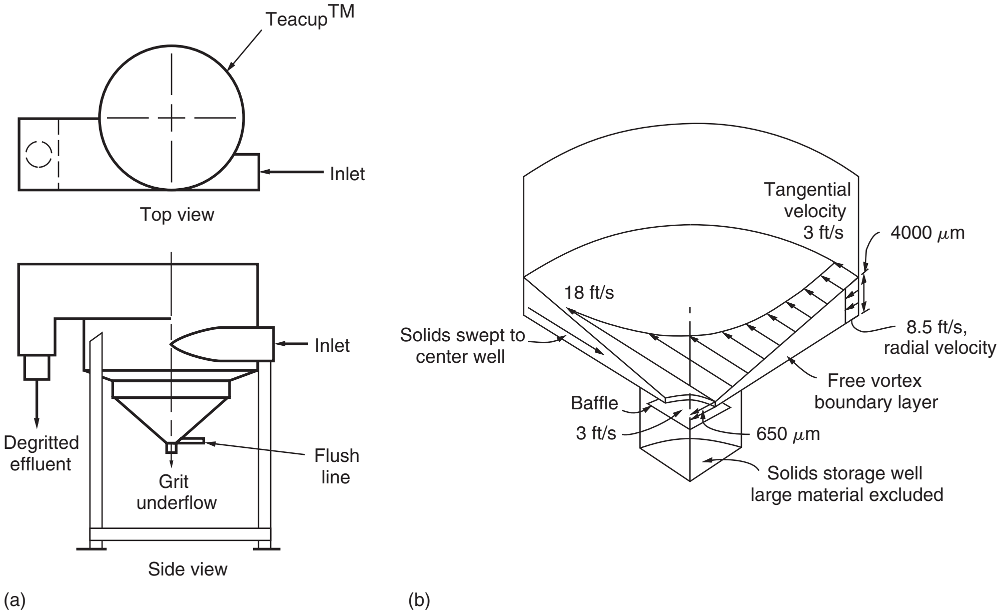


Figure 5–29

Accelerated gravity separator: (a) outline sketch and (b) definition sketch. (From Hydro International.)

the entrance to the discharge port is 4.5 m/s (15 ft/s). The centrifugal force experienced by a particle within this flow field is equal to the square of the velocity divided by the radius. Because the centrifugal force is also proportional to the inverse of the radius, a fivefold decrease in the radius results in a 125-fold increase in the centrifugal force.

Because of the high centrifugal forces near the discharge port, some of the particles, depending on their size, density, and drag, are retained within the body of the free vortex near the center of the separator, while other particles are swept out of the unit. Grit and sand particles will be retained while organic particles are discharged from the unit. Organic particles having the same settling velocity as sand will typically be from 4 to 8 times as large. The corresponding drag forces for these organic particles will be from 16 to 64 times as great. As a result, the organic particles tend to move with the fluid and are transported out of the separator. The particles held in the free vortex ultimately settle to the bottom of the unit under the force of gravity. Organic particles that sometimes settle usually consist of oil and grease attached to grit or sand particles.

5–5 GRIT REMOVAL

Grit in wastewater consists of sand, gravel, cinders, or other heavy solid materials that have subsiding velocities or specific gravities substantially greater than those of the organic putrescible solids in wastewater. Grit removal is necessary to (1) reduce formation of heavy deposits in aeration tanks, aerobic digesters, pipelines, channels, and conduits; (2) reduce the frequency of digester cleaning caused by excessive accumulations of grit; and (3) protect moving mechanical equipment from abrasion and accompanying abnormal wear. The removal of grit is essential for equipment with closely machined metal surfaces, such as comminutors, fine screens, centrifuges, heat exchangers, and high-pressure diaphragm pumps.

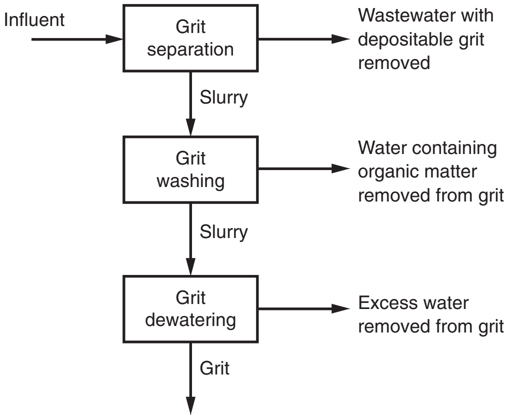

Figure 5–30

A complete grit removal system, including grit separation, washing, and dewatering. (Adapted from Wilson et al., 2007.)

The overall objectives of the grit removal system are to remove all depositable grit during normal and peak wet-weather flow and to produce an end product suitable for landfill disposal. As illustrated on Fig. 5–30, a complete grit removal system consists of three distinct unit processes each with a specific objective: (1) grit separation, (2) grit washing, and (3) grit dewatering. Before discussing these three distinct unit processes, it is appropriate to consider the characteristics of wastewater grit, as they will affect significantly the selection and design of the grit removal system. Grit separators for combined collection systems and stormwater are also reviewed along with degritting of primary sludge where grit removal is not used before primary sedimentation.

Wastewater Grit Characteristics

Traditionally, grit removal systems have been designed based on the assumption that grit consists of inorganic settleable solids ranging in size from 0.050 to 1.0 mm with settling characteristics similar to clean, spherical silica sand with a specific gravity of 2.65 and a particle size predominantly larger than 0.210 mm. As a consequence of these assumptions, many existing grit removal systems fall short of performance expectations resulting in excessive maintenance and operating costs.

Grit Composition. Grit consists of sand, gravel, cinders, and other heavy materials. It also includes organic matter such as eggshells, bone chips, seeds, and coffee grounds. As grit travels through the collection system, grit particles come in contact with organic matter and surface active agents (SAAs) that can adhere to the grit particles. The presence of these constituents can alter the size and settling characteristics of the grit particles.

Generally, what is removed from the wastewater flow as grit is predominantly inert and relatively dry material. However, the composition can be highly variable, with moisture content ranging from 13 to 65 percent, and volatile content from 1 to 56 percent with a wide range of specific gravity. Often, enough organics are present in the grit so that it quickly putrefies if not properly handled after removal from the wastewater.

Grit Particle Size. Based on the limited available information, the actual size distribution of collected grit exhibits wide variation due to differences in collection system characteristics, as well as variations in grit-removal efficiency (see Fig. 5–31). Generally, most collected grit particles are retained on a 0.15 mm (100-mesh) sieve, reaching nearly 100 percent retention in some instances; however, particle size can vary significantly. In urban, high-density environments, wastewater grit tends to be coarser. In coastal, lower density environments, grit tends to be finer. In the southeastern United States, where fine

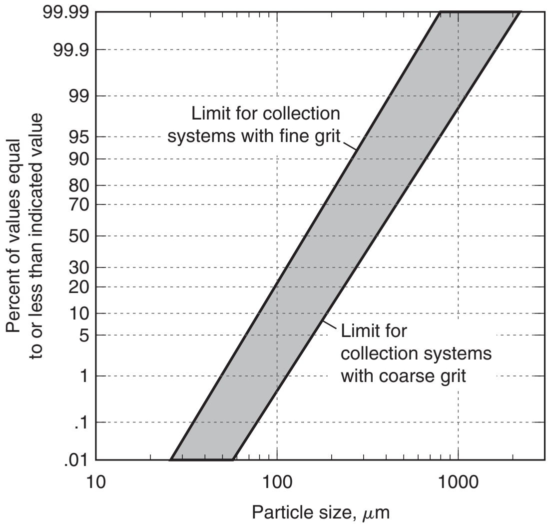

Figure 5–31

Typical grit particle size distribution range. Shaded region corresponds to the range of grit particle sizes measured at various wastewater treatment plants. (Adapted from Wilson et al., 2007.)

sand known as "sugar sand" constitutes a portion of the grit, less than 60 percent of the grit was retained on a 0.15 mm (100-mesh) screen in some cases.

Grit Quantities. The quantities of grit will vary greatly from one location to another, depending on the type of sewer system, the characteristics of the drainage area, the condition of the collection system, the frequency of street sanding to counteract icing conditions, the types of industrial wastes, the number of households with food waste grinders, and amount of infiltration in areas with sandy soils. Sand drift from beach areas in coastal cities is also a major contributor. Another factor in combined sewer systems is the occurrence of a first flush associated with rainfall events. The higher flowrates associated with wet weather events resuspend grit that settled in the collection system during dry weather. Thus, heavier grit loads are experienced in wastewater treatment plants soon after the start of a heavy rainfall.

Grit removal data are difficult to interpret because grit is poorly characterized and almost no data exists on relative removal efficiencies. The information on grit characteristics derives from what has been collected rather than the grit in the influent wastewater. Sieve analyses are not normally performed on grit chamber influents and effluents. For these reasons, the efficiencies of grit removal systems cannot be compared. A comparison of the reported quantities of grit removed from separate and combined sewer systems is presented in Table 5–15.

Grit Settling Characteristics. The settling characteristics of grit vary considerably from the point of entry in the collection system and its location in the treatment plant. Grit moves through gravity sewers within the collection system in three more-or-less distinct layers (see Fig. 5–32). The deposit limit for clean, inorganic grit particles for most collection systems is 0.225 mm. Consequently, particles above this size cannot be transported hydraulically under normal flow conditions and will deposit within the collection system. As SAAs in the wastewater pass over the deposited particles, some adhere to the deposited grit particles. When a sufficient amount of SAAs have accumulated, the coated grit particle buoyancy increases and deposited grit rises into the bed load. Here, the coated grit moves slowly to the treatment plant along the base of the collection system at less than the average wastewater velocity. Above the bed load is the suspended load consisting of the

Table 5–15

Comparison of quantities of grit removed from wastewater from separate and combined collection systems in aerated grit chambers

Type of collection system	Ratio of maximum day to average day	Average grit quantity	
		ft^3/Mgal	m^3/1000 m^3
Separate	1.5 to 3:1	0.5–5	0.004–0.037
Combined	3 to 15:1	0.5–27	0.004–0.20

lighter grit particles. This suspended grit load has a settling velocity of less than that of clean inorganic grit particles that are less than 0.225 mm in diameter and is the primary grit load that reaches the treatment plant under normal (day-to-day) conditions. Given that, traditionally, grit removal systems have been designed to remove clean inorganic grit particles that are greater than 0.210 mm, most grit passes through the grit removal flows under normal conditions. During periods of high flow, particularly in combined sewers, the heavier, deposited grit is re-suspended and the quantity of grit reaching the treatment plant increases substantially. It is, therefore, important that the grit removal system not only operate efficiently during normal flow conditions but also under sustained peak flows when the greatest volume of grit reaches the plant.

Because of SAAs, grit particles reaching the treatment plant under normal conditions are often lighter than anticipated during design. The impact of SAAs on particles size is demonstrated graphically on Fig. 5–33. Assuming that the specific gravity of clean sand is constant, the settling velocity of clean sand increases as particle size increases [see Fig. 5–33(a)]. However, the settling velocity of wastewater grit is independent of particle size because of the buoyant effect of SAAs [see Fig. 5–33(b)]. Consequently, wastewater grit passes through traditionally designed grit removal processes to the primary settling tanks where they settle out with the primary sludge or are passed to the aeration tanks. When exposed to biological activity, the SAAs decompose and the remaining high density grit particles settle rapidly. As a result, there is often excessive grit deposition in biological reactors, such as aeration tanks, aerobic digesters, and anaerobic digesters, that leads to frequent and costly cleaning to maintain process efficiency. Typically, two-thirds of grit that enters a WWTP is larger than the deposit limit size of clean sand.

Sand Equivalent Size. Many grit removal systems have been designed based on grit particles having a specific gravity of 2.65 (similar to silica sand) and a particle size predominantly larger than 0.210 mm and settling characteristics similar to clean sand. Yet, grit particles that are 0.210 mm and larger are often cited as the cause of most downstream problems. The sand equivalent size (SES) relates the settling velocity of wastewater grit to that of clean sand as shown on Fig. 5–33(c). As shown, a wastewater grit particle (coated

Figure 5–32

Distribution of suspended, bed load, and deposited grit particles in a collection system. (Adapted from Wilson et al., 2007.)

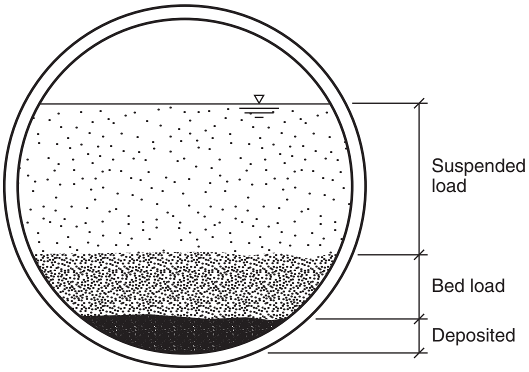

Figure 5–33

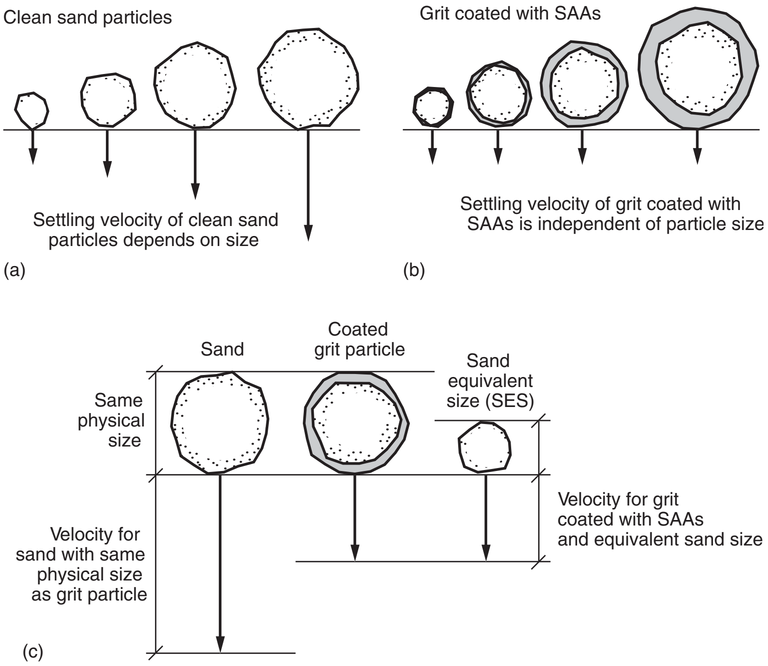
Settling velocities of grit particles reaching the treatment plant: (a) clean sand, (b) frothy grit coated with surface active agents, (c) equivalent size of coated grit particles as compared to clean sand particles. (Adapted from Wilson et al., 2007.)



with SAAs) with the same physical size as a clean particle of sand will have a lower settling velocity than the clean sand particle. The SES of a wastewater grit particle is the equivalent size to that of a clean sand particle size that has the same settling velocity.

Settling Velocity of Wastewater Grit. The level of grit that must be removed should be decided on a case-by-case basis. It is dependent on the characteristics of the wastewater grit entering the treatment plant and the level of removal that is required to protect the downstream treatment processes and equipment. While previous practice targeted clean particles of 0.225 mm, modern removal systems will typically target wastewater grit with a much lower SES. High, efficiency grit systems typically target grit with an SES ranging from 0.075 to 0.150 mm.

When possible, a grit study should be conducted to determine the SES of the incoming wastewater grit and the design SES to achieve the desired level of grit removal. If a grit study is not viable, regional data can be used as a substitute. When data are not available, design can be based on a qualitative evaluation of the collection system. The physical size of wastewater grit particles with their associated SES due to the impact of SAAs as measured at various locations are compared on Fig. 5–34(a). The physical size and the SES of wastewater grit begins to diverge at 0.106 mm with the disparity increasing as the physical size increases. For example, a physical particle size of 0.210 mm, the SES could vary from 0.106 to 0.210 mm. Consequently, to remove particles with a physical size of 0.210 mm, an SES as low as 0.106 mm may have to be used as a basis of design.

A design based on an SES of 0.106 mm will result in 90 percent grit removal for most collection systems. However, for those collection systems where fine silt is expected, the grit removal efficiency might be significantly lower (50 to 65 percent). If the goal is to achieve 90 percent grit removal, a design SES as low as 0.075 mm may be required.

Once the design SES has been identified, the surface loading rate (settling velocity) of the targeted grit particle can be established using the settling characteristics of clean sand [see Fig. 5–34(b)]. For an SES of 0.106 mm, the surface loading rate is 0.49 m/min

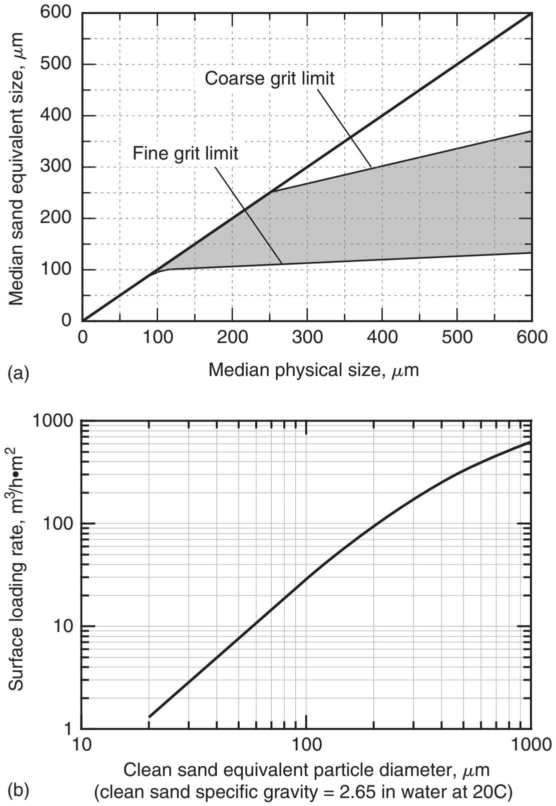


Figure 5–34

Process design information for vortex type grit removal units: (a) comparison of median physical size to SES at various US wastewater treatment plants (adapted from Hydro International) and (b) surface loading rate for sizing vortex grit units based on Eq. (5–18).

(12 gal/ft^2·min). For an SES of 0.075 mm, the required surface loading rate is 0.24 m/min (6 gal/ft^2·min), which doubles the size of the required grit removal system.

Grit Separators for Wastewater

The separation of grit from wastewater is usually accomplished in separate grit chambers designed to physically separate heavy grit particles from lighter organic solids. Grit chambers are most often located after the bar screens and before the primary sedimentation tanks to prevent screening debris from impacting the operation and maintenance of the grit removal equipment. For those treatment plants using comminution equipment, the grit chambers should be located upstream to reduce the wear on cutting blades. There are three general types of grit separation devices: horizontal-flow grit chambers, of either a rectangular or a square configuration, aerated grit chambers, or vortex grit chambers. Each type is considered separately below along with the associated washing and drying equipment that is typically provided. Grit washing drying and disposal are considered after the discussion of the grit separation processes.

Horizontal-Flow Grit Chambers. Rectangular and square horizontal-flow grit chambers have been used for many years. Their use, however, in new installations has been limited in favor of aerated and vortex-type grit chambers.

Rectangular Horizontal-Flow Grit Chambers. The oldest type of grit chamber used is the rectangular horizontal-flow, velocity-controlled type. Representative design data for

Table 5–16

Typical design information for horizontal-flow grit chambers

[a] If the specific gravity of the grit is significantly less than 2.65, lower velocities should be used.

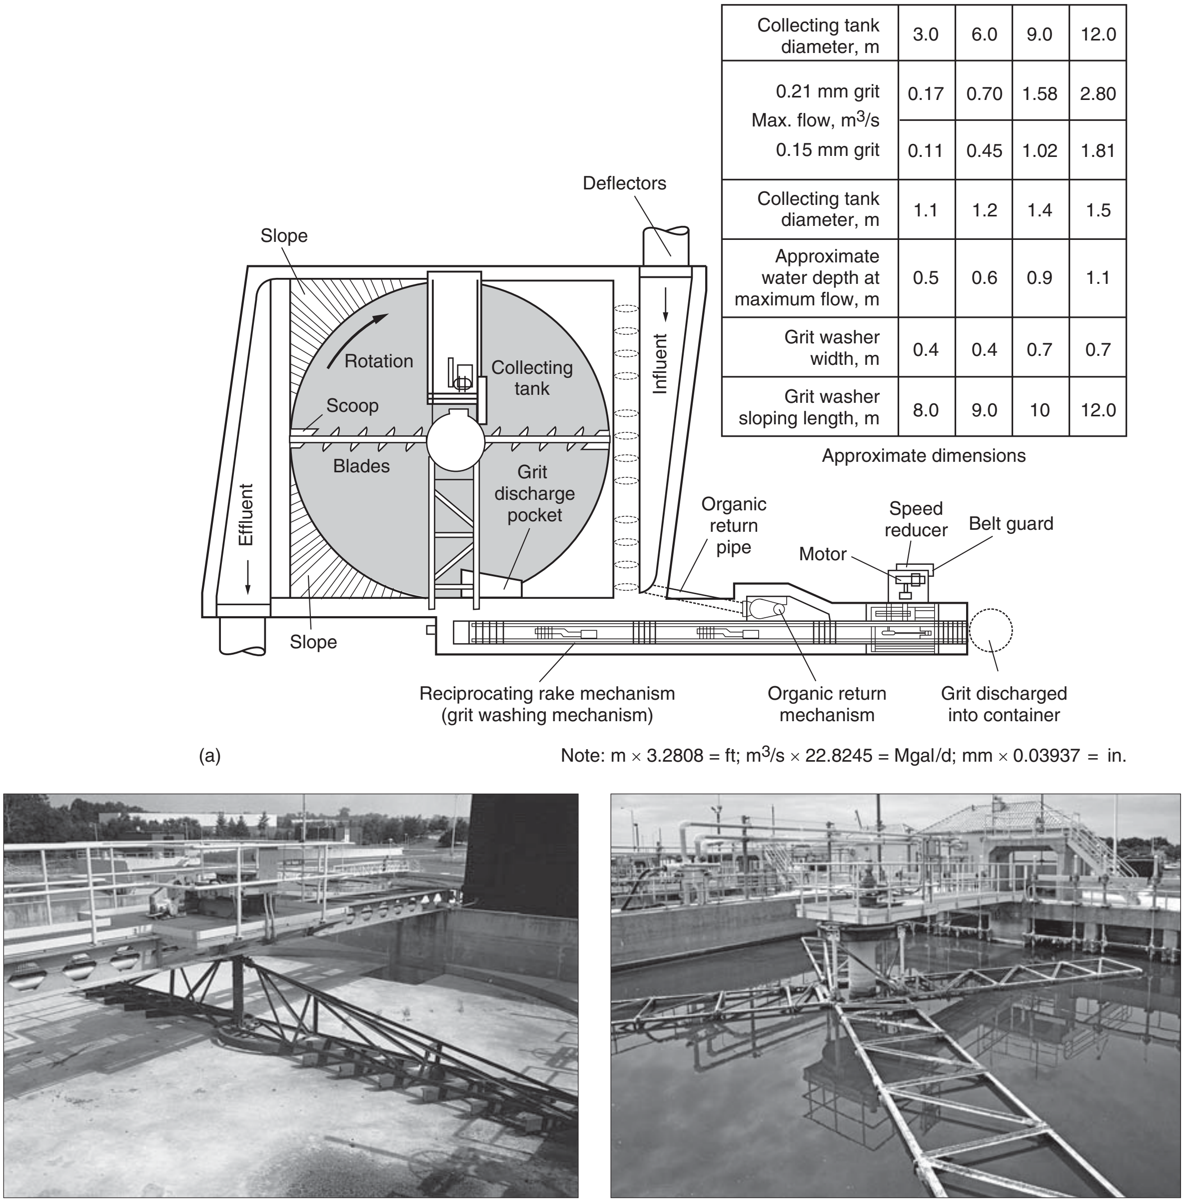
[b] For Parshall flume control.

rectangular horizontal-flow grit chambers are presented in Table 5–16. These units are designed to maintain a velocity as close to 0.3 m/s (1.0 ft/s) as practical and to provide sufficient time for grit particles to settle to the bottom of the chamber. The design velocity will carry most organic particles through the chamber and will tend to re-suspend any organic particles that settle but will permit the heavier grit to settle out.

The basis of design of rectangular horizontal-flow grit chambers is that, under the most adverse conditions, the lightest particle of depositable grit will reach the bed of the channel prior to its outlet end. Typically, grit chambers were designed to remove all grit particles that will be retained on a 0.21-mm-diameter (70-mesh) screen, although many chambers have been designed to remove grit particles retained by a 100-mesh screen (i.e., 0.15-mm-diameter). The settling velocity to be used should be based on the SES of the wastewater grit using the settling rates from Fig. 5–34(b). The length of channel is governed by the depth required by the settling velocity and the control section, and the cross-sectional area will be governed by the rate of flow and by the number of channels. Additional channel length should be added to allow for inlet and outlet turbulence.

Grit removal from horizontal-flow grit chambers is accomplished usually by a conveyor with scrapers, buckets, or plows. Screw conveyors or bucket elevators are used to elevate the removed grit for washing or disposal. In small plants, grit chambers are sometimes cleaned manually.

Square Horizontal-Flow Grit Chambers. Square horizontal-flow grit chambers, such as those shown on Fig. 5–35, have also been in use for over 60 y. Influent to the units is distributed over the cross section of the tank by a series of vanes or gates, and the



Collecting tank diameter, m		3.0	6.0	9.0	12.0

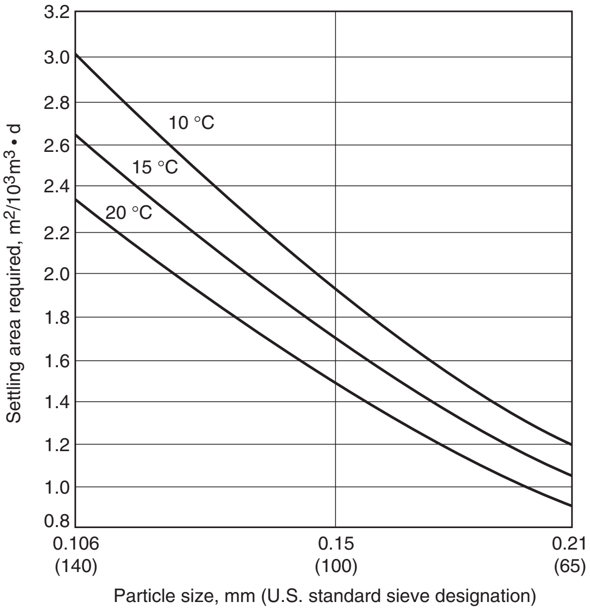
distributed wastewater flows in straight lines across the tank and overflows a weir in a free discharge. Where square grit chambers are used, it is generally advisable to use at least two units. These types of grit chambers are designed on the basis of overflow rates that are dependent on particle size and the temperature of the wastewater. Typically, these units have been designed to remove 95 percent of the 0.15-mm-diameter particles at peak flow.

Figure 5–36

Effect of wastewater temperature on the area required for settling grit particles with a specific gravity of 2.65 in a horizontal-flow grit chamber.



A typical set of design curves is shown on Fig. 5–36. The SES should be used for determining the settling area required.

In square grit chambers, the solids are removed by a rotating raking mechanism to a sump at the side of the tank (see Fig. 5–35). Settled grit may be moved up an incline by a reciprocating rake mechanism or an inclined screw conveyor. Grit may also be pumped from the tank through a cyclone degritter to separate the remaining organic material and concentrate the grit. The concentrated grit may then be washed again in a classifier using a submerged reciprocating rake or an inclined-screw conveyor. By either method, organic solids are separated from the grit and flow back into the basin, resulting in a cleaner, dryer grit.

Aerated Grit Chambers. In aerated grit chambers, air is introduced along one side of a rectangular tank to create a spiral flow pattern perpendicular to the flow through the tank (see Fig. 5–37). Wastewater, as shown on Fig. 5–37(b), will move through the tank in a spiral path and will make two to three passes across the bottom of the tank at maximum flow and more passes at average flow. The heavier grit particles settle to the bottom of the tank. Lighter, principally organic particles remain in suspension and pass through the tank. The velocity of roll or agitation governs the size of particles of a given specific gravity that will be removed. If the velocity is too high, grit will be carried out of the chamber; if it is too low, organic material will be removed with the grit. The quantity of air is easily adjusted. With proper adjustment, almost 100 percent of depositable grit will be removed and the grit will be well washed.

Design Considerations. Aerated grit chambers have been designed to remove 0.21-mm-diameter particles or larger, with 2- to 5-min detention periods at the peak hourly rate of flow. The cross section of the tank is similar to that provided for spiral circulation in activated-sludge aeration tanks, except that a grit hopper about 0.9 m (3 ft) deep with steeply sloping sides is located along one side of the tank under the air diffusers (see Fig. 5–37). The air diffusers are located about 0.45 to 0.6 m (1.5 to 2 ft) above the normal plane of the bottom. Influent and effluent baffles are used frequently for hydraulic control and improved grit-removal effectiveness. To determine the required headloss through the

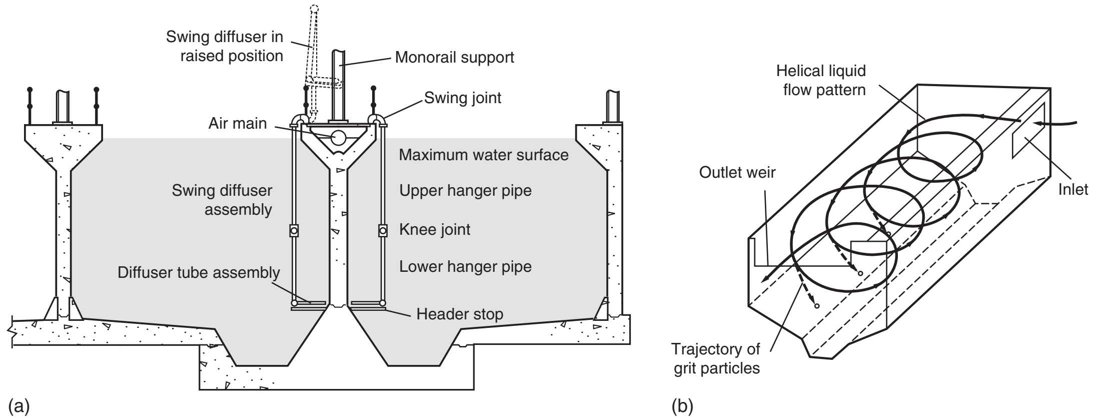


Figure 5–37

Typical aerated grit chamber: (a) cross-section through grit chamber and (b) schematic of helical flow pattern through an aerated grit chamber.

chamber, the expansion in volume caused by the air must be considered. Basic design data for aerated grit chambers are presented in Table 5–17. The design of aerated grit chambers is illustrated in Example 5–8.

Grit Removal Facilities. The removal of grit from aerated grit chambers can be accomplished using grab buckets traveling on monorails and centered over the grit collection and storage trough. Other installations have been equipped with chain-and-bucket conveyors, running the full length of the storage troughs, which move the grit to one end of the trough and elevate it above the wastewater level in a continuous operation. Screw conveyors, tubular conveyors, jet pumps, and airlifts have also been used to remove the collected grit. Grit-removal equipment for aerated grit chambers is subject to the same wear as experienced in the horizontal-flow units.

[a] From combined collection system.

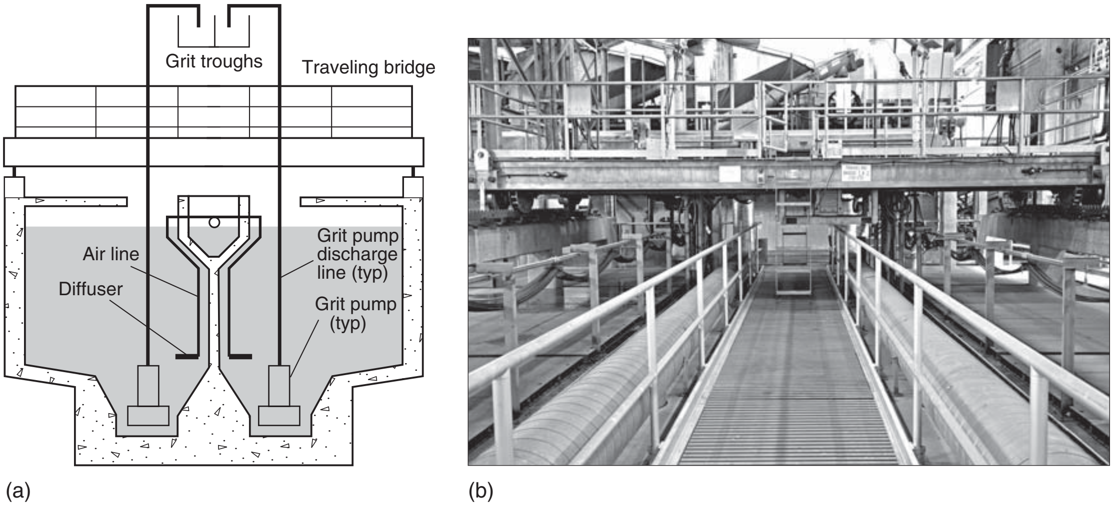

Figure 5–38

Aerated grit chamber with traveling bridge type grit removal system: (a) pumps mounted on the traveling bridge for removal of grit from the grit hopper [diffusers create the helical flow pattern as shown in Fig. 5–37(b)] and (b) view of covered aerated grit chamber equipped with traveling bridge.

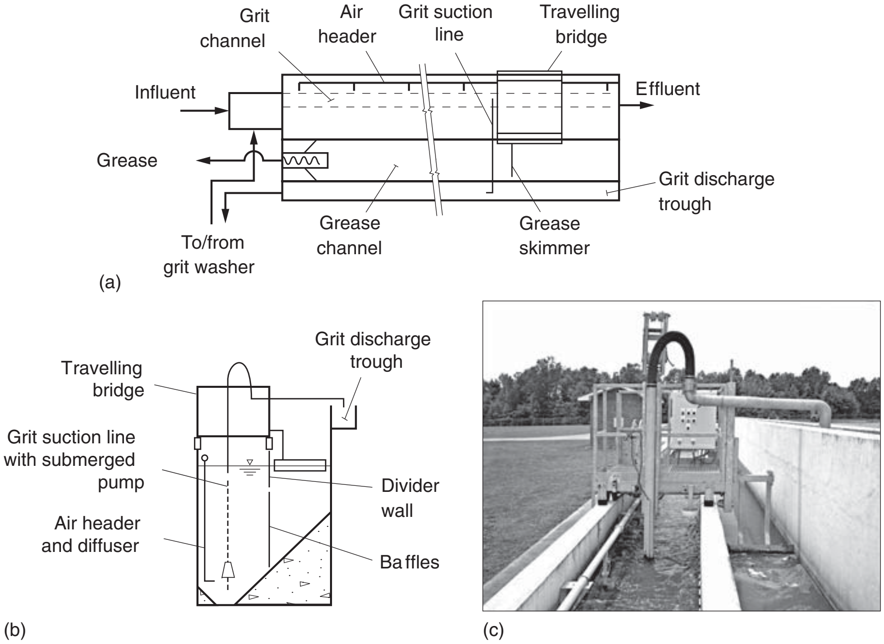
For large installations, traveling-bridge grit collectors, as shown on Fig. 5–38, are being used. Grit pumps are immersed in the grit chambers and travel the entire length, pumping grit into a stationary grit collection trough. The pumps can operate continuously or they can be programmed to run on cycles based on time or flow. A variation of this system uses a grit air lift pump installed on the traveling bridge for each grit tank rather than grit pumps. In another variation, a scraper blade attached to a traveling bridge is used in combination with grit air lifts to push heavier accumulations of grit to a pit at the inlet end of the grit chamber where it is removed using a grit pump. The scraper blade is installed on a pivoting arm and is raised during reverse travel of the bridge. Troughs receiving the pumped grit slurry must be designed for abrasion resistance.

Scum Removal. Aerated grit chambers may also be designed or existing grit chambers modified to provide FOG/scum removal (see Fig. 5–39). In this application, a baffle wall is provided that passes longitudinally through the aerated grit chamber. The baffle wall extends below the water surface and separates the tank into two parallel channels; a grit channel and a grease channel. The rising air buoys up entrained grease within the wastewater and brings it to the surface where the spiral roll moves the grease across the grit channel towards the longitudinal baffle. The lighter grease particles move through openings in the baffle to the grease channel. The heavier grit particles settle and move downward, where they collect in the channel hopper at the bottom, similar to a conventional aerated grit chamber. The grease collected in the grease channel is continuously moved by air/water skimming jets to the discharge end of the channel, where the collected grease is removed by a grease removal screw.

Emissions from Aerated Grit Chambers. Influent wastewater may contain constituents that when subjected to air agitation may be stripped from the wastewater. Where wastewater has been retained in the collection system for a long time, especially in warm

Figure 5–39

Aerated grit chamber with scum and FOG removal for small and intermediate size treatment plant: (a) plan view, (b) typical cross section, and (c) view of grit chamber (adapted from Schreiber).



climates, hydrogen sulfide and other odorous gases may be released from aerated grit chambers. In areas where industrial wastewater is discharged to the collection system, the release of volatile organic compounds (VOCs) may need to be considered as the release of significant amounts of VOCs can be a health risk to the treatment plant operators. Where emissions are an important consideration, covers may be required or non-aerated-type grit chambers used.

EXAMPLE 5–8 **Design of Aerated Grit Chamber** Design an aerated grit chamber for the treatment of municipal wastewater. The average flowrate is 0.5 m^3/s (11.4 Mgal/d), and the peaking factor curve given on Fig. 3–13 is applicable.

Solution

1. Establish the peak flowrate for design. Assume that the aerated grit chamber will be designed for the 1-d sustained peak flowrate. From Fig. 3–11, the peaking factor is found to be 2.75, and the peak design flowrate is

   $$\text{Peak flowrate} = 0.5\ \text{m}^3/\text{s} \times 2.75 = 1.38\ \text{m}^3/\text{s}$$

2. Determine the grit chamber volume. Because it will be necessary to drain the chamber periodically for routine maintenance, use two chambers. Assume the average detention time at the peak flowrate is 3 min.

   $$\text{Grit chamber volume, m}^3\ \text{(each)} = (1/2)(1.38\ \text{m}^3/\text{s})(3\ \text{min})(60\ \text{s/min}) = 124.2\ \text{m}^3$$

3. Determine the dimensions of each grit chamber. Use a width-to-depth ratio of 1.2:1 and assume that the depth is 3 m.
   a. Width = 1.2 (3 m) = 3.6 m

   $$\text{b. Length} = \frac{\text{volume}}{\text{width} \times \text{depth}} = \frac{124.2\ \text{m}^3}{3\ \text{m} \times 3.6\ \text{m}} = 11.5\ \text{m}$$

4. Determine the average detention time in each grit chamber at average flow.

$$\text{Detention time} = \frac{124.2\ \text{m}^3}{(0.25\ \text{m}^3/\text{s})} = 496.8\ \text{s}\left(\frac{1\ \text{min}}{60\ \text{s}}\right) = 8.28\ \text{min}$$

5 Determine the air supply requirement. Assume that 0.3 $\text{m}^3/\text{min}\cdot\text{m}$ of length will be adequate.

$$\begin{aligned}\text{Air required (length basis)} &= (11.5\ \text{m})(0.3\ \text{m}^3/\text{min}\cdot\text{m})\\ &= 3.45\ \text{m}^3/\text{min for each grit chamber}\end{aligned}$$

$$\text{Total air supply required} = 3.45 \times 2 = 6.9\ \text{m}^3/\text{min}\ (244\ \text{ft}^3/\text{min})$$

6. Estimate the daily quantity of grit. Assume a value of 0.05 $\text{m}^3/10^3\ \text{m}^3$.

$$\begin{aligned}\text{Volume grit} &= [(0.5\ \text{m}^3/\text{s})(86{,}400\ \text{s/d})(0.05\ \text{m}^3/10^3\ \text{m}^3)]\\ &= 2.16\ \text{m}^3/\text{d}\ (76\ \text{ft}^3/\text{d})\end{aligned}$$

Comment In designing aerated grit chambers, methods of regulating the air flowrate should be provided to control grit removal and improve the cleanliness of the grit.

Vortex-Type Grit Chambers. Grit is also removed in devices that use a vortex flow pattern. Three types of devices are shown on Fig. 5–40 and discussed below.

Mechanically Induced Vortex. In the mechanically induced vortex unit illustrated on Fig. 5–40(a), wastewater is directed to the vortex unit by a long, straight inlet channel that is designed to guide the wastewater flow into the vortex unit while the grit is directed downward. The toroidal motion caused by the tangential entry is enhanced by a rotating turbine impeller within the unit that causes the grit to move along the flat floor towards the center where it passes under a separating plate into a grit slurry hopper while the lighter organic materials are maintained in suspension and are guided to the surface where they leave the unit through the tangential exit. The grit hopper contents are kept fluidized by the axial flow propeller or by supplemental water jets. Grit may be removed by a grit slurry or air-lift pump. Typical design data are presented in Table 5–18. If more than two units are installed, special arrangements for flow splitting are required to prevent settling of grit upstream of grit chambers.

Hydraulically Induced Vortex. In the hydraulically induced vortex unit, the vortex, illustrated on Fig. 5–40(c), the vortex is generated by the flow entering the unit without any mechanical rotating devices. Wastewater is directed to the unit by a long, straight inlet channel and enters tangentially into the cylindrical unit, causing the contents to rotate slowly about the vertical axis. Flow spirals down the perimeter, allowing the grit and sand particles to settle. The internal components direct the main flow away from the perimeter and back to the middle where the degritted effluent is discharged near the center of the unit into an effluent channel. The heavy grit moves down a spiral path to the center where it passes under a center cone to the grit slurry hopper.

Headloss in the unit is a function of the size particle to be removed and increases significantly for very fine particles. Vortex grit-removal units are sized to handle peak flowrates up to 0.3 m^3/s (7 Mgal/d) per unit. Grit is removed from the unit by a cleated belt conveyor. Because of its overall height, this type of grit system requires a deep basement, or a lift station if it is installed above grade.

[a] Based on grit with a specific gravity of 2.5 to 2.65.

Multi-tray Vortex Grit Separator. The proprietary multi-tray vortex grit separator consists of multiple stacked trays which maximizes surface area and minimizing settling distances on Fig. 5–40(e). This allows for a very compact installation with low headloss. Flow is directed into the multiple tray unit by an influent distributor header which feeds a manifold which evenly distributes influent tangentially into the multiple-tray system. The tangential feed establishes a hydraulically forced vortex flow pattern where grit settles by gravity along the sloped surface of each tray and through a center opening which allows collected grit from each tray to settle into a single sump located below the center of the unit. Degritted effluent flows out of the space between the trays and into the surrounding basin where it then exits over a weir.

Grit Separators for Combined Wastewater and Stormwater

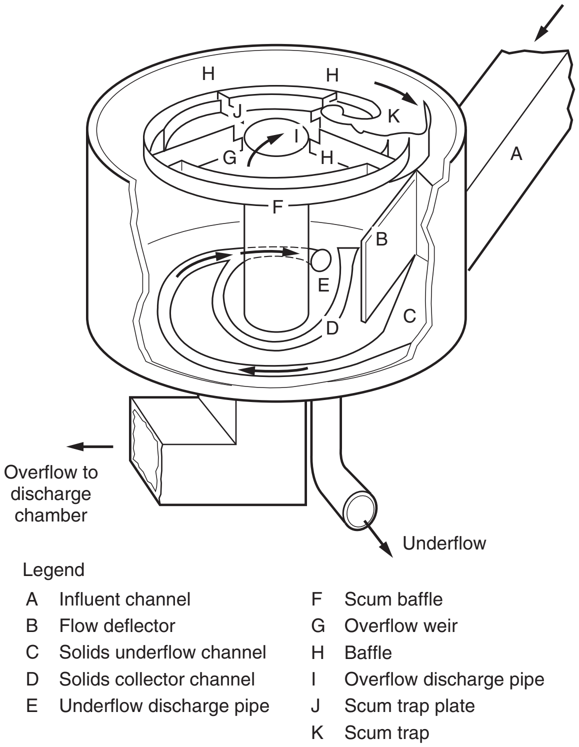
Solids-separation devices such as swirl concentrators and vortex separators have been used in Europe and, to a lesser extent, in the United States for the treatment of combined sewer overflows (CSOs) and stormwater. These devices are compact solids separation units with no moving parts.

Vortex-Type Separators. A typical vortex-type CSO solids-separation unit is illustrated on Fig. 5–41. Operation of vortex separators is based on the movement of particles within the unit. Water velocity moves the particles in a swirling action around the separator, additional flow currents move the particles toward the vortex, gravity pulls particles down, and a sweeping action moves heavier particles across the sloping floor toward the central drain.

During wet weather, the outflow from the unit is throttled, causing the unit to fill and to self-induce a swirling vortex-like flow regime. In the device shown on Fig. 5–41, secondary flow currents rapidly separate settleable grit and floatable matter. Concentrated foul matter is intercepted for treatment while the cleaner, treated flow is discharged to receiving waters. The device is intended to operate under extremely high flow regimes.

Figure 5–41

Typical vortex separator used for solids removal from combined sewer overflows.



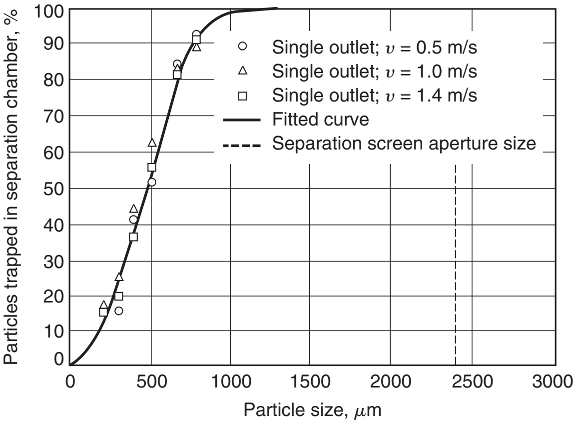
Continuous Deflection Separator. A device more recently developed and termed the continuous deflection separator (CDS) differs from the more traditional vortex separator in that it utilizes a filtration mechanism for solids separation and does not rely on secondary flow currents induced by the vortex action. The CDS system (pictured previously on Fig. 5–5(b) involves a single flow path and has one outlet point while other types of vortex separators discharge flows at the top and bottom of the units. The flow conditions within the CDS separation chamber have a different velocity profile. The surface velocity increases with increasing distance from the center of the separation chamber of the CDS unit, the reverse of that normally observed in conventional vortex separators. Solids separation is enhanced by a large expanded stainless-steel plate that acts as a filter screen with an outer volute outlet passage. The perforations in the separation screen are typically elongated in shape and are aligned with the longer axis in the vertical direction. The separation screen is installed so that the leading edge of each perforation extends into the flow stream of the containment chamber. Perforations in the screen can range from 1200 to 4700 mm (0.0475 to 0.185 in.). The CDS device is most appropriately used to capture the "first flush" and set up to divert all flows up to a threshold discharge. In tests conducted by Wong (1997), greater than 90 percent capture was reported for solids as small as 900 microns (see Fig. 5–42). Headloss through the separation unit varies depending on flowrate and screen openings.

Grit Washing

As some of the heavier organic matter remains normally with the grit, grit washers are used to provide a second stage of volatile solids separation. Grit separated from the main wastewater flow, is transported in a slurry to a washing process to remove organic material. Unwashed grit may contain 50 percent or more of putrescible, organic material, has

Figure 5–42

Solids capture from a continuous deflection separator (Wong, et al., 1997).



a distinctly disagreeable odor, and may attract insects and rodents. The objective of the grit washing process is to achieve a clean grit with a low volatile solids content. Typically, a grit washing system can be expected to result in a clean grit with a volatile solids content of less than 20 percent while retaining at least 95 percent of the depositable grit.

Two principal types of grit washers are available. One type relies on an inclined submerged rake that provides the necessary agitation for separation of the grit from the organic materials and, at the same time, raises the washed grit to a point of discharge above water level (similar to the inclined ramp shown on Fig. 5–35). Another type of grit washer (see Fig. 5–43) uses an inclined screw and moves the grit up the ramp. Both types can be equipped with water sprays to assist in the cleansing action. Hydrocyclone separators are often installed at the inlet to the grit washer to improve grit separation and organics removal.

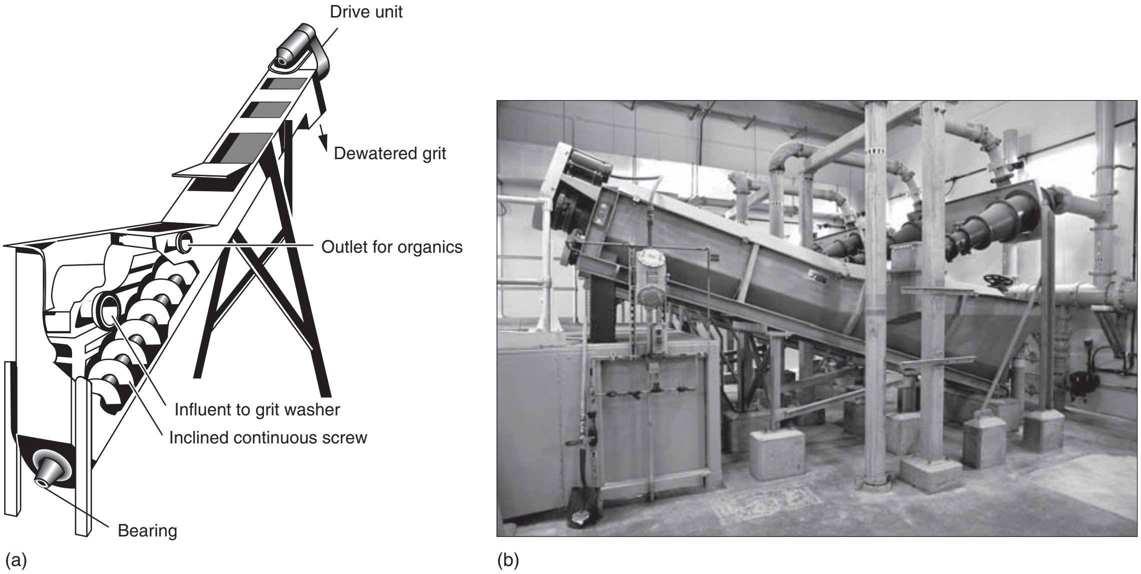


Figure 5–43

Example of grit separation and washing unit: (a) schematic and (b) view of typical installation.

Grit Drying

The clean grit must then be dewatered to remove all free water prior to disposal. Typically, grit is disposed in sanitary landfills and depending on local regulations may have to pass a paint filter liquid test (U.S. EPA, 2004). The objective of the drying process is to achieve a clean, dry grit with a total solids concentration greater than 60 percent while retaining at least 95 percent of the depositable grit.

Disposal of Grit

The most common method of grit disposal is transport to a landfill. In some large plants, grit is incinerated with solids. As with screenings, some states require grit to be lime stabilized before disposal in a landfill. Disposal in all cases should be done in conformance with the appropriate environmental regulations. In larger plants where trucks are used to transfer grit, elevated grit storage facilities may be provided with bottom-loading gates. Difficulties experienced in getting the grit to flow freely from the storage hoppers have been minimized by using steep slopes on the storage hoppers, by applying air beneath the grit, and by the use of hopper vibrators. Drainage facilities for collection and disposal of drippings from the bottom-loading gates are desirable. Grab buckets operating on a monorail system may also be used to load trucks directly from the grit chambers. Pneumatic conveyors are sometimes used to convey grit short distances. Advantages of pneumatic conveying include (1) no elevated storage hoppers are required and (2) attendant odor problems associated with storage are eliminated. The principal disadvantage is the considerable wear on piping, especially at bends.

Solids (Sludge) Degritting

Where grit chambers are not used and the grit is allowed to settle in the primary settling tanks, grit removal is accomplished by pumping dilute quantities of primary sludge to a cyclone degritter. The cyclone degritter acts as a centrifugal separator in which the heavy particles of grit and solids are separated by the action of a vortex and discharged separately from the lighter particles and the bulk of the liquid. The principal advantage of cyclone degritting is the elimination of the cost of constructing, operating, and maintaining grit chambers. The disadvantages are (1) pumping of dilute quantities of solids usually requires solids thickeners and (2) pumping of grit with the liquid primary solids increases the cost of operating and maintaining solids collectors and the primary sludge pumps.

5–6 PRIMARY SEDIMENTATION

The objective of treatment by sedimentation is to remove readily settleable solids and floating material found in wastewater and thus reduce the suspended solids content. Primary sedimentation is typically the first step in the further processing of the wastewater following the removal of coarse solids and grit. Efficiently designed and operated, from 50 to 70 percent of the suspended solids and from 25 to 40 percent of the BOD can be removed by primary sedimentation tanks.

Sedimentation tanks have also been used as stormwater retention tanks to provide a moderate detention period (10 to 30 min) for overflows from either combined sewers or storm sewers. The purpose of sedimentation is to remove a substantial portion of the organic solids that otherwise would be discharged directly to the receiving waters. Sedimentation tanks have also been sized to provide detention periods sufficient for effective disinfection of such overflows. The purpose of this section is (1) to describe the various

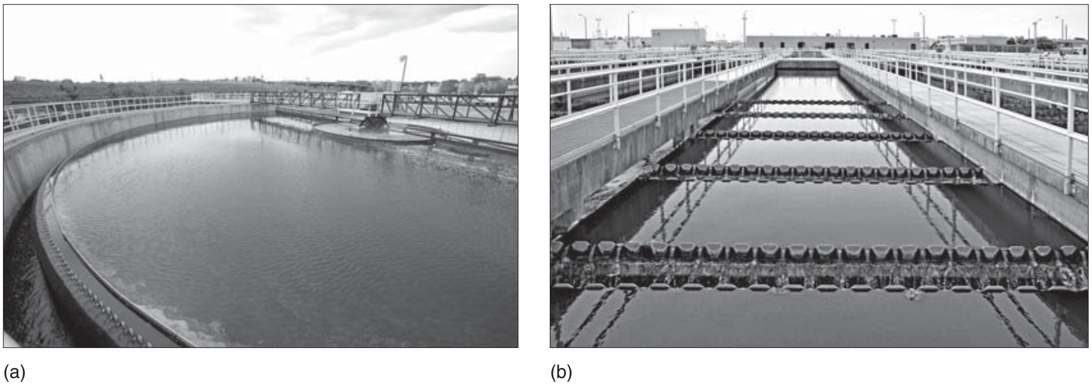

Figure 5–44

Typical sedimentation basins used at wastewater treatment plant: (a) circular with peripheral V-notch effluent weirs and (b) rectangular with inboard V-notch effluent weirs.

types of sedimentation facilities, (2) to consider their performance, and (3) to review important design considerations. Sedimentation tanks used for secondary treatment are considered in Chap. 8.

Description

Almost all treatment plants that have primary sedimentation use mechanically cleaned sedimentation tanks of standardized circular or rectangular design (see Fig. 5–44). The selection of the type of sedimentation unit for a given application is governed by the size of the installation, by rules and regulations of local control authorities, by local site conditions, and by the experience and judgment of the engineer. Two or more tanks should be provided so that the process may remain in operation while one tank is out of service for maintenance and repair work. At large plants, the number of tanks is determined largely by size limitations.

Rectangular Tanks. Rectangular sedimentation tanks may use either chain-and-flight solids collectors or traveling-bridge-type collectors. A rectangular tank that uses a chain-and-flight-type collector is shown on Fig. 5–45. Multiple rectangular tanks require less land area than multiple circular tanks and find application where site space is at a premium. Rectangular tanks also lend themselves to nesting with preaeration tanks and aeration tanks in activated-sludge plants, thus permitting common wall construction and reducing construction costs. They are also used generally where tank roofs or covers are required. While construction costs may be less, the chain-and-flight collector systems used in rectangular tanks generally require more maintenance than the rotating sludge collector mechanism used with circular settling tanks. Important issues with rectangular tanks include (1) sludge removal, (2) flow distribution, and (3) scum removal.

Sludge Removal. Equipment for settled solids removal generally consists of a pair of endless conveyor chains, manufactured of alloy steel, cast iron, or thermoplastic. Attached to the chains at approximately 3 m (10 ft) intervals are scraper flights made of wood or fiberglass, extending the full width of the tank or bay [see Fig. 5–45(d)]. The solids settling in the tank are scraped to solids hoppers in small tanks and to transverse troughs in large tanks. The transverse troughs are equipped with collecting mechanisms (cross collectors),

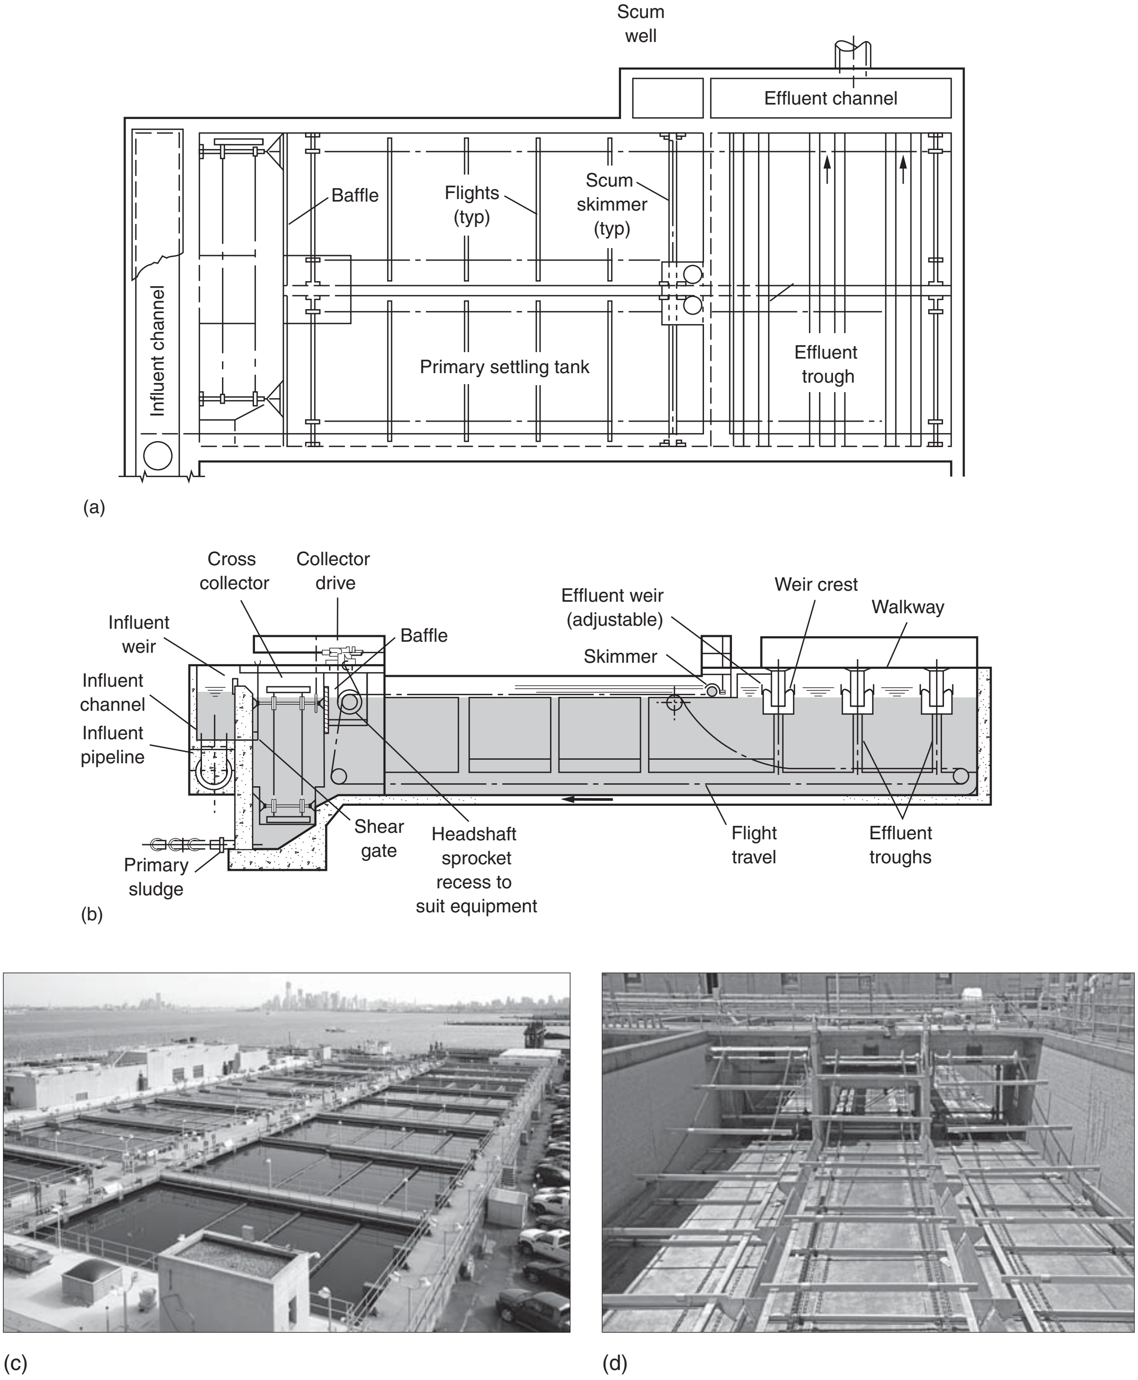

Figure 5–45

Typical rectangular primary sedimentation tank: (a) plan, (b) section, (c) view of large rectangular sedimentation tank with weirs similar to those shown on (b), and (d) view of empty tank with sludge removal mechanism.

usually either chain-and-flight or screw-type collectors, which convey solids to one or more collection hoppers. In very long units (over 50 m), two collection mechanisms can be used to scrape solids to collection points near the middle of the tank length.

Where possible, it is desirable to locate solids pumping facilities close to the collection hoppers. Where cross collectors are not provided, multiple solids hoppers must be installed. Solids hoppers have operating difficulties, notably solids accumulation on the slopes and in the corners and arching over the solids drawoff piping. Wastewater may also be drawn through the solids hopper, bypassing some of the accumulated solids and resulting in a “rathole” effect. A cross collector is more advisable, except possibly in small plants, because a more uniform and concentrated solids can be withdrawn and many of the problems associated with solids hoppers can be eliminated. Rectangular tanks may also be cleaned by a bridge-type mechanism that travels up and down the tank on rubber wheels or on rails supported on the sidewalls. One or more scraper blades are suspended from the bridge. Some of the bridge mechanisms are designed so that the scraper blades can be lifted clear of the solids blanket on the return travel.

Flow Distribution. Because flow distribution in rectangular tanks is critical, one of the following inlet designs is used: (1) full-width inlet channels with inlet weirs, (2) inlet channels with submerged ports or orifices, (3) or inlet channels with wide gates and slotted baffles. Inlet weirs, while effective in spreading flow across the tank width, introduce a vertical velocity component into the solids hopper that may re-suspend the solids particles. The weirs also introduce additional headloss in the plant hydraulic profile. Inlet ports can provide good distribution across the tank width if the velocities are maintained in the 3 to 9 m/min (10 to 30 ft/min) range. Inlet baffles are effective in reducing the high initial velocities and distribute flow over the widest possible cross-sectional area. Where full-width baffles are used, they should extend from 150 mm (6 in.) below the surface to 300 mm (12 in.) below the entrance opening.

For installations of multiple rectangular tanks, below-grade pipe and equipment galleries can be constructed integrally with the tank structure and along the influent end. The galleries are used to house the sludge pumps and sludge drawoff piping. The galleries also provide access to the equipment for operation and maintenance. Galleries can also be connected to service tunnels for access to other plant units.

Scum Removal. Scum is usually collected at the effluent end of rectangular tanks with the flights returning at the liquid surface. The scum is moved by the flights to a point where it is trapped by baffles before removal. Water sprays can also move the scum. The scum can be scraped manually up an inclined apron, or it can be removed hydraulically or mechanically, and for scum removal a number of means have been developed. For small installations, the most common scum drawoff facility consists of a horizontal, slotted pipe that can be rotated by a lever or a screw. Except when drawing scum, the open slot is above the normal tank water level. When drawing scum, the pipe is rotated so that the open slot is submerged just below the water level, permitting the scum accumulation to flow into the pipe. Use of this equipment results in a relatively large volume of scum liquor.

Another method for removing scum is by a transverse rotating helical wiper attached to a shaft. Scum is removed from the water surface and moved over a short inclined apron for discharge to a cross-collecting scum trough. The scum may then be flushed to a scum ejector or hopper ahead of a scum pump. Another method of scum removal consists of a chain-and-flight type of collector that collects the scum at one side of the tank and scrapes it up a short incline for deposit in scum hoppers, whence it can be pumped to disposal units. Scum is also collected by special scum rakes in rectangular tanks that are equipped with the carriage or bridge type of sedimentation tank equipment. In installations where appreciable amounts of scum are collected, the scum hoppers are usually equipped with mixers to provide a homogeneous mixture prior to pumping. Scum is usually disposed of with the solids and biosolids produced at the plant; however, separate scum disposal is used at many plants.

Circular Tanks. Circular sedimentation tanks are customarily arranged in groups of two or four. The flow is divided among the tanks by a flow-split structure, commonly located between the tanks. Solids are usually withdrawn by sludge pumps for discharge to the solids processing and disposal units. Important considerations include (1) method of introducing flow, (2) energy dissipation, and (3) sludge removal.

Flow Pattern. In circular tanks the flow pattern is radial (as opposed to horizontal in rectangular tanks). To achieve a radial flow pattern, the wastewater to be settled can be introduced in the center or around the periphery of the tank, as shown on Fig. 5–46. Both flow configurations have proved to be satisfactory generally, although the center-feed type is more commonly used, especially for primary treatment. In the center-feed design [see Fig. 5–46(a)], the wastewater is transported to the center of the tank in a pipe suspended from the bridge, or encased in concrete beneath the tank floor. At the center of the tank, the wastewater enters a circular well designed to distribute the flow equally in all directions [see Fig. 5–46(a)]. The center well has a diameter typically between 15 and

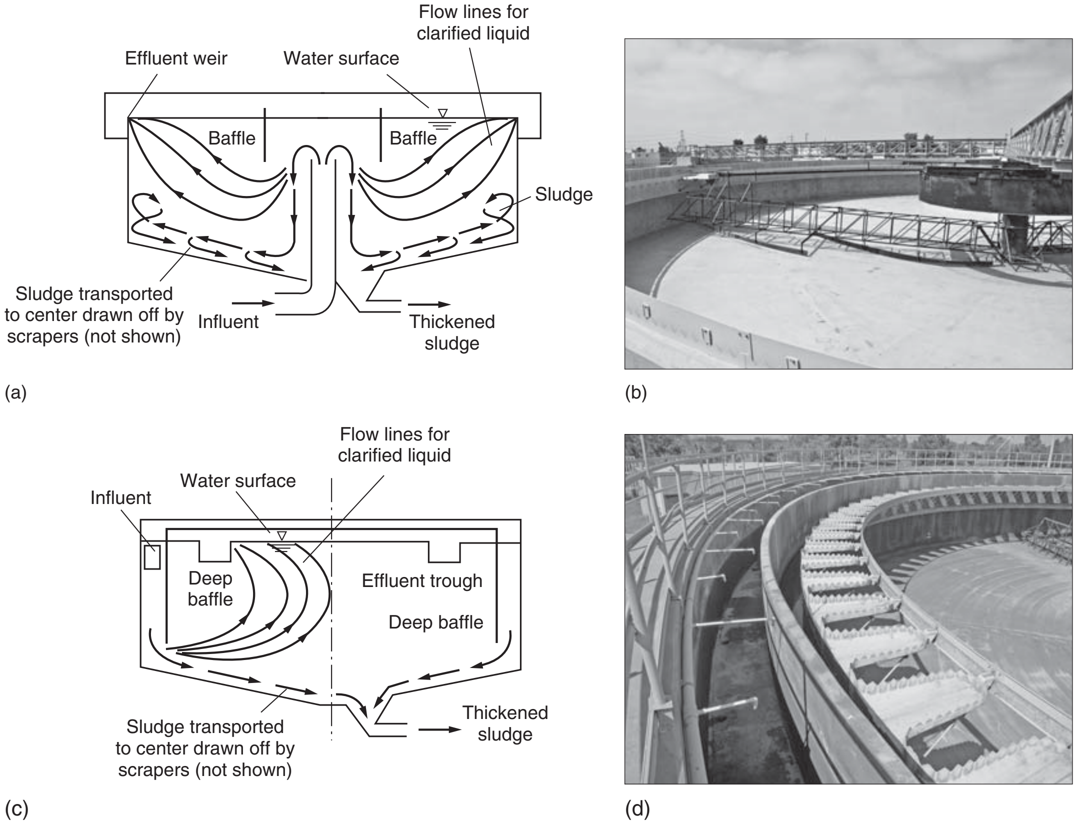

Figure 5–46

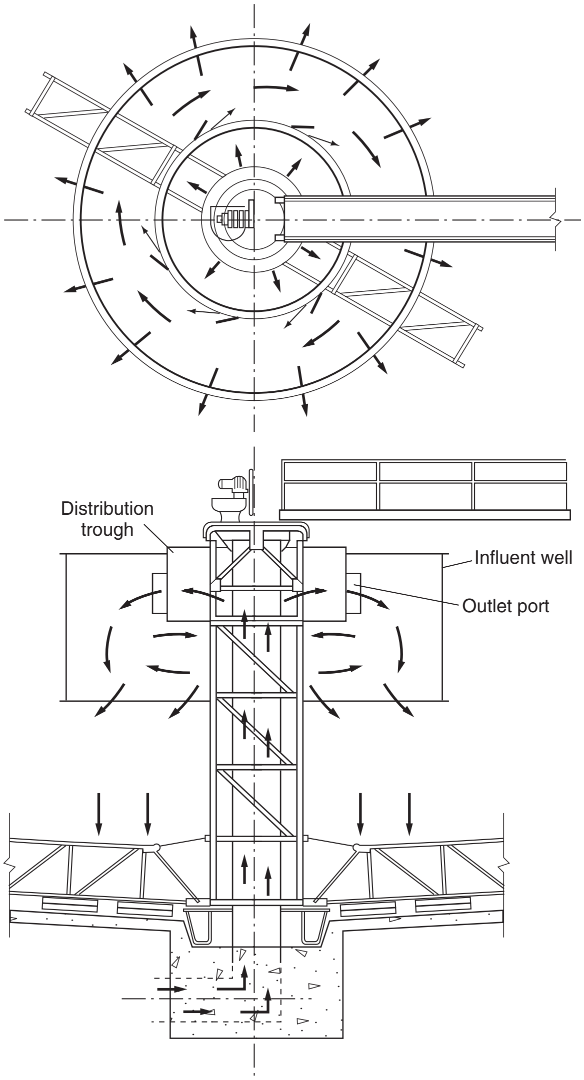
Typical circular sedimentation tanks: (a) schematic of center feed, (b) view of center feed unit, (c) schematic of peripheral feed, and (d) view of a peripheral feed unit.

Figure 5–47

Typical energy dissipating and flow distribution inlet for a center-feed sedimentation tank. The inner ring is used to create a tangential flow pattern (Randle, et al., 1992).



25 percent of the total tank diameter and ranges from 1 to 2.5 m (3 to 8 ft) in depth and should have a tangential energy-dissipating inlet within the feedwell.

Energy Dissipation. The energy-dissipating device (see Fig. 5–47) functions to collect influent from the center column and discharge it tangentially into the upper 0.5 to 0.7 m of the feedwell. The discharge ports are sized to produce a velocity of 0.75 m/s at maximum flow and 0.30 to 0.45 m/s at average flow. The feedwell should be sized so that the maximum downward velocity does not exceed 0.75 m/s. The depth of the feedwell should extend about 1 meter below the energy-dissipating inlet ports (Randall et al., 1992). An alternative approach to energy dissipation is to taper the inlet riser pipe so that the pipe increases in size from bottom to top. A center column formed in concrete can provide this configuration. The outlet of the riser pipe should terminate below the water surface. Vertical supports extending upward from the center column are used to support the center drive for the sludge collector mechanism. The tapered inlet with submerged outlet has the effect of reducing the inlet velocity of flow to the feedwell, thereby dissipating inlet energy.

In the peripheral-feed design [see Fig. 5–46(b)], a suspended circular baffle forms an annular space into which the inlet wastewater is discharged in a tangential direction. The wastewater flows spirally around the tank and underneath the baffle, and the clarified liquid is skimmed off over weirs on both sides of a centrally located weir trough. Grease and scum are confined to the surface of the annular space. Peripheral feed tanks are used generally for secondary clarification.

Sludge Removal. Circular tanks 3.6 to 9 m (12 to 30 ft) in diameter have the solids-removal equipment supported on beams spanning the tank. Tanks 10.5 m (35 ft) in diameter and larger have a central pier that supports the mechanism and is reached by a walkway or bridge. The bottom of the tank is sloped at about 1 in 12 (vertical:horizontal) to form an inverted cone, and the solids are scraped to a relatively small hopper located near the center of the tank. Airlift pumps can also be used to withdraw sludge minimizing the costs associated with operating and maintaining sludge pumps.

Combination Flocculator-Clarifier. Combination flocculator-clarifiers are often used in water treatment and sometimes used for wastewater treatment, especially in cases where enhanced settling, such as for industrial wastewater treatment or for biosolids concentration, is required. Inorganic chemicals or polymers can be added to improve flocculation. Circular clarifiers are ideally suited for incorporation of an inner, cylindrical flocculation compartment (see Fig. 5–48). Wastewater enters through a center shaft or well and flows into the flocculation compartment, which is generally equipped with a paddle-type or low-speed mixer. The gentle stirring causes flocculent particles to form. From the flocculation compartment, flow then enters the clarification zone by passing down and radially outward. Settled solids and scum are collected in the same way as in a conventional clarifier.

Stacked (Multilevel) Clarifiers. Stacked clarifiers originated in Japan in the 1960s where limited land area is available for the construction of wastewater treatment facilities. Since that time, stacked clarifiers have been used in the United States, the most notable installation of which is at the Deer Island Wastewater Treatment Plant constructed in Boston Harbor. Design of these types of clarifiers recognizes the importance of settling

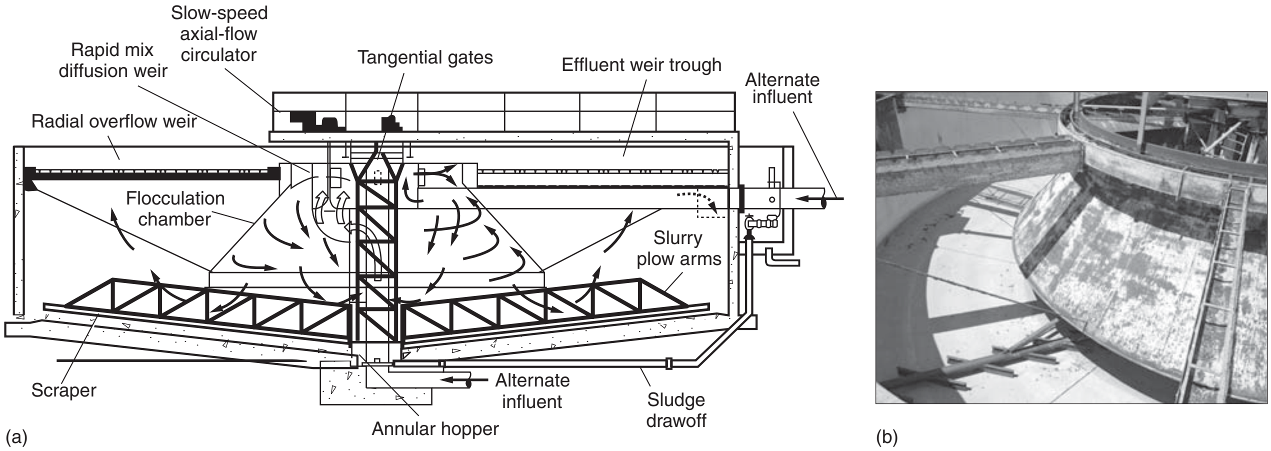


Figure 5–48

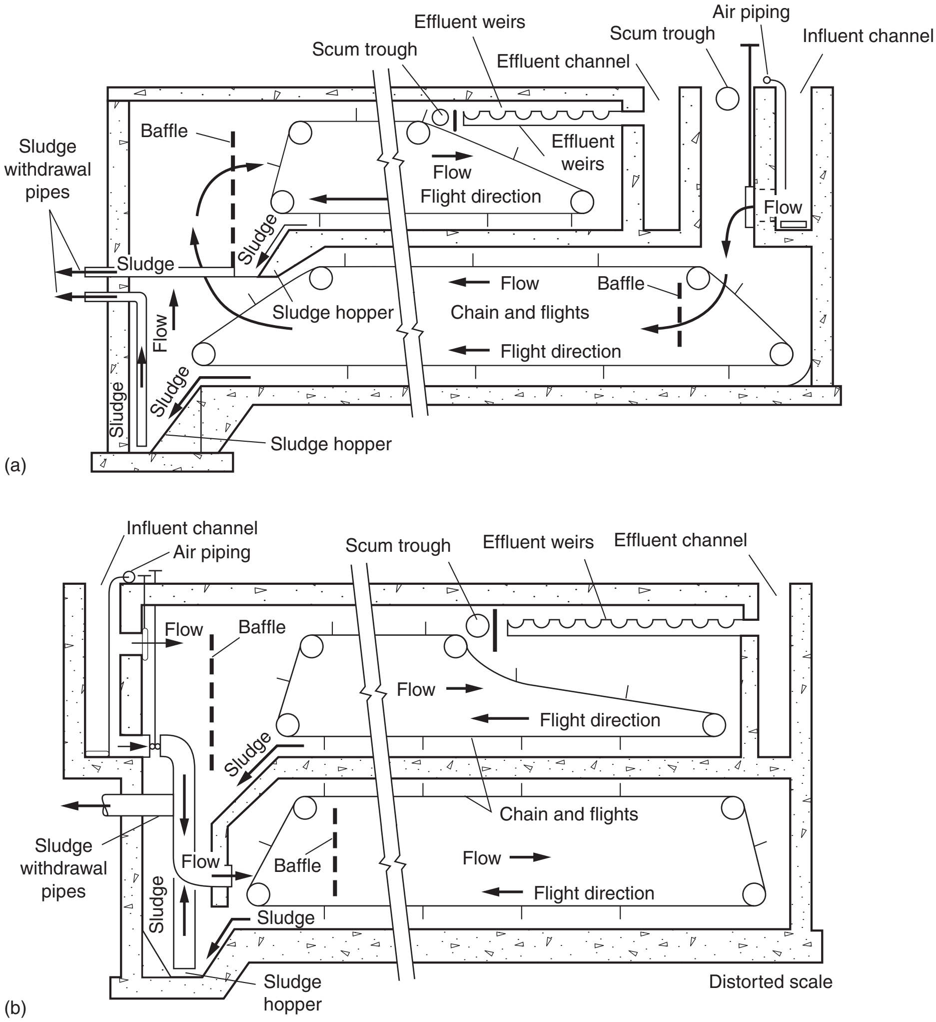
Typical flocculator-clarifier: (a) schematic and (b) view of empty tank. In some designs, turbine or propeller mixers are included in the flocculation chamber.

Figure 5–49

Typical section through a stacked clarifier (a) series flow and (b) parallel flow type used at the Deer Island Wastewater Treatment Plant, Boston, MA. Note: In the parallel flow type, the upper effluent weirs serve both the upper and lower clarifiers. Channels for the discharge of effluent from the lower to the upper clarifier are located on either side of the sludge collection mechanism in the upper clarifier.



area to settling efficiency. Operation of stacked rectangular clarifiers is similar to conventional rectangular clarifiers in terms of influent and effluent flow patterns and solids collection and removal. The stacked clarifiers are actually two (or more) tanks, one located above the other, operating on a common water surface (see Fig. 5–49). Each clarifier is fed independently, resulting in parallel flow through the lower and upper tanks. Settled solids are collected from each tank with chain and flight solids collectors, discharging to a common hopper. In addition to saving space, advantages claimed for stacked clarifiers include less piping and pumping requirements. Because the facilities are more compact and have less exposed surface area, better control of odors and volatile organic compound emissions is possible. Disadvantages include higher construction cost than conventional clarifiers and more complex structural design. Design criteria for stacked clarifiers, as regards overflow and weir rates, are similar to conventional primary and secondary clarifiers.

Sedimentation Tank Weirs. Settled effluent from sedimentation tanks is discharged over weirs into an effluent launder which, in turn, discharges into a conduit or open channel leading to the biological treatment process. Small rectangular settling tanks are often fitted with a single transverse weir on the discharge end wall. However, larger rectangular settling tanks require additional weir length to minimize headloss and avoid short circuiting. Headloss and short circuiting can be minimized by adding a series of inboard launders with double weirs that are aligned either longitudinally (parallel to the length of the settling tank) or transversely (perpendicular to the length of the settling tank) [see Fig. 5–45(c)] or both longitudinally and transversely [see Fig. 5–50(a)].

Figure 5–50

Typical sedimentation tank appurtenances used for sedimentation tanks: (a) internal longitudinal and transverse weirs in rectangular sedimentation tanks, (b) peripheral V-notch effluent weirs launders in peripheral feed circular basin, (c) and (d) covered peripheral weirs to limit algal growth, and (e) and (f) covers for primary clarifiers to eliminate the release of odors.

Because most circular settling tanks are designed with center feed, treated effluent is discharged over a series of V-notch weirs located peripherally at the tank wall [see Figs. 5–46(a) and (b)]. A similar arrangement is used for peripheral feed circular clarifier [see Fig. 5–50(b)]. For large circular settling tanks, inboard launders with double weirs may be provided to increase the number of V-notches and reduce the headloss at high flow [see Fig. 5–46(d)]. In these cases the weir plates must be designed to balance the flow from both weirs by proportioning the number of V-notches on each launder by the proportion of tank surface area that it serves.

The V-notches are spaced equally along the tank circumference and provide a simple means to detect short circuiting when the weir is not level. The V-notches are normally 90 degree Vs and have a total depth of 75 mm (3 in.). The number of V-notches used is based on limiting the depth from about 13 to 63 mm (0.5 to 2.5 in.) from low to high flow. Surface baffles are placed in front of the peripheral weir to retain surface scum [see Figs. 5–46(b) and Fig. 5–50(b)]. Density currents tend to form along the floor and wall of the settling tanks that can re-suspend solids. Consequently, the weir launder box is constructed on the inside of the perimeter wall or horizontal baffles are provided on the tank wall to redirect the density currents. To minimize maintenance cost and to limit algal growth, peripheral weirs are often covered [see Figs. 5–50(c) and (d)].

Covers for Sedimentation Tanks. In many locations where residential development has surrounded a pre-existing wastewater treatment plant, primary sedimentation facilities are often covered to limit odorous emissions. A variety of different types of covers have been used (see Fig. 5–50(e) and (f)). The use of covers and the processing of the gases released from the sedimentation tanks is considered in greater detail in Chap. 16.

Sedimentation Tank Performance

The efficiency of sedimentation basins with respect to the removal of BOD and TSS is reduced by (1) eddy currents formed by the inertia of the incoming fluid, (2) wind-induced circulation cells formed in uncovered tanks, (3) thermal convection currents, (4) cold or warm water causing the formation of density currents that move along the bottom of the basin and warm water rising and flowing across the top of the tank, and (5) thermal stratification in hot, arid climates (Fair and Geyer, 1954). Factors that affect performance are considered in the following discussion.

BOD and TSS Removal. Typical performance data for the removal of BOD and TSS in primary sedimentation tanks, as a function of the detention time and constituent concentration, are presented on Fig. 5–51. The curves shown on Fig. 5–51 are derived from observations of the performance of actual sedimentation tanks. The curvilinear relationships in the figure can be modeled as rectangular hyperbolas using the following relationship (Crites and Tchobanoglous, 1998):

$$R = \frac{t}{a + bt} \tag{5–45}$$

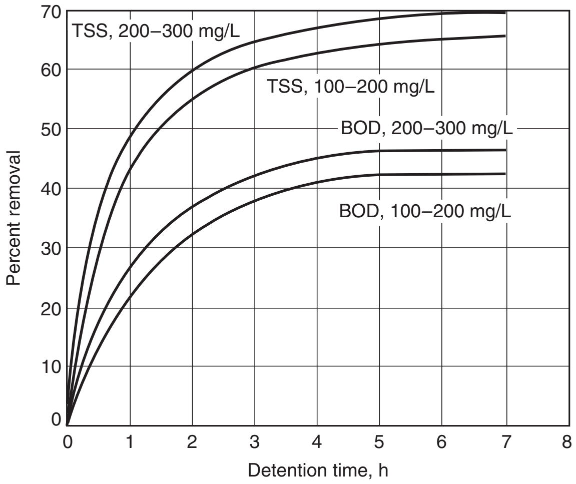
where R = expected removal efficiency
t = nominal detention time, T
a, b = empirical constants

Typical values for the empirical constants in Eq. (5–45) at 20°C are as follows:

Item	b	a
BOD	0.020	0.018
TSS	0.014	0.0075

Figure 5–51

Typical BOD and TSS removal in primary sedimentation tanks (Greeley, 1938).

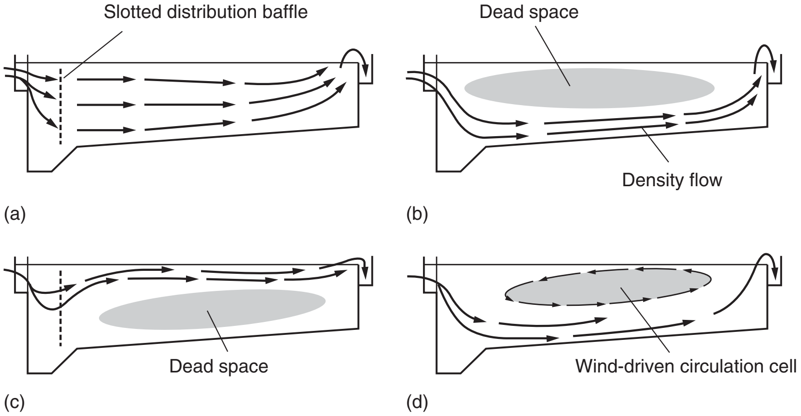


A fact that is often overlooked in sedimentation tank performance is the change in the wastewater characteristics that occurs through the sedimentation process. Larger, more slowly biodegradable suspended solids settle first, leaving a more volatile fraction in suspension that remains in the primary tank effluent. The strict use of removal curves, such as those given on Fig. 5–51, does not account for the transformation in wastewater characteristics that actually occurs. Where possible for domestic wastewater, primary tank influent and effluent should be characterized to determine concentration and composition of the constituents. Such characterization is important when determining the organic loading rate required to be treated by the succeeding biological treatment units. Further discussion on the effects of wastewater characterization on biological processes is contained in Chaps. 7 and 8.

Short Circuiting and Hydraulic Stability. In an ideal sedimentation basin, a given block of entering water should remain in the basin for the full detention time (see Fig. 5–52(a)). Short circuiting, which can lead to reduced treatment performance, can result from temperature differences [see Figs. 5–52(b) and (c)], wind driven circulation patterns [see Fig. 5–52(d)], and the presence of dead zones resulting from poor design, inadequate mixing and dispersion (see Fig. H-1 in Appendix H).

Figure 5–52

Typical flow patterns observed in rectangular sedimentation tanks: (a) ideal flow, (b) effect of density flow or thermal stratification (water in tank is warmer than influent), (c) effect of density stratification (influent wastewater is warmer than water in tank) and (d) formation of wind-driven circulation cell (Crites and Tchobanoglous, 1998).



Temperature Effects. Temperature effects can be significant in sedimentation basins. It has been shown that a 1°C temperature differential between the incoming wastewater and the wastewater in the sedimentation tank will cause a density current to form. The impact of the temperature effects on performance will depend on the material being removed and its characteristics. Temperature effects can be more pronounced in secondary settling tanks where a less dense sludge is processed.

Wind Effects. Wind blowing across the top of open sedimentation basins can cause circulation cells to form. When circulation cells form, the effective volumetric capacity of the basin is reduced. As with temperature effects, the impact of the reduced volume on performance will depend on the material being removed and its characteristics.

Modeling Basin Performance. To determine if short circuiting exists and to what extent, tracer studies should be performed, as discussed in Appendix H. Time-concentration curves should be developed for analysis. If in the repeated tests the time-concentration curves are similar, then the basin is stable. If the time-concentration curves (also known as residence time distribution (RTD) curves (see Appendix H) are not repeatable, the basin is unstable and the performance of the basin will be erratic (Fair and Geyer, 1954). The method of influent flow distribution, as discussed above, will also affect short circuiting. The effects of short circuiting on the performance of sedimentation tanks and other reactors was examined extensively by Morrill (1932), who based on his work developed the Morrill Dispersion Index (MDI) for the evaluation of reactor performance (see Appendix H). The application of the MDI method of analysis is illustrated in Example 12–8 in Chap. 12.

Design Considerations

If all solids in wastewater were discrete particles of uniform size, uniform density, uniform specific gravity, and uniform shape, the removal efficiency of these solids would be dependent on the surface area of the tank and time of detention. The depth of the tank would have little influence, provided that horizontal velocities would be maintained below the scouring velocity. However, the solids in most wastewaters are not of such regular character but are heterogeneous in nature, and the conditions under which they are present range from total dispersion to complete flocculation. Design parameters for sedimentation are considered below. Typical design information and dimensions for rectangular and circular sedimentation tanks used for primary treatment are presented in Tables 5–19 and 5–20, respectively. Additional details on the analysis and design of sedimentation tanks may be found in WPCF, 1985. A design procedure is illustrated in Example 5–9.

Detention Time. The bulk of the finely divided solids reaching primary sedimentation tanks is incompletely flocculated but is susceptible to flocculation. Flocculation is aided by eddying motion of the fluid within the tanks and proceeds through the coalescence of fine particles, at a rate that is a function of their concentration and of the natural ability of the particles to coalesce upon collision. As a general rule, coalescence of a suspension of solids becomes more complete as time elapses; thus, detention time is a consideration in the design of sedimentation tanks. The mechanics of flocculation are such, however, that as the time of sedimentation increases, less and less coalescence of remaining particles occurs.

Normally, primary sedimentation tanks are designed to provide 1.5 to 2.5 h of detention based on the average rate of wastewater flow. Tanks that provide shorter detention periods (0.5 to 1 h), with less removal of suspended solids, are sometimes used for preliminary

Table 5–19

Typical design information for primary sedimentation tanks[a]

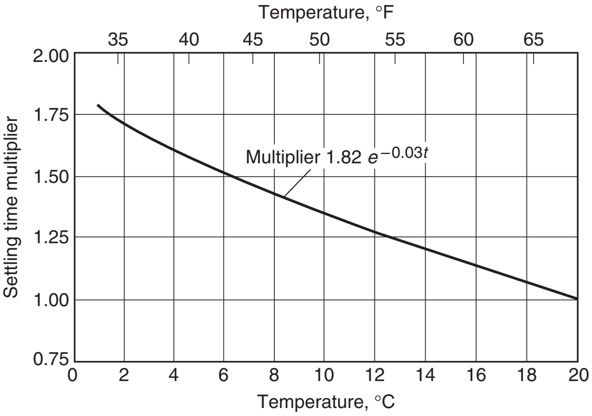
[a] If widths of rectangular mechanically cleaned tanks are greater than 6 m (20 ft), multiple bays with individual cleaning equipment may be used, thus permitting tank widths up to 24 m (80 ft) or more.

Figure 5–53

Curve of the increase in detention time required at cooler temperatures to achieve the same sedimentation performance as achieved at 20°C.



treatment ahead of biological treatment units. In cold climates, increases in water viscosity at lower temperatures retard particle settling in clarifiers and reduce performance at wastewater temperatures below 20°C (68°F). A curve showing the increase in detention time necessary to equal the detention time at 20°C is presented on Fig. 5–53 (WPCF, 1985). For wastewater having a temperature of 10°C, for example, the detention period is 1.38 times that required at 20°C to achieve the same efficiency. Thus, in cold climates, safety factors should be considered in clarifier design to ensure adequate performance.

Surface Loading Rates. Sedimentation tanks are normally designed on the basis of a surface loading rate (commonly termed *overflow rate*) expressed as cubic meters per square meter of surface area per day, $m^3/m^2 \cdot d$ (gallons per square foot of surface area per day, $gal/ft^2 \cdot d$). The selection of a suitable loading rate depends on the type of suspension to be separated. Typical values for various suspensions, without and with return activated sludge, are reported in Table 5–19. Designs for municipal plants must also meet the approval of state regulatory agencies, many of which have adopted standards for surface loading rates that must be followed. When the area of the tank has been established, the detention period in the tank is governed by water depth. Overflow rates in current use result in nominal detention periods of 2.0 to 2.5 h, based on average design flow.

The effect of the surface loading rate and detention time on suspended solids removal varies widely depending on the character of the wastewater, proportion of settleable solids, concentration of solids, and other factors. It should be emphasized that overflow rates must be set low enough to ensure satisfactory performance at peak rates of flow, which may vary from over 3 times the average flow in small plants to 2 times the average flow in large plants (see discussion of peak flowrates in Chap. 3).

Weir Loading Rates. In general, weir loading rates have little effect on the efficiency of primary sedimentation tanks and should not be considered when reviewing the appropriateness of clarifier design. For general information purposes only, typical weir loading rates are given in Table 5–19. The placement of weirs and baffles in secondary sedimentation applications is discussed in Sec. 8–8 of Chap. 8. Baffles should be placed ahead of effluent weirs in primary settling tanks to reduce hydraulic short circuiting. The baffles also prevent the discharge of scum into the effluent.

Scour Velocity. To avoid the resuspension (scouring) of settled particles, horizontal velocities through the tank should be kept sufficiently low. Using the results from studies by Shields (1936) and Camp (1946) developed the following equation for the critical velocity.

$$v_H = \left[\frac{8k(s - 1)gd}{f}\right]^{1/2} \tag{5–46}$$

where v_H = horizontal velocity that will just produce scour, LT^{-1} (m/s)
k = constant that depends on type of material being scoured (unitless)
s = specific gravity of particles
g = acceleration due to gravity, LT^{-2} (9.81 $\mathrm{m/s^2}$)
d = diameter of particles, L
f = Darcy-Weisbach friction factor (unitless)

Typical values of k are 0.04 for unigranular sand and 0.06 for more sticky, interlocking matter. The term f (the Darcy-Weisbach friction factor) depends on the characteristics of the surface over which flow is taking place and the Reynolds number. Typical values of f are 0.02 to 0.03. Either SI or U.S. customary units may be used in Eq. (5–46), so long as they are consistent, because k and f are dimensionless.

Computational fluid dynamic (CFD) modeling is sometimes used to optimize the design of settling tanks, particularly large diameter circular settling tanks. CFD modeling can be used to optimize feedwell diameter, feedwell depth, center column height and tank depth.

EXAMPLE 5–9 **Design of a Primary Sedimentation Basin** The average flowrate at a small municipal wastewater treatment plant is 20,000 $\mathrm{m^3/d}$. The highest observed peak daily flowrate is 50,000 $\mathrm{m^3/d}$. Design rectangular primary clarifiers with a channel width of 6 m (20 ft). Use a minimum of two clarifiers. Calculate the scour velocity, to determine if settled material will become resuspended. Estimate the BOD and TSS removal at average and peak flow. Use an overflow rate of 40 $\mathrm{m^3/m^2{\cdot}d}$ at average flow (see Table 5–19) and a side water depth of 4 m (13.1 ft).

Solution

1. Calculate the required surface area. For average flow conditions, the required area is

$$A = \frac{Q}{OR} = \frac{(20{,}000\ \mathrm{m^3/d})}{(40\ \mathrm{m^3/m^2\cdot d})} = 500\ \mathrm{m^2}$$

2. Determine the tank length.

$$L = \frac{A}{W} = \frac{500\ \mathrm{m}}{2 \times 6\ \mathrm{m}} = 41.7\ \mathrm{m}$$

However, for the sake of convenience, the surface dimensions will be rounded to 6 m by 42 m.

3. Compute the detention time and overflow rate at average flow.
Using the assumed sidewater depth of 4 m,

$$\text{Tank volume} = 4\ \mathrm{m} \times 2(42\ \mathrm{m} \times 6\ \mathrm{m}) = 2016\ \mathrm{m^2}$$

$$\text{Overflow rate} = \frac{Q}{A} = \frac{(20{,}000\ \mathrm{m^3/d})}{2(6\ \mathrm{m} \times 42\ \mathrm{m})} = 39.7\ \mathrm{m^3/m^2\cdot d}$$

$$\text{Detention time} = \frac{V}{Q} = \frac{(2016\ \mathrm{m^3})(24\ \mathrm{h/d})}{(20{,}000\ \mathrm{m^3/d})} = 2.42\ \mathrm{h}$$

4. Determine the detention time and overflow rate at peak flow.

$$\text{Overflow rate} = \frac{Q}{A} = \frac{(50{,}000\ \text{m}^3/\text{d})}{2(6\ \text{m} \times 42\ \text{m})} = 99.2\ \text{m}^3/\text{m}^2\cdot\text{d}$$

$$\text{Detention time} = \frac{V}{Q} = \frac{(2016\ \text{m}^3)(24\ \text{h/d})}{(50{,}000\ \text{m}^3/\text{d})} = 0.97\ \text{h}$$

5. Calculate the scour velocity (Eq. 5–46), using the following values:

Cohesion constant:	$k = 0.05$
Specific gravity:	$s = 1.25$
Acceleration due to gravity:	$g = 9.81\ \text{m/s}^2$
Diameter of particles:	$d = 100\ \mu\text{m} = 100 \times 10^{-6}\ \text{m}$
Darcy-Weisbach friction factor:	$f = 0.025$

$$v_{H(p)} = \left[\frac{8k(s-1)gd}{f}\right]^{1/2} = \left[\frac{(8)(0.05)(0.25)(9.81)(100 \times 10^{-6})}{0.025}\right]^{1/2} = 0.063\ \text{m/s}$$

6. Compare the scour velocity calculated in the previous step to the peak flow horizontal velocity (the peak flow divided by the cross-sectional area through which the flow passes).

The peak flow horizontal velocity through the settling tank is

$$v_{H(p)} = \frac{Q}{A_x} = \left[\frac{(50{,}000\ \text{m}^3/\text{d})}{2(6\ \text{m} \times 4\ \text{m})}\right]\left[\frac{1}{(24\ \text{h/d})(3600\ \text{s/h})}\right] = 0.012\ \text{m/s}$$

The horizontal velocity value, even at peak flow, is substantially less than the scour velocity. Therefore, settled matter should not be resuspended.

7. Use Eq. (5–45) and the accompanying coefficients to estimate the removal rates for BOD and TSS at average and peak flow.

a. At average flow:

$$\text{BOD removal} = \frac{t}{a+bt} = \frac{2.42}{0.018 + (0.020)(2.42)} = 36\%$$

$$\text{TSS removal} = \frac{t}{a+bt} = \frac{2.42}{0.0075 + (0.014)(2.42)} = 58\%$$

b. At peak flow:

$$\text{BOD removal} = \frac{t}{a+bt} = \frac{0.97}{0.018 + (0.020)(0.97)} = 26\%$$

$$\text{TSS removal} = \frac{t}{a+bt} = \frac{0.97}{0.0075 + (0.014)(0.97)} = 46\%$$

Characteristics and Quantities of Solids (Sludge) and Scum

Typical values of specific gravity and solids concentration of solids (sludge) and scum removed from primary sedimentation tanks are presented in Table 5–21. Scum consists of a variety of floatable materials, and solids concentrations vary widely. In primary sedimentation tanks used in activated-sludge plants, provision may be required for handling the excess activated sludge that may be discharged into the influent of the primary tanks for

Table 5–21

Typical values of specific gravity and solids concentration of solids and scum removed from primary sedimentation tanks

Type of solids (sludge)	Specific gravity	Solids concentration, %[a] Range	Solids concentration, %[a] Typical
Primary only:			
Medium strength wastewater	1.03	4–12	6
From combined sewer system	1.05	4–12	6.5
Primary and waste activated sludge	1.03	2–6	3
Primary and trickling filter humus sludge	1.03	4–10	5
Scum	0.95	*b*	—

[a] Percent dry solids.
[b] Range is highly variable.

settlement and consolidation with the primary sludge. For treatment plants where waste-activated sludge is returned to the primary sedimentation tanks, the primary sedimentation tanks should include provisions for light flocculent solids of 98 to 99.5 percent moisture and for concentrations ranging from 1500 to 10,000 mg/L in the influent mixed liquor.

The volume of solids produced in primary settling tanks must be known or estimated so that these tanks and subsequent solids pumping, processing, and disposal facilities can be properly designed. The solids volume will depend on (1) the characteristics of the untreated wastewater, including strength and freshness; (2) the period of sedimentation and the degree of purification to be effected in the tanks; (3) the condition of the deposited solids, including specific gravity, water content, and changes in volume under the influence of tank depth or mechanical solids-removal devices; and (4) the period between solids-removal operations. Additional information on the characteristics and quantities of solids produced during primary sedimentation and other treatment operations and processes is provided in Chap. 13.

5–7 HIGH-RATE CLARIFICATION

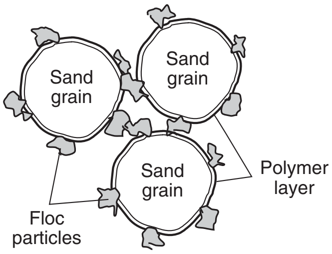
High-rate clarification employs physical/chemical treatment and utilizes special flocculation and sedimentation systems to achieve rapid settling. The essential elements of high-rate clarification are enhanced particle settling and the use of inclined plate or tube settlers. Advantages of high-rate clarification are (1) units are compact and thus reduce space requirements, (2) start-up times are rapid (usually less than 30 min) to achieve peak efficiency, and (3) a highly clarified effluent is produced. Enhanced particle flocculation and high-rate clarification applications are discussed in this section. Inclined plate and tube settlers were discussed previously in Sec. 5–4.

Enhanced Particle Flocculation

Enhanced particle flocculation has been used in Europe for more than 15 y but has only been introduced relatively recently in the United States. In its most basic form, enhanced particle flocculation involves the addition of an inert ballasting agent (usually silica sand or recycled chemically conditioned sludge) and a polymer to a coagulated and partially flocculated suspension. The polymer appears to coat the ballasting particles and forms the "glue" that binds the chemical floc to the ballasted particles (see Fig. 5–54). After contact with the ballasting agent, the mixture is stirred gently in a maturation tank that allows the floc particles to grow. The particles grow as the larger, faster-settling particles overtake and collide with slower-settling particles [see Fig. 5–11(b)]. The velocity gradient *G* for flocculation is important as a high gradient will cause a breakdown in the

Figure 5–54

Schematic of microsand ballasted floc particles. Polymer layer is used to absorb chemical flocs onto sand grains. (Adapted from Kruger.)



floc particles, and insufficient agitation will inhibit floc formation. Velocity gradients for enhanced particle settling of wastewater generally range from 200 to 400 s^{-1}.

Analysis of Ballasted Particle Flocculation and Settling

The settling velocity of the ballasted particle is increased, when compared to an unballasted floc particle, by (1) increasing the density of the particle, (2) decreasing the coefficient of drag and increasing the Reynolds number, and (3) decreasing the shape factor through the formation of more dense spherical-shaped particles [see Eq. (5–18)]. The ballasted floc particles appear to be more spherical than the floc particles alone. In effect, ballasted flocculent particles settle with a velocity closer to that of a discrete particle than that of flocculent particles that have very high shape factors. The comparative settling velocities of ballasted particles compared to other particles are illustrated in Example 5–10.

EXAMPLE 5–10 Calculation of Settling Velocities of Ballasted Floc and Other Particles

Determine the settling velocities at 20°C, for a ballasted floc particle, a spherical particle, and an irregularly shaped untreated wastewater particle, having the characteristics tabulated below. Use the alternative computation method involving the multiplication of the coefficient of drag times the shape factor.

	Particle type		
Particle characteristics	Ballasted floc	Spherical	Wastewater particle
Equivalent diameter, μm	200	150	500
Specific gravity	2.6	2.65	1.4
Shape factor, ϕ	2.5	1	18

Solution

Using Eq. (5–22) and the same computation procedure as Example 5–5, calculate the particle settling velocity for a ballasted floc particle and compare to spherical and wastewater floc particles.

1. Determine the terminal settling velocity for the ballasted floc particle.

$$\upsilon_p = \frac{g(sg_p - 1)d_p^2}{18\nu}$$

$$d_p = 200\ \mu\text{m} = 200 \times 10^{-6}\ \text{m}$$

$$\nu = 1.003 \times 10^{-6}\ \text{m}^2/\text{s at } 20°\text{C (from Appendix C)}$$

$$\upsilon_p = \frac{(9.81\ \text{m/s}^2)(2.6 - 1)(200 \times 10^{-6}\ \text{m})^2}{18(1.003 \times 10^{-6}\ \text{m}^2/\text{s})}$$

$$= 0.0348\ \text{m/s}$$

2. Check the Reynolds number (Eq. 5–20).

$$N_R = \frac{v_p d_p}{\nu} = \frac{(0.0348\ \text{m/s})(200 \times 10^{-6}\ \text{m})}{(1.003 \times 10^{-6}\ \text{m}^2/\text{s})} = 6.9$$

Because the Reynolds number > 1.0, Newton's Law [Eq. (5–18)] must be used to determine the settling velocity in the transition region (see Fig. 5–20). Follow the iterative procedure described in Example 5–5.

3. For the first assumed settling velocity, use the Stokes' Law settling velocity calculated above. Using the resulting Reynolds number, also determined previously, compute the drag coefficient.

$$C_d = \frac{24}{N_R} + \frac{3}{\sqrt{N_R}} + 0.34 = \frac{24}{6.9} + \frac{3}{\sqrt{6.9}} + 0.34 = 4.96$$

4. Use the drag coefficient in Newton's equation to determine the particle settling velocity in Eq. (5–21), which incorporates the shape factor.

$$v_p = \sqrt{\frac{4g(sg - 1)d}{3C_d\phi}} = \sqrt{\frac{4(9.81\ \text{m/s}^2)(2.6 - 1)(200 \times 10^{-6}\ \text{m})}{(3)(4.96)(2.5)}}$$
$$= 0.018\ \text{m/s}$$

Because the initial assumed settling velocity (0.035 m/s) does not equal the Newton's equation settling velocity (0.018 m/s), additional iterations are necessary.

5. For a following iteration, assume a settling velocity value of 0.012 m/s, and calculate the Reynolds number (the assumed value is based on several trial iterations for various velocities). Use the Reynolds number to determine the drag coefficient, and use the drag coefficient in Newton's equation to find the settling velocity.

$$N_R = \frac{(0.012\ \text{m/s})(200 \times 10^{-6}\ \text{m})}{(1.003 \times 10^{-6}\ \text{m}^2/\text{s})} = 2.39$$

$$C_d = \frac{24}{2.39} + \frac{3}{\sqrt{2.39}} + 0.34 = 12.3$$

$$v_p = \sqrt{\frac{4(9.81\ \text{m/s}^2)(2.6 - 1)(200 \times 10^{-6}\ \text{m})}{(3)(12.3)(2.5)}} = 0.012\ \text{m/s}$$

The assumed and calculated settling velocities (0.012 m/s) are in agreement.

6. Using the same computational procedure, calculate the settling velocities for the spherical and wastewater particles. The results of the calculations for the three particle settling velocities are summarized below:

Ballasted floc particle = 0.012 m/s = 43 m/h
Spherical particle = 0.0164 m/s = 59 m/h
Wastewater particle = 0.002 m/s = 7.2 m/h

Comment Although the particle settling velocities vary widely because of the particle characteristics (specific gravity, shape, and size), as illustrated in this example, by forming a ballasted floc particle the settling velocity can be enhanced significantly. Increasing the size and density of the wastewater particles by various means of ballasting is one of the premises of high-rate clarification. Because an iterative process is needed to calculate settling velocities in the transition zone, a spreadsheet program can expedite the computation process by allowing several assumed velocities to be tried to effect closure with the computed velocity.

Process Application

Three basic types of process used for high-rate clarification: (1) ballasted flocculation with lamella plate clarification, (2) three-stage flocculation with lamella plate clarification, and (3) dense-solids flocculation/clarification with lamella plate clarification are illustrated on Fig. 5–55. Each of these processes can operate at high overflow rates that allow significant reduction in the physical size of the sedimentation units. A summary of the principal

Figure 5–55

High-rate clarification processes: (a) ballasted flocculation, (b) lamella plate clarification, and (c) dense-sludge.

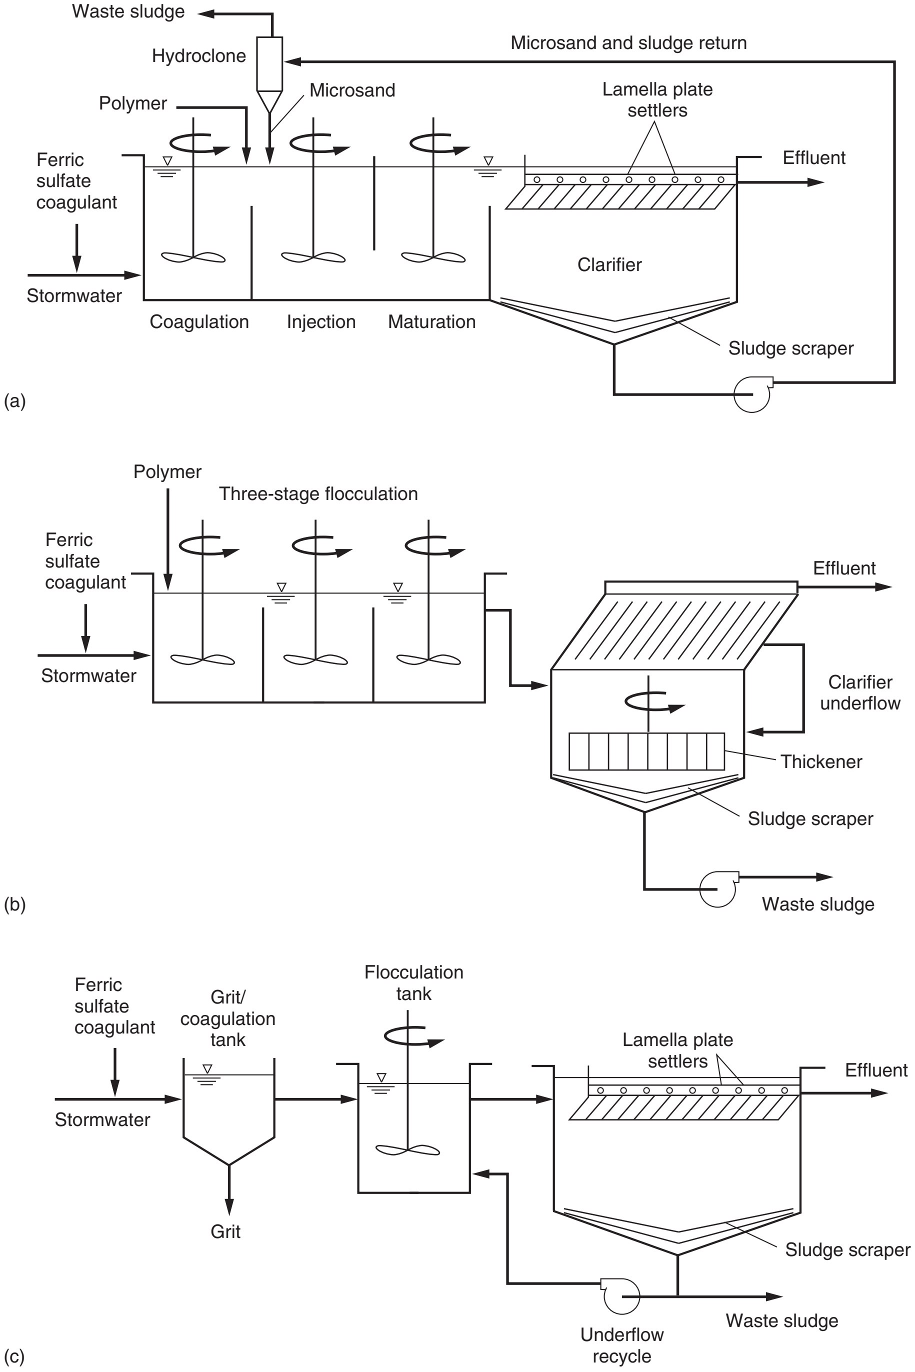


Table 5–22

Summary of features of high-rate clarification processes

Process	Features
Microsand ballasted flocculation and clarification [see Fig. 5–55(a)]	• Microsand provides nuclei for floc formation • Floc is dense and settles rapidly • Lamella clarification, when used, provides high rate settling in a small tank volume
Chemical addition, multi-stage flocculation, and lamella clarification [see Fig. 5–55(b)]	• Three-stage flocculation enhances floc formation • Lamella clarification provides high rate settling in a small tank volume
Air-mixing zone with grit separation and chemical addition followed by two-stage flocculation with chemically-conditioned recycled sludge, and lamella clarification [see Fig. 5–55(c)]	• Settled sludge solids are recycled to accelerate floc formation • Dense floc is formed that settles rapidly • Lamella clarification provides high rate settling in a small tank volume

features of each high-rate clarification process is presented in Table 5–22. Applications for high-rate clarification include (1) providing advanced primary treatment, (2) treating wet-weather flows and combined sewer overflows, (3) treating waste filter backwash water, and (4) treating return flows from solids-processing facilities. Ranges of overflow rates and BOD and TSS removals for treating wet-weather flows (domestic wastewater plus infiltration/inflow) are reported in Table 5–23 (Sawey, 1998).

Ballasted Flocculation. Ballasted flocculation employs a proprietary process, shown on Fig. 5–55(a), in which a flocculation aid and a ballasting agent (typically silica microsand) are used to form dense microfloc particles. The resulting floc particles are thus

Table 5–23

Ranges of overflow rates and BOD and TSS removals from high-rate clarification processes treating wet weather flows

Parameter/Process	Ballasted flocculation	Lamella plate clarification	Dense sludge
Overflow rates			
Low, $m^3/m^2 \cdot d$	1200–2900	880	2300
($gal/min \cdot ft^2$)	(20–50)	(15)	(40)
Medium, $m^3/m^2 \cdot d$	1800–3500	1200	2900
($gal/min \cdot ft^2$)	(30–60)	(20)	(50)
High, $m^3/m^2 \cdot d$	2300–4100	1800	3500
($gal/min \cdot ft^2$)	(40–70)	(30)	(60)
BOD removals, %			
At low overflow rates	35–50	45–55	25–35
At medium overflow rates	40–60	35–40	40–50
At high overflow rates	30–60	35–40	50–60
TSS removals, %			
At low overflow rates	70–90	60–70	80–90
At medium overflow rates	40–80	65–75	70–80
At high overflow rates	30–80	40–50	70–80

"ballasted" and settle rapidly. The treatment system consists of three compartments or zones: a mixing zone, maturation zone, and settling zone. Depending on the manufacturer of the process equipment, separate, serial compartments can be used to perform the process functions, or the functions can be combined in a single vessel. Either lamella plate settling or conventional gravity clarification can be used.

Typically, screened wastewater is introduced to the ballasted flocculation reactor where a chemical coagulant (typically an iron salt) is injected to destabilize the solids. The wastewater then enters a mixing zone where microsand and polymer are injected to maximize the efficiency of flocculation and enhance settling of suspended solids. In the mixing zone, the polymer acts as a bonding agent for adhering the destabilized solids to the microsand. The maturation zone follows and is used to keep the solids in suspension while floc particles continue to develop and grow. Once developed, the ballasted floc particles settle rapidly to the bottom of the clarifier. Sand and floc particles removed from the clarified water are pumped to a cyclone separator (hydroclone) for separation of the sand. The separated sand is returned to the injection tank, and solids from the hydroclone are sent to the biosolids processing facilities. The microsand usually ranges in size from 100 to 150 mm for treating wastewater and combined wastewater flows and has a specific gravity greater than 2.6 to enhance settling.

Lamella Plate Clarification. Lamella plate clarification uses chemical addition followed by three-stage flocculation and a lamella plate clarifier [see Fig. 5–55(b)]. Coagulant and polymer are injected into the influent wastewater prior to entrance into the flocculation zone. When chemically conditioned wastewater passes through each of the three flocculation zones, the mixing energy gradient is decreased as the wastewater proceeds from one stage to the next. The chemically conditioned/flocculated wastewater then passes to the lamella clarifier for solids separation. A portion of the clarifier underflow can be recycled to the influent of the process to enhance settling, or the entire underflow can be sent to a thickening tank and the solids processing facilities.

Dense-Sludge Process. The dense-sludge system is a proprietary process and differs from ballasted flocculation in that recycled chemically conditioned solids are used to form microfloc particles with the incoming wastewater instead of microsand. As shown on Fig. 5–55(c), the influent wastewater enters an air-mixing zone where grit separation occurs and coagulant (usually ferric sulfate) is injected. After mixing, the wastewater flows into the first stage of a two-stage flocculation tank where polymer is added together with chemically conditioned, recirculated solids. Recirculated solids accelerate the flocculation process and ensure the formation of dense, homogeneous floc particles. In the second stage of flocculation, grease and scum begin separating and are removed. Flow from the flocculation tank enters a presettling zone and then passes into a lamella plate settler. Most of the suspended flocculated solids are separated directly in the presettling zone; the residual flocculated particles are removed in the lamella settler. A portion of the settled solids is recirculated, and the remainder is sent to the solids processing and disposal system.

5–8 FLOTATION

Flotation is a unit operation used to separate solid or liquid particles from a liquid phase. Separation is brought about by introducing fine gas (usually air) bubbles into the liquid phase. The bubbles attach to the particulate matter, and the buoyant force of the combined particle and gas bubbles is great enough to cause the particle to rise to the surface. Particles that have a higher density than the liquid can thus be made to rise. The rising of particles with lower density than the liquid can also be facilitated (e.g., oil suspension in water).

In wastewater treatment, flotation is used principally to remove suspended matter and to concentrate biosolids (see Chap. 14). The principal advantages of flotation over sedimentation are that very small or light particles that settle slowly can be removed more completely and in a shorter time. Once the particles have been floated to the surface, they can be collected by a skimming operation.

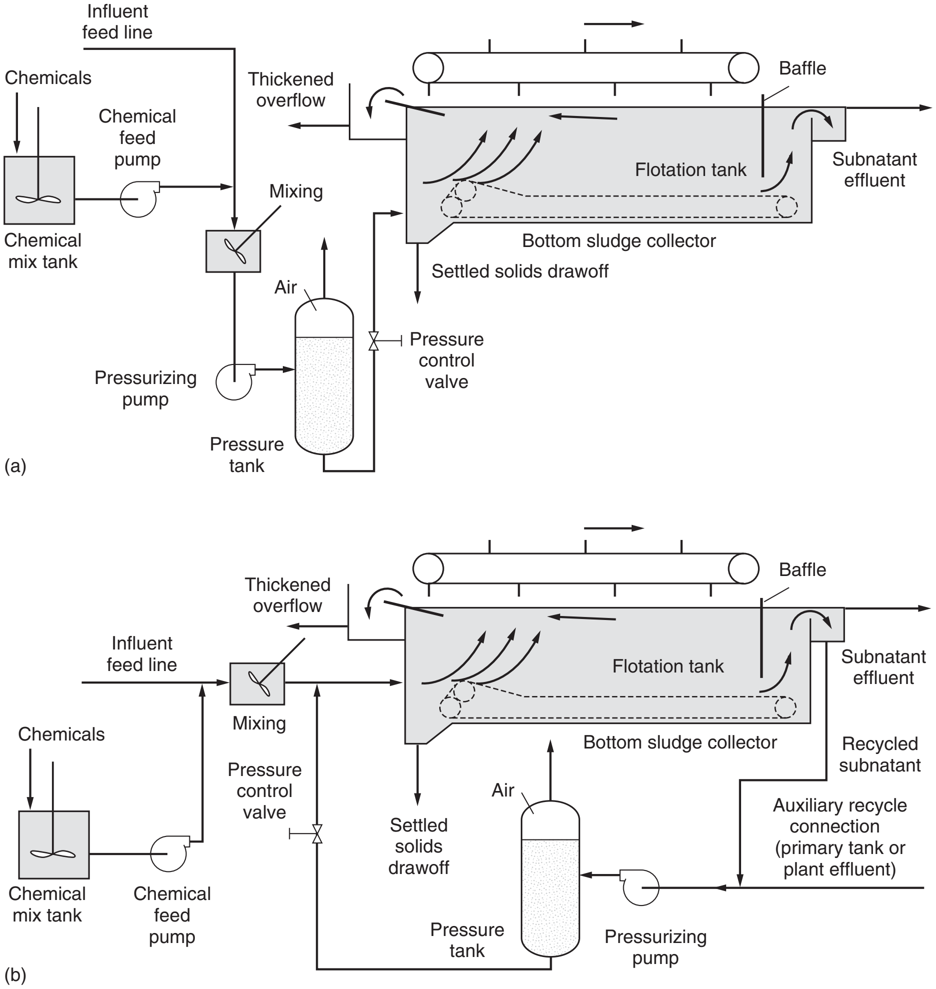
Description

The present practice of flotation as applied to wastewater treatment is confined to the use of air as the flotation agent. Air bubbles are added or caused to form by (1) injection of air while the liquid is under pressure, followed by release of the pressure (dissolved-air flotation), and (2) aeration at atmospheric pressure (dispersed-air flotation). In these systems, the degree of removal can be enhanced through the use of various chemical additives. In municipal wastewater treatment, dissolved-air flotation is frequently used, especially for thickening of waste biosolids.

Dissolved-Air Flotation. In dissolved-air flotation (DAF) systems, air is dissolved in the wastewater under a pressure of several atmospheres, followed by release of the pressure to the atmospheric level (see Fig. 5–56). In small pressure systems, the entire flow

Figure 5–56

Schematic of dissolved-air flotation systems: (a) without recycle in which the entire flow is passed through the pressurizing tank and (b) with recycle in which only the recycle flow is pressurized. The pressurized flow is mixed with the influent before being released into the flotation tank.



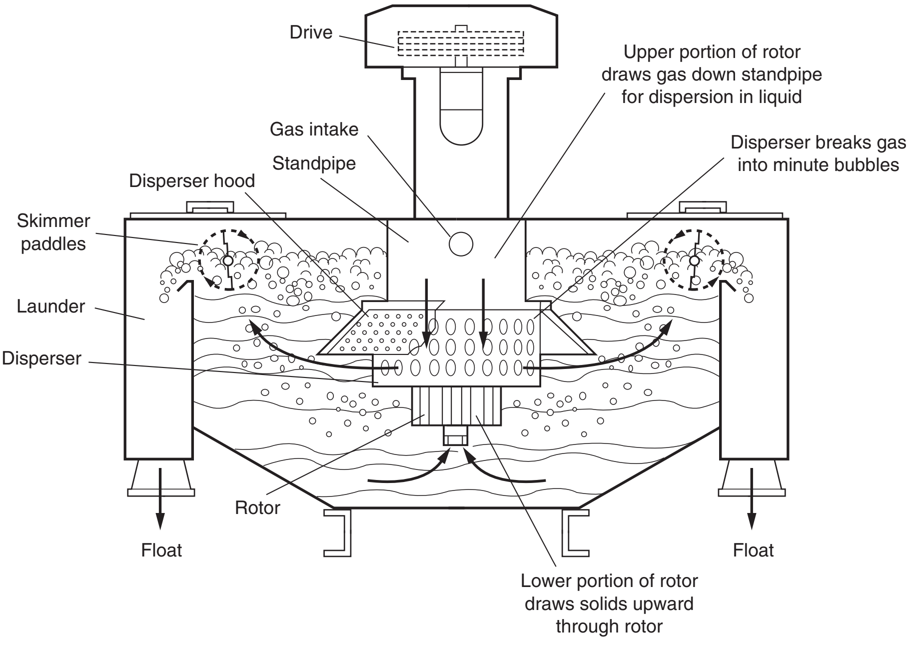
may be pressurized by means of a pump to 275 to 350 kPa (40 to 50 $lb_f/in.^2$ gage) with compressed air added at the pump suction [see Fig. 5–56(a)]. The entire flow is held in a retention tank under pressure for several minutes to allow time for the air to dissolve. It is then admitted through a pressure-reducing valve to the flotation tank, where the air comes out of solution in very fine bubbles.

In the larger units, a portion of the DAF effluent (15 to 120 percent) is recycled, pressurized, and semisaturated with air [see Fig. 5–56(b)]. The recycled flow is mixed with the unpressurized main stream just before admission to the flotation tank, with the result that the air comes out of solution in contact with particulate matter at the entrance to the tank. Pressure types of units have been used mainly for the treatment of industrial wastes and for the concentration of solids.

Dispersed-Air Flotation. Dispersed-air (sometimes referred to as induced-air) flotation is seldom used in municipal wastewater treatment, but it is used in industrial applications for the removal of emulsified oil and suspended solids from high-volume waste or process waters. In dispersed-air flotation systems, air bubbles are formed by introducing the gas phase directly into the liquid phase through a revolving impeller. The spinning impeller acts as a pump, forcing fluid through disperser openings and creating a vacuum in the standpipe (see Fig. 5–57). The vacuum pulls air (or gas) into the standpipe and thoroughly mixes it with the liquid. As the gas/liquid mixture travels through the disperser, a mixing force is created that causes the gas to form very fine bubbles. The liquid moves through a series of cells before leaving the unit. Oil particles and suspended solids attach to the bubbles as they rise to the surface. The oil and suspended solids gather in dense froth at the surface and are removed by skimming paddles. The advantages of a dispersed-air flotation system are (1) compact size, (2) lower capital cost, and (3) capacity to remove relatively free oil and suspended solids. The disadvantages of induced-air flotation include higher connected power requirements than the pressurized system, performance is dependent on strict hydraulic control, and less flocculation flexibility. The quantities of float

Figure 5–57

Dispersed-air flotation unit. Air is induced and dispersed into the liquid by pumping action of the inductors. (Courtesy of Eimco.)



skimmings are significantly higher than the pressurized unit: 3 to 7 percent of the incoming flow as compared to less than 1 percent for dissolved-air systems (Eckenfelder, 2000).

Chemical Additives. Chemicals are commonly used to aid the flotation process. These chemicals, for the most part, function to create a surface or a structure that can easily absorb or entrap air bubbles. Inorganic chemicals, such as the aluminum and ferric salts and activated silica, can be used to bind the particulate matter together and, in so doing, create a structure that can easily entrap air bubbles. Various organic polymers can be used to change the nature of either the air-liquid interface or the solid-liquid interface, or both. These compounds usually collect on the interface to bring about the desired changes.

Design Considerations for Dissolved-Air Flotation Systems

Because flotation is very dependent on the type of surface of the particulate matter, laboratory and pilot-plant tests should be performed to yield the necessary design criteria. Factors that must be considered in the design of flotation units include the concentration of particulate matter, quantity of air used, the particle-rise velocity, and the solids loading rate. In the following analysis, dissolved-air flotation is discussed because it is the method most commonly used.

The performance of a dissolved-air flotation system depends primarily on the ratio of the volume of air to the mass of solids (A/S) required to achieve a given degree of clarification. The ratio will vary with each type of suspension and must be determined experimentally using a laboratory flotation cell. A typical laboratory flotation cell is shown on Fig. 5–58. Procedures for conducting the necessary tests may be found in Higbie (1935), WEF (1988c), and Edzwald and Haarhoff (2012). Typical A/S ratios encountered in the thickening of solids and biosolids in wastewater treatment plants vary from about 0.005 to 0.060.

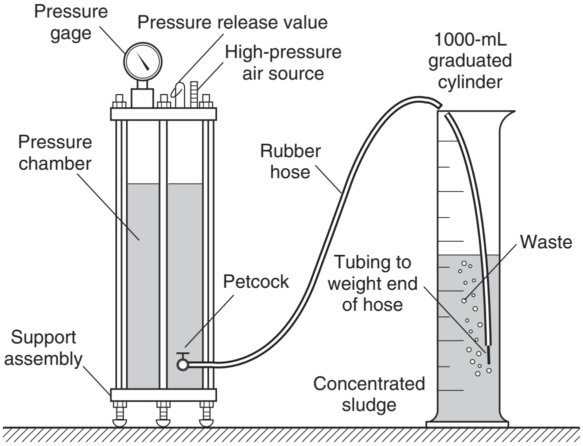
The relationship between the A/S ratio and the solubility of air, the operating pressure, and the concentration of solids for a system in which all the flow is pressurized is given in Eq. (5–47).

$$\frac{A}{S} = \frac{1.3 s_a (fP - 1)}{S_a} \tag{5–47}$$

where A/S = air to solids ratio, mL air/mg solids
s_a = air solubility, mL/L
f = fraction of air dissolved at pressure P, usually 0.5

Figure 5–58

Schematic of dissolved-air flotation test apparatus.



P = pressure, atm

$$= \frac{p + 101.35}{101.35} \text{ (SI units)}$$

$$= \frac{p + 14.7}{14.7} \text{ (U.S. customary units)}$$

p = gage pressure, kPa ($\text{lb}_\text{f}/\text{in.}^2$ gage)
S_a = influent suspended solids, g/m^3 (mg/L)

Temp., °C	0	10	20	30
s_a, mL/L	29.2	22.8	18.7	15.7

The corresponding equation for a system with only pressurized recycle is

$$\frac{A}{S} = \frac{1.3 s_a (fP - 1)R}{S_a Q} \tag{5–48}$$

where R = pressurized recycle, m^3/d (Mgal/d)
Q = mixed-liquor flow, m^3/d (Mgal/d)

In both of the foregoing equations, the numerator represents the weight of air and the denominator the weight of the solids. The factor 1.3 is the weight in milligrams of 1 mL of air and the term (1) within the brackets accounts for the fact that the system is to be operated at atmospheric conditions. The use of these equations is illustrated in Example 5–11. Additional information of the theory and application of flotation may be found in Eckenfelder (2000) and Edzwald and Haarhoff (2012).

The required area of the thickener is determined from a consideration of the rise velocity of the solids, 8 to 160 L/m²·min (0.2 to 4.0 gal/min·ft²), depending on the solids concentration, degree of thickening to be achieved, and the solids loading rate (see Table 14–20).

EXAMPLE 5–11 **Flotation Thickening of Activated-Sludge Mixed Liquor** Design a flotation thickener without and with pressurized recycle to thicken the solids in activated-sludge mixed liquor from 0.3 to about 4 percent. Assume that the following conditions apply:

1. Optimum A/S ratio = 0.008 mL/mg
2. Temperature = 20°C
3. Air solubility = 18.7 mL/L
4. Recycle-system pressure = 275 kPa
5. Fraction of saturation = 0.5
6. Surface-loading rate = 8 L/m²·min
7. Sludge flowrate = 400 m³/d

Solution (without recycle)

1. Compute the required pressure using Eq. (5–47).

$$\frac{A}{S} = \frac{1.3 s_a (fP - 1)}{S_a}$$

$$0.008 \text{ mL/mg} = \frac{1.3(18.7 \text{ mL/L})(0.5P - 1)}{(3000 \text{ mg/L})}$$

$$0.5\,P = 0.99 + 1$$

$$P = 3.98\ \text{atm} = \frac{p + 101.35}{101.35}$$

$$p = 302\ \text{kPa}\ (43.8\ \text{lb}_f/\text{in.}^2\text{gage})$$

2. Determine the required surface area.

$$A = \frac{(400\ \text{m}^3/\text{d})(10^3\ \text{L}/1\ \text{m}^3)}{(8\ \text{L/m}^2 \cdot \text{min})(1440\ \text{min/d})} = 34.7\ \text{m}^2$$

3. Check the solids loading rate.

$$\text{kg/m}^2 \cdot \text{d} = \frac{(400\ \text{m}^3/\text{d})(3000\ \text{g/m}^3)}{(34.7\ \text{m}^2)(10^3\ \text{g}/1\ \text{kg})} = 34.6\ \text{kg/m}^2$$

Solution (with recycle)

1. Determine pressure in atmospheres.

$$P = \frac{275 + 101.35}{101.35} = 3.73\ \text{atm}$$

2. Determine the required recycle rate using Eq. (5–48).

$$\frac{A}{S} = \frac{1.3 s_a (fP - 1)R}{S_a Q}$$

$$0.008\ \text{mL/mg} = \frac{1.3(18.7\ \text{mL/L})[0.5(3.73) - 1]R}{(3000\ \text{mg/L})(400\ \text{m}^3/\text{d})}$$

$$R = 461.9\ \text{m}^3/\text{d}$$

3. Determine the required surface area.

$$A = \frac{(461.9\ \text{m}^3/\text{d})(10^3\ \text{L/m}^3)}{(8\ \text{L/m}^2 \cdot \text{min})(1440\ \text{min/d})} = 40.1\ \text{m}^2$$

Comment Alternatively, the recycle flowrate could have been set and the pressure determined. In an actual design, the costs associated with the recycle pumping, pressurizing systems, and tank construction can be evaluated to find the most economical combination.

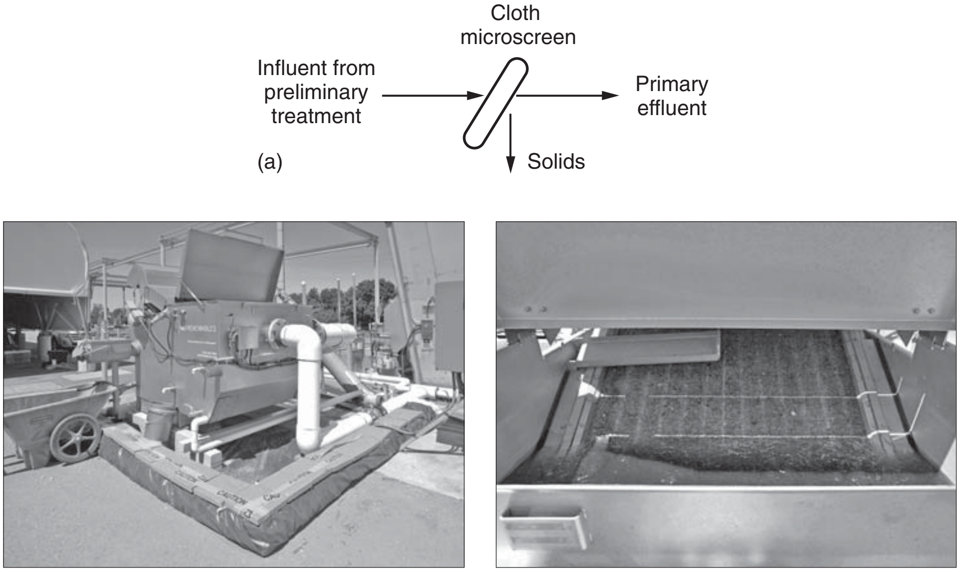
5–9 NEW APPROACHES FOR PRIMARY TREATMENT

In addition to the well-established physical treatment processes, as described previously in this chapter, a number of other physical processes have been or are being tested for various primary treatment applications. Three processes which have been demonstrated successfully are introduced in the following discussion. Those processes are (1) microscreening of raw wastewater, (2) charged bubble flotation, and (3) primary effluent filtration.

Given the current emphasis on energy conservation and recovery, three applications for these technologies are as follows. The first application is for the reduction of the organic loading rate to the biological treatment process to reduce the energy requirement for the oxidation of the carbonaceous organic material. The solids removed would be sent to the solids processing facility, most commonly to an anaerobic digester for the recovery of energy. In the second application, these technologies would be used to achieve load equalization to the biological treatment process by diverting organic material during peak energy demand periods and shifting the load to the early morning hours. In the third

Figure 5–59

Cloth screen used for the filtration of untreated wastewater: (a) schematic, (b) view of cloth screen filter unit with front cover open, and (c) excess water being removed by gravity from solids accumulated on the belt.



(b)

(c)

application, the diverted organic matter could be sent to a fermenter for the production of volatile fatty acids, which in turn could be used for phosphorus removal.

Microscreening of Raw Wastewater

Two cloth screens have been developed that can be used to filter raw wastewater following the removal of coarse solids. Views of a typical screen are shown on Fig. 5–59. Operationally, as shown on Fig. 5–59(a) untreated wastewater is introduced above the rotating screen which moves up the incline. Initially, when the clean screen comes in contact with the wastewater, the filtration rate is essentially the same as the clean water filtration rate. As the screen moves upward along the incline, the solids accumulate and auto-filtration (i.e., the removed solids form a filter) occurs in addition to screening. As the screen moves out of the water, excess water is removed gravimetrically [see Fig. 5–59(c)].

The partially dewatered accumulated solids are removed as the screen passes over the upper roller. Depending on the nature of the raw wastewater, water jets, located above the upper roller, are used to enhance the removal of the accumulated solids. The solids removed from the roller can be processed further (e.g., thickened) or fed to a digester directly. The performance data for the removal of BOD (25 to 35 percent) and TSS (60 to 70 percent) are similar to or somewhat better than that achieved with primary sedimentation. The fact that the screen alters the particle size distribution of the solids to be treated and the small footprint are significant relative to conventional primary clarification.

Charged Bubble Flotation

The principal components of the charged bubble flotation (CBF) process are illustrated on Fig. 5–60. The CBF process uses an externally generated suspension of micron-sized (about 7 to 50 μm) bubbles in water, achieving 40 to 50 percent volumetric air content. Each of the bubbles is coated (encapsulated) with a thin soap film made from an electrically charged surfactant, either anionic or cationic depending on the application. The charged bubbles provide a large interfacial area for the absorption of charged and hydrophobic molecules

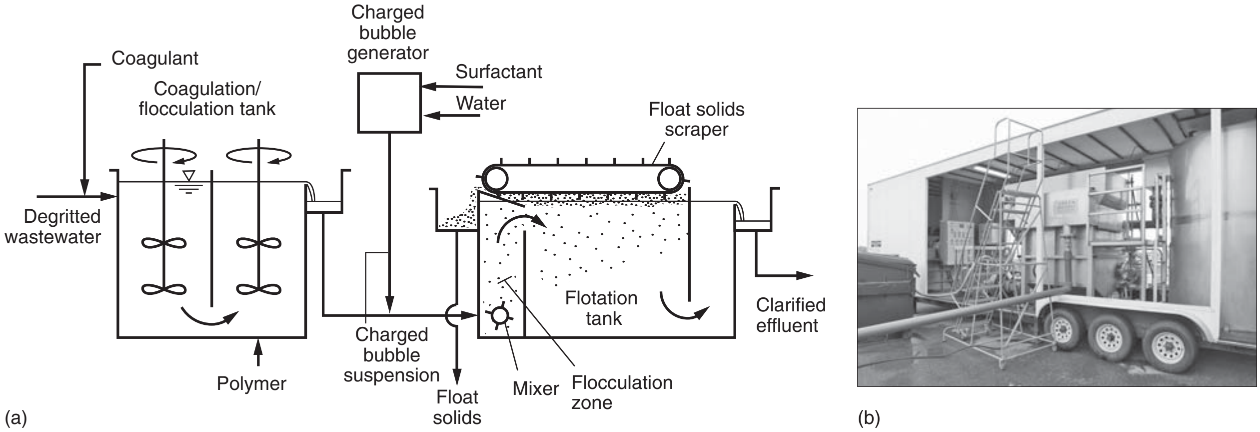


Figure 5–60

Charged bubble flotation process: (a) schematic flow diagram and (b) view of trailer mounted pilot-scale test unit.

(Jauregi and Varley, 1999). In the literature, these micron-sized bubbles in suspension have been called *colloidal gas aphrons,* a term coined by the inventor (Sebba, 1987). Because the air bubbles are charged, they do not coalesce and are attracted readily to oppositely charged flocculated wastewater solids. For the flotation of screened raw wastewater, a coagulant and polymer are used, as the natural charge density of the solids is too low for effective flotation with CBF.

Operationally, coagulant is dosed to the wastewater and conditioned for a few minutes. Polymer and charged bubble suspension are then introduced in the flocculation chamber in the flotation tank where they are contacted with the solids in the wastewater. The flocculated wastewater is introduced into the flotation tank where the float rises to the surface and is removed by skimming, and the clarified underflow passes underneath a baffle and over a weir into a launder. Typical performance data for the removal of BOD and TSS from raw wastewater are 50 to 70 and 70 to 99 percent, respectively, depending on the type of conditioning chemicals used and the corresponding dosages.

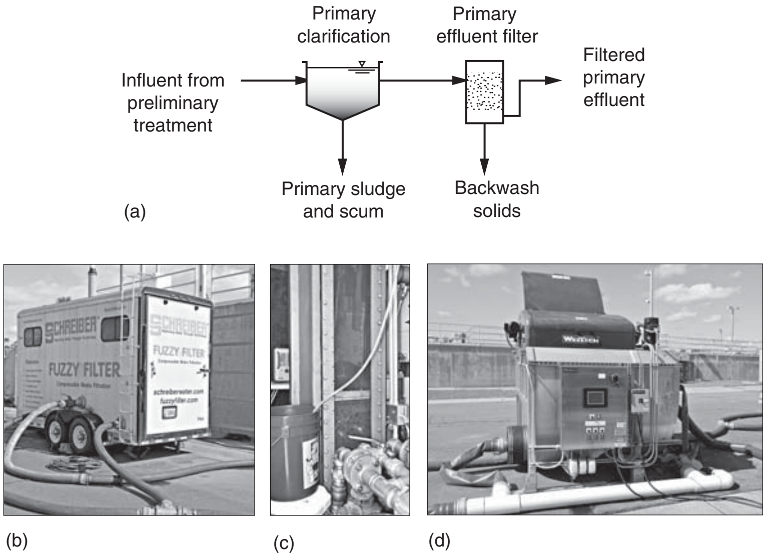
The CBF process, used for screened raw wastewater, can replace three unit processes: grit removal (except for the largest and densest particles), primary clarification, and primary scum handling. The CBF process can also be employed as an alternative to chemically enhanced primary clarification or primary effluent filtration. Other applications for the CBF process are in secondary clarification, waste activated sludge thickening, clarification of algae-laden waters (especially as pretreatment for tertiary filtration), and digested sludge thickening. The principal advantages of the CBF process include smaller footprint (less than one-fifth the size of a conventional primary clarifier), low power requirement, the ability to handle high concentrations of suspended solids (up to 15,000 mg/L), and high solids separation efficiency.

Primary Effluent Filtration

Primary effluent filtration (PEF) involves the filtering of the effluent from primary sedimentation tanks. First studied and introduced in 1980 (Matsumoto et al., 1980 and 1982; England et al., 1994) and one or more full-scale plants were built in the early 1980s. The process was effective but did not catch on because market energy costs were so low at the time that the return on investment was not favorable. More recently, the process has been

Figure 5–61

Primary effluent filtration:
(a) schematic flow diagram,
(b) and (c) view of test filters.
Information on the Schreiber and WesTech test filters can be found in Sec. 11–5 in Chap. 11.



investigated using new filter technologies including the Fuzzy Filter (compressible filter medium) and the WesTech disk cloth filter. Both filters have been tested successfully (see Fig. 5–61). Typical performance data for the removal of BOD and TSS are 25 to 35 and 45 to 75 percent, respectively. It is interesting to note that the backwash water percentage is extremely low as compared to the filtration of settled secondary effluent. The reason secondary effluent is more difficult to filter is due to the presence of extracellular polymers produced during biological treatment that are associated with the residual solids that do not settle and must be removed by filtration.

5–10 GAS LIQUID MASS TRANSFER

In the unit separation processes described in the previous sections, change is brought about by the force of gravity. There are, however, a number of important physical unit processes used for the treatment of wastewater involving the transfer of material (e.g., mass) from one phase to another, as summarized in Table 5–24. Physical unit processes such as aeration (Secs. 5–11, 8–9, and 16–4), carbon adsorption (Sec. 11–8), gas stripping (Secs. 11–8, 15–5 and 16–4), reverse osmosis (Sec. 11–6) and ion exchange (Sec. 11–10) are examples of processes that involve mass transfer. The transfer of gas to or from a liquid is introduced in this section. Following a brief history of the development of gas transfer theories, the two-film theory of gas transfer is introduced, and the basic concepts are applied to absorption and desorption of a gas from a liquid. Aeration systems are introduced in the following section.

Historical Development of Gas Transfer Theories

Over the past 50 y a number of mass transfer theories have been proposed to explain the mechanism of gas transfer across gas-liquid interfaces. The simplest and most commonly used is the two-film theory proposed by Lewis and Whitman (1924). The penetration model proposed by Higbie (1935) and the surface-renewal model proposed by Danckwerts (1951) are more theoretical and take into account more of the physical phenomena involved. The two-film theory remains popular because in more than 95 percent of the situations encountered, the results obtained are essentially the same as those obtained with the more complex theories. Even in the 5 percent where there is some disagreement between the

Table 5–24

Principal applications of mass transfer operations and processes in wastewater treatment

Type of reaction	Phase equilibria	Application
Absorption	Gas → liquid	Addition of gases to water (e.g., O_2, O_3, CO_2, Cl_2, SO_2), NH_3 scrubbing in acid
Adsorption	Gas → solid	Removal of organics with activated carbon
	Liquid → solid	Removal of organics with activated carbon, dechlorination
Desorption	Solid → liquid	Sediment scrubbing
	Solid → gas	Reactivation of spent activated carbon
Drying (evaporation)	Liquid → gas	Drying of sludges
Gas stripping (also known as desorption)	Liquid → gas	Removal of gases (e.g., CO_2, O_2, H_2S, NH_3, volatile organic compounds, NH_3 from digester supernatant)
Ion exchange	Liquid → solid	Selective removal of chemical constituents, demineralization

[a] Adapted from Crittenden, et al. (2012).

two-film theory and other theories, it is not clear which approach is more correct. Thus, the focus of the following discussion is on the two-film theory.

The Two-Film Theory of Gas Transfer

The two-film theory is based on a physical model in which two films exist at the gas-liquid interface, as shown on Fig. 5–62. Two conditions are shown on Fig. 5–62: (a) "absorption,"

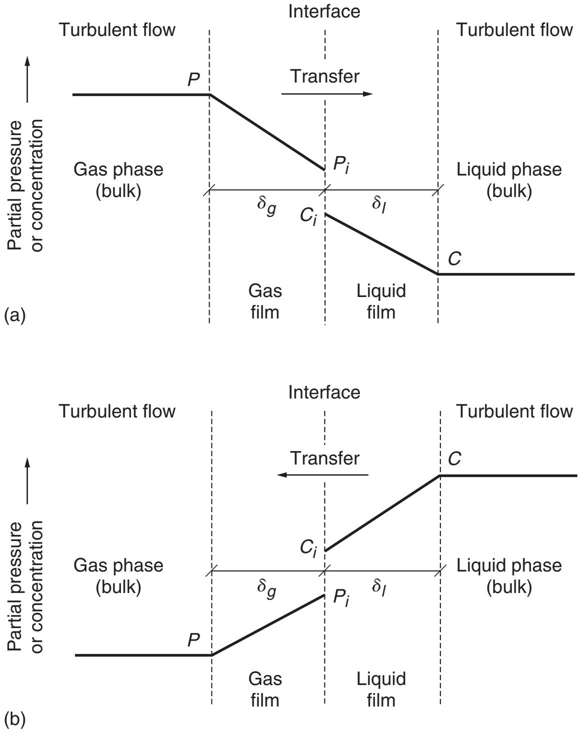


Figure 5–62

Definition sketch for the two-film theory of gas transfer: (a) absorption and (b) desorption.

in which a gas is transferred from the gas phase to the liquid phase, and (b) "desorption," in which a gas is transferred out of the liquid phase into the gas phase. The two films, one liquid and one gas, provide the resistance to the passage of gas molecules between the bulk-liquid and the bulk-gaseous phases. It is very important to note that in the application of the two-film theory, it is assumed that the concentration and partial pressure in both the bulk-liquid and bulk-gas phase are uniform (i.e., mixed completely).

Steady-State Mass Transfer. Under steady-state conditions, the rate of mass transfer of a gas through the gas film must be equal to the rate transfer through the liquid film. Using Fick's first law [Eq. (1–54)], the mass flux for each phase for absorption (gas addition) is written as follows (Lewis and Whitman, 1924):

$$r = k_G(P_G - P_i) = k_L(C_i - C_L) \tag{5–49}$$

where r = rate of mass transferred per unit area per unit time
k_G = gas film mass transfer coefficient
P_G = partial pressure of constituent A in the bulk of the gas phase
P_i = partial pressure of constituent A at the interface in equilibrium with concentration C_i of constituent A in liquid
k_L = liquid film mass transfer coefficient
C_i = concentration of constituent A at the interface in equilibrium with partial pressure P_i of constituent A in the gas
C_L = concentration of constituent A in the bulk liquid phase

It should be noted that the gas and liquid film mass transfer coefficients depend on the conditions at the interface. The terms $(P_G - P_i)$ and $(C_i - C_L)$ represent the driving force causing transfer in the gas and liquid phase, respectively. If the terms $(P_G - P_i)$ and $(C_i - C_L)$ are divided by their respective film thickness values (δ_G and δ_L), the driving force can be expressed in terms of unit thickness. Thus, the degree of mass transport can be enhanced by reducing the thickness of the film, depending on which is the controlling film.

Overall Mass Transfer Coefficients. Because it is difficult to measure the values of k_G and k_L at the interface, it is common to use overall coefficients K_G and K_L, depending on whether the resistance to mass transfer is on the gas or liquid side. If it is assumed that essentially all of the resistance to mass transfer is caused by the liquid film, then the rate of mass transfer can be defined as follows in terms of the overall liquid mass transfer coefficient:

$$r = K_L(C_s - C_L) \tag{5–50}$$

where r = rate of mass transferred per unit area per unit time
K_L = overall liquid mass transfer coefficient
C_s = concentration of constituent A at the interface in equilibrium with the partial pressure of constituent A in the bulk gas phase
C_L = concentration of constituent A in the bulk liquid phase

If the two expressions given by Eqs. (5–50) and (5–49) above are equated, the following relationship can be derived between the overall liquid mass transfer coefficient and the gas and liquid film coefficients:

$$r = K_L(C_s - C_L) = k_G(P_G - P_i) = k_L(C_i - C_L) \tag{5–51}$$

Because it was assumed that essentially all of the resistance to mass transfer is caused by the liquid film, the following relationships, based on Henry's law (see Chap. 2), must apply at the interface:

$$P_G = HC_s \quad \text{and} \quad P_i = HC_i$$

It will now be noted that the overall driving force $(C_s - C_L)$ in Eq. (5–51) can be written as

$$(C_s - C_L) = (C_s - C_i) + (C_i - C_L) \tag{5–52}$$

Substituting for P_G and P_i in Eq. (5–51) and combining Eq. (5–51) and Eq. (5–52), the following relationship is obtained where the liquid film controls the mass transfer:

$$\frac{r}{K_L} = \frac{r}{k_L} + \frac{r}{Hk_G} \quad \text{or} \quad \frac{1}{K_L} = \frac{1}{k_L} + \frac{1}{Hk_G} \tag{5–53}$$

In a similar manner it can be shown that the following relationship holds if the transfer of mass is controlled by the gas film:

$$\frac{1}{K_G} = \frac{1}{k_G} + \frac{H}{k_L} \tag{5–54}$$

The relationship between the overall liquid and gas phase transfer coefficients is

$$\frac{1}{K_L} = \frac{1}{K_G H} \tag{5–55}$$

It should be noted that in Eqs. (5–54) and (5–55) the overall transfer coefficients include the resistance to mass transfer offered by both the gas and liquid phases. The fact that the overall resistance to mass transfer is the sum of the gas and liquid phase resistances was first demonstrated by Lewis and Whitman (1924). Referring to Eq. (5–53), it is interesting to note that if the Henry's constant is large, then the liquid phase resistance will typically control the mass transfer process. For the transfer of gas molecules from the gas phase to the liquid phase, slightly soluble gases (e.g., O_2, N_2, and CO_2 in water) encounter the primary resistance to transfer from the liquid film, and very soluble gases (e.g., NH_3 in water) encounter the primary resistance to transfer from the gaseous film. Gases of intermediate solubility (e.g., H_2S in water) encounter significant resistance from both films.

Flux of a Slightly Soluble Gas. To estimate the flux of a slightly soluble gas from the gas to the liquid phase (liquid film controls transfer rate), Eq. (5–50) can be approximated by substituting C_t for C_L as follows:

$$r = K_L(C_s - C_t) \tag{5–56}$$

where r = rate of mass transferred per unit area per unit time, $ML^{-2}T^{-1}$
K_L = overall liquid mass transfer coefficient, LT^{-1}
C_t = concentration in liquid bulk phase at time t, ML^{-3}
C_s = concentration in equilibrium with gas as given by Henry's law, ML^{-3}

The corresponding rate of mass transfer per unit volume per unit time is obtained by multiplying Eq. (5–56) by the area A and dividing by the volume V.

$$r_V = K_L\frac{A}{V}(C_s - C_t) = K_La(C_s - C_t) \tag{5–57}$$

where r_V = rate of mass transfer per unit volume per unit time, $ML^{-3}T^{-1}$
K_La = volumetric mass transfer coefficient, T^{-1}
A = area through which mass is transferred, L^2
V = volume in which constituent concentration is increasing, L^3
a = interfacial area for mass transfer per unit volume, A/V, L^{-1}

The term K_La, known as the volumetric mass transfer coefficient, depends on water quality and the type of aeration equipment and is unique for each situation. Numerical values for K_La are usually determined experimentally (see Sec. 5–11). Equation (5–57) is the basic relationship used in solving problems involving the addition of oxygen to water as in aeration, the removal of volatile organics from wastewater by bubbling air through the wastewater, and for the stripping of dissolved constituents such as ammonia from digested supernatant.

Absorption of Gases Under Turbulent Conditions

The application of the gas-liquid mass transfer relationship developed above will be illustrated by considering the absorption of a gas in a turbulent liquid (see Fig. 5–63a). Consider, for example, a storage basin open to the atmosphere with surface area *A* and depth *h*. If the concentration of dissolved oxygen in the basin is initially undersaturation, how long would it take for the oxygen concentration to increase by a given amount? The approach to this mass transfer problem can be outlined as follows.

First, a mass balance is written for the open basin as follows:

1. General word statement:

$$\begin{array}{c} \text{Rate of accumulation} \\ \text{of a gas within the} \\ \text{system boundary} \end{array} = \begin{array}{c} \text{rate of flow of} \\ \text{a gas into the} \\ \text{system boundary} \end{array} - \begin{array}{c} \text{rate of flow of} \\ \text{a gas out of the} \\ \text{system boundary} \end{array} + \begin{array}{c} \text{amount of gas} \\ \text{absorbed through} \\ \text{system boundary} \end{array} \quad (5\text{–}58)$$

2. Simplified word statement:

$$\text{Accumulation} = \text{inflow} - \text{outflow} + \text{increase due to absorption} \quad (5\text{–}59)$$

3. Symbolic representation at equilibrium (refer to Fig. 5–62a):

$$\frac{dC}{dt}(V) = 0 - 0 + r_V V \quad (5\text{–}60)$$

where dC/dt = change in concentration with time, $\text{ML}^{-3}\text{T}^{-1}$, ($\text{g/m}^3\cdot\text{s}$)
V = volume in which constituent concentration is increasing, L^3, (m^3)
r_V = mass of constituent transferred per unit volume per unit time, $\text{ML}^{-3}\text{T}^{-1}$, ($\text{g/m}^3\cdot\text{s}$)

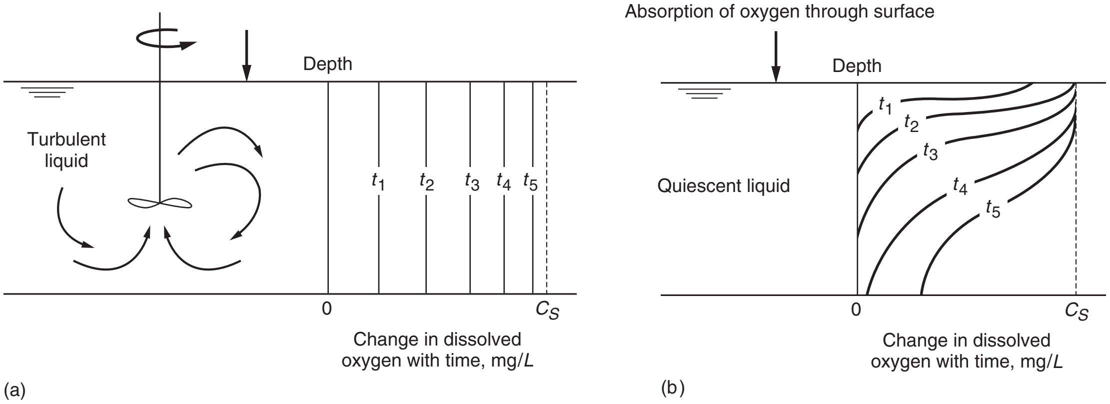

Figure 5–63

Definition sketch for the absorption of a gas: (a) under turbulent conditions where the concentration of gas in the gaseous and liquid phases is uniform and (b) under quiescent conditions. (Adapted from Tchobanoglous and Schroeder, 1985.)

Using Eq. (5–57) to describe the mass transfer through the surface of the basin, Eq. (5–60) can be written as follows, which is the same as Eq. (5–57):

$$\frac{dC}{dt} = K_L a(C_s - C_t) \tag{5–61}$$

Integrating Eq. (5–61) between the limits of $C = C_o$ and $C = C_t$ and $t = 0$ and $t = t$, where C_o is the initial concentration and C_t is the concentration at some time t

$$\int_{C_o}^{C_t} \frac{dC}{C_s - C_t} = K_L a \int_0^t dt \tag{5–62}$$

yields

$$\frac{C_s - C_t}{C_s - C_o} = e^{-(K_L a)t} \tag{5–63}$$

In Eq. (5–63), the term $(C_s - C_t)$ represents, as noted above, the degree of undersaturation at any time t and the term $(C_s - C_o)$ represents the initial degree of undersaturation. The application of Eq. (5–63) is illustrated in Example 5–12.

EXAMPLE 5–12 **Time Required to Absorb a Gas** Dechlorinated secondary effluent is placed in a storage basin until needed for reuse. If the initial dissolved oxygen concentration is 1.5 mg/L, estimate the time required for the dissolved oxygen concentration to increase to 8.5 mg/L due to surface reaeration assuming the water in the storage basin is circulated and not stagnant. Assume the K_L value for oxygen is equal to 0.03 m/h. The surface area of the storage basin is 400 m^2 and the depth is 3 m. Assume the temperature is 20°C and that the saturation value for DO is 9.09 (see Appendix E).

Solution

1. The time required for the concentration of oxygen to be increased from 1.5 to 8.5 can be estimated using Eq. (5–63).

   $$\frac{C_s - C_t}{C_s - C_o} = e^{-(K_L a)t}$$

   a. The oxygen saturation value from Example 2–6 is 9.09 mg/L.
   b. Solve for the term $(K_L a)t$.

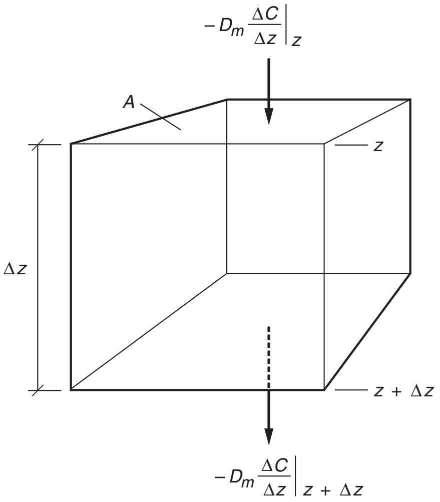
   $$\ln\left(\frac{9.09 - 8.5}{9.09 - 1.5}\right) = -2.55 = -(K_L a)t$$

2. The time required is
   a. The value for a, the interfacial area for mass transfer per unit volume:
   $a = A/V = 400\ \text{m}^2/(400\ \text{m}^2 \times 3\ \text{m}) = 0.33/\ \text{m}$
   b. Solve for t.
   $t = 2.55/[(0.03\ \text{m/h})(0.33\ /\text{m})] = 257\ \text{h} = 10.7\ \text{d}$

Comment The importance of the surface area exposed to the atmosphere is illustrated in this example. The larger the surface area relative to the depth, the greater the rate of oxygen transfer. In biological wastewater treatment either many small gas bubbles, released at the bottom of a reactor, are used to transfer oxygen to the active biomass or small droplets of water containing the active biomass are sprayed into the atmosphere to maximize the rate of oxygen transfer.

Figure 5–64

Definition sketch for the absorption of a gas under quiescent conditions due to molecular diffusion.



Absorption of Gases Under Quiescent Conditions

The transfer of a slightly soluble gas into a liquid under quiescent conditions (see Fig. 5–63b) occurs as a result of molecular diffusion. Applying the materials-balance approach to the control volume shown on Fig. 5–64, the quiescent transfer of a gas across the open surface can be modeled as follows:

First, a mass balance is written for the open basin as follows:

1. General word statement:

$$\begin{array}{c} \text{Rate of accumulation} \\ \text{of a gas within} \\ \text{the system boundary} \end{array} = \begin{array}{c} \text{rate of diffusion} \\ \text{of a gas into the} \\ \text{system boundary} \end{array} - \begin{array}{c} \text{rate of diffusion} \\ \text{of gas out of the} \\ \text{system boundary} \end{array} \tag{5–64}$$

2. Simplified word statement:

$$\text{Accumulation} = \text{inflow} - \text{outflow} \tag{5–65}$$

3. Symbolic representation at equilibrium (refer to Fig. 5–63):

$$\frac{\partial C}{\partial t}(A\Delta z) = -D_m A \frac{\Delta C}{\Delta z}\bigg|_z + D_m A \frac{\Delta C}{\Delta z}\bigg|_{z+\Delta z} \tag{5–66}$$

where $\partial C/\partial t$ = change in concentration per unit time, $ML^{-3}T^{-1}$, (g/m³·s)
A = surface area through which mass is transferred, L^2,(m²)
Δz = distance in z direction, L, (m)
D_m = coefficient of molecular diffusion, L^2T^{-1},(m²/s)
$\Delta C/\Delta z$ = change in concentration with distance, $ML^{-3}L^{-1}$, (g/m³·s)

Taking the limit as Δz approaches zero yields

$$\frac{\partial C}{\partial t} = D_m A \frac{\partial^2 C}{\partial z^2} \tag{5–67}$$

Equation (5–67) is also known as Fick's second law of diffusion (Crank, 1957). Typical values for the coefficient of molecular diffusion for gases of low solubility are reported in Table 5–25. It should be noted that the mechanism of adsorption of moderately soluble gases in water was studied extensively by Lewis and Whitman (1924), mentioned

Table 5–25

Approximate coefficients of molecular diffusion and coefficients of diffusion for gases of low solubility in water at 20°C[a]

Gas	Coefficient of molecular diffusion, cm²/h	Gas transfer coefficient, cm/h	Estimated film thickness, cm
Oxygen, O_2	6.7×10^{-2}	$32.3 \times 1.018^{T-20}$	$\sim 2 \times 10^{-3}$
Nitrogen, N_2	6.4×10^{-2}	$34.0 \times 1.019^{T-20}$	$\sim 2 \times 10^{-3}$
Carbon dioxide, CO_2	$\sim 6.5 \times 10^{-2}$		$\sim 2 \times 10^{-3}$
Air		$32.1 \times 1.019^{T-20}$	$\sim 2 \times 10^{-3}$

[a] Adapted from Adeney and Becker (1920), Becker (1924).

previously, and by Adeney and Becker (1919), and Becker (1924) among others and that their work is still valid today. Solutions to Eq. (5–67) for a variety of boundary conditions may be found in Carlslaw and Jaeger (1947), Crank (1957), Danckwertz (1970), and Thibodeaux (1996).

Desorption (Removal) of Gases

The application of the gas-liquid mass transfer relationship for the removal of a gas from a liquid will be illustrated by considering the volatilization of a constituent from a liquid. The same approach used for the addition of a gas will be followed, but noting that for the removal of a gas from a liquid Eq. (5–61) is written as follows:

$$\frac{dC}{dt} = -K_L a(C_t - C_s) \qquad (5\text{–}68)$$

where the term $(C_t - C_s)$ represents the degree of supersaturation at any time t. If Eq. (5–68) is integrated between the limits of $C = C_s$ and $C = C_t$ and $t = 0$ and $t = t$, the integrated form of Eq. (5–68), corresponding to Eq. (5–63), for the volatilization of a gas from a supersatured liquid is given by

$$\frac{C_t - C_s}{C_o - C_s} = e^{-(K_L a)t} \qquad (5\text{–}69)$$

In Eq. (5–69), the term $(C_o - C_s)$ represents the initial degree of supersaturation. The application of Eq. (5–69) is illustrated in Example 5–13.

EXAMPLE 5–13 **Time Required for a Gas to Volatilize from a Liquid** A quantity of benzene was spilled accidentally into a treated wastewater storage basin. Estimate the time required for the concentration of benzene to drop by 50 percent from the initial concentration due to volatilization. Assume the $K_L a$ value for benzene is 0.144/h.

Solution

1. If it is assumed that the concentration of the specific volatile chemical is not common to the atmosphere, then $C_s \sim 0$, and Eq. (5–69) can be written as follows:

$$\frac{C_t}{C_o} = e^{-(K_L a)t}$$

2. Knowing the value of K_La, the time for the concentration to dissipate to one half of the initial concentration can be determined by rewriting the equation developed in Step 1 as:

$$\frac{0.5C_o}{1.0C_o} = e^{-(K_La)t_{1/2}}$$

Solving for $t_{1/2}$ yields

$$t_{1/2} = \frac{0.69h}{K_La}$$

3. Using a K_La value of 0.144 m/h for benzene, the time for 50 percent of the initial concentration to dissipate is

$$t_{1/2} = \frac{(0.69)(2\,\text{m})}{(0.144\,\text{m/h})} = 9.6\,\text{h}$$

The application of gas-liquid mass transfer is considered further in the following section on aeration systems.

5–11 AERATION SYSTEMS

The functioning of aerobic processes, such as activated sludge, biological filtration, and aerobic digestion, depends on the availability of sufficient quantities of oxygen. Because of the low solubility of oxygen in water and the consequent low rate of oxygen transfer, sufficient oxygen to meet the requirements of aerobic waste treatment does not enter water through normal surface air-water interfaces. To transfer the large quantities of oxygen that are needed, additional interfaces must be formed. Either air or oxygen can be introduced into the liquid, or the liquid in the form of droplets can be exposed to the atmosphere.

Oxygen can be supplied by mechanical devices designed to increase surface air-water interfaces or by means of submerged diffusion of air or pure-oxygen bubbles to the water to create additional gas-water interfaces. Submerged-bubble aeration is most frequently accomplished by dispersing air bubbles in the liquid at depths up to 10 m (30 ft). Mechanical devices may also be used to create smaller bubbles and more air-water interfaces by impinging a flow of liquid at an orifice to break up the air bubbles into smaller sizes. Turbine mixers may be used to disperse air bubbles introduced below the center of the turbine; they are designed both to mix the liquid in the basin and to expose it to the atmosphere in the form of small liquid droplets.

Oxygen Transfer

Commercial equipment used for oxygen transfer are rated in accordance with established test procedures using clean water and reported in terms of oxygen transfer under standard conditions. The definition of standard conditions varies among industries and geographical areas. The definition used in this textbook is defined as follows:

Standard temperature, $T_s = 20°\text{C}$ (68°F)
Standard pressure, $P_s = 1.0$ atm [101.325 kPa (14.7 $\text{lb}_f/\text{in.}^2$)]

It is important to determine the standard conditions being used for equipment rating and when dealing with foreign equipment manufacturers.

Application of Correction Factors. The actual amount of oxygen required must be obtained by applying factors to a standard oxygen requirement in clean water that reflect the effects of the wastewater (or process water) characteristic, such as the concentration of solids, salinity, surface tension, temperature, elevation, diffused depth (for diffused aeration systems), the desired oxygen operating level, and the effects of mixing intensity and basin configuration. The interrelationship of these factors is given by the following expression:

$$\text{OTR}_f = (\text{SOTR})\left[\frac{(\tau\beta\Omega C^*_{\infty 20} - C)}{C^*_{\infty 20}}\right][(\theta)^{t-20}](\alpha)(F) \tag{5–70}$$

Where: OTR_f = field oxygen transfer rate estimated for the system operating under process conditions at an average DO concentration, C, and temperature, T, kg O_2/h

SOTR = oxygen transfer rate under standard conditions (20°C, 1 atm, $C = 0$ mg/L), kg O_2/h

τ = temperature correction factor $= C^*_{\text{st}}/C^*_{\text{s20}}$

C^*_{st} = dissolved oxygen surface saturation concentration at operating temperature, mg/L (see Appendix E)

C^*_{s20} = dissolved oxygen surface saturation concentration at standard temperature (20°C), mg/L (see Appendix E)

β = relative DO saturation to clean water, typically 0.95 to 0.98.
$= C^*_{\infty\,(\text{wastewater})}/C^*_{\infty\,(\text{tap water})}$ (see following discussion)

C^*_{∞} = steady-state DO saturation concentration obtained from nonlinear regression analysis of clean water test results (also available from aeration equipment manufacturers)

Ω = pressure correction factor
$= P_b/P_s$

P_b = barometric pressure at test site, m, kPa (see Appendix B)

P_s = standard barometric pressure (1.00 atm, 10.33 m, 101.325 kPa)

$C^*_{\infty,20}$ = saturated DO value at sea level and standard temperature (20°C) for diffused aeration, mg/L. It is higher than C_{st} as it is affected by oxygen transfer from bubbles under pressure in water column. The value of $C^*_{\infty,20}$ can be estimated using the following equation (U.S. EPA, 1989):

$$C^*_{\infty 20} = C^*_{\text{s20}}\left[1 + d_e\left(\frac{D_f}{P_s}\right)\right]$$

d_e = mid-depth correction factor; may vary from 0.25–0.45 (0.40)

D_f = depth of diffusers in basin, m

C = average dissolved oxygen concentration within the entire process water volume, mg/L

θ = empirical temperature correction factor, typically 1.024 (see following discussion)

T = field temperature, °C

T_s = standard temperature, °C

α = relative oxygen transfer rate in process water versus clean water (see following discussion)
$= K_La_{f\,20(\text{wastewater})}/K_La_{20(\text{tap water})}$

F = fouling factor, typically 0.65 to 0.9 (For surface aerators, $F = 1$)

Note that the OTR_f and SOTR values given above can also be expressed as transfer efficiencies. The fouling factor F is used to account for both internal and external fouling of air diffusers. Internal fouling is caused by impurities in the compressed air, whereas external fouling is caused by the formation of biological slimes and inorganic precipitants. The oxygen necessary for the biological process can be supplied by using air or pure oxygen. Three commonly used methods to introduce oxygen into the liquid in the aeration tank are

(1) mechanical aeration, (2) injection of diffused air, and (3) injection of high-purity oxygen. The application of Eq. (5–70) for aeration in biological treatment systems is illustrated in Example 8–3 in Chap. 8.

Evaluation of Alpha (α) Correction Factor

For a given volume of water being aerated, aeration devices are evaluated on the basis of the quantity of oxygen transferred per unit of air introduced to the water for equivalent conditions (temperature and chemical composition of the water, depth at which the air is introduced, etc.). The evaluation of the oxygen transfer coefficient in clean water and wastewater is considered in the following discussion.

Oxygen Transfer in Clean Water. The accepted procedure for determining the overall oxygen transfer coefficient in clean water, as detailed in ASCE (1992), may be outlined as follows. The accepted test method involves the removal of dissolved oxygen (DO) from a known volume of water by the addition of sodium sulfite followed by reoxygenation to near the saturation level. The DO of the water volume is monitored during the reaeration period by measuring DO concentrations at several different points selected to best represent the contents of the tank. The minimum number of points, their distribution, and range of DO measurements made at each determination point are specified in the procedure (ASCE, 1992).

The data obtained at each determination point are then analyzed by a simplified mass transfer model (Eq. (5–63) given previously:

$$\frac{C_s - C_t}{C_s - C_o} = e^{-(K_L a)t}$$

where $K_L a$ = overall liquid film coefficient
C_t = concentration in liquid bulk phase at time t, mg/L
C_s = concentration in equilibrium with gas as given by Henry's law
C_o = initial concentration

Equation (5–63) is used to estimate the apparent volumetric mass transfer coefficient $K_L a$ and the equilibrium concentration C_x^*, obtained as the aeration period approaches infinity. The term C_x^* is substituted for the term C_s in Eq. (5–63). A nonlinear regression analysis is employed to fit Eq. (5–63) to the DO profile measured at each determination point during reoxygenation test period. In this way, estimates of $K_L a$ and C_x^* are obtained at each determination point. These estimates are adjusted to standard conditions and the standard oxygen transfer rate (mass of oxygen dissolved per unit time at a hypothetical concentration of zero DO) is obtained as the average of the products of the adjusted point $K_L a$ values, the corresponding adjusted point C_x^* values, and the tank volume (ASCE, 1992).

Oxygen Transfer in Wastewater. In an activated-sludge system, the $K_L a$ value can be determined by considering the uptake of oxygen by microorganisms. Typically, oxygen is maintained at a level of 1 to 3 mg/L and the microorganisms use the oxygen as rapidly as it is supplied. In equation form,

$$\frac{dC}{dt} = K_L a(C_s - C) - r_M \tag{5–71}$$

where C = concentration of oxygen in solution
r_M = rate of oxygen used by the microorganisms

Typical values of r_M vary from 2 to 7 g/d·g MLVSS (gram of mixed-liquor volatile suspended solids). If the oxygen level is maintained at a constant level, dC/dt is zero and

$$r_M = K_L a\,(C_s - C) \tag{5–72}$$

C in this case is constant also.

Values of r_M can be determined in a laboratory by using a respirometer. In this case, $K_L a$ can easily be determined as follows:

$$K_L a = \frac{r_M}{(C_s - C)} \tag{5–73}$$

Prediction of in-process oxygen transfer rates is nearly always based on an oxygen rate model. ASCE has developed standard guidelines for performing in-process tests (ASCE, 1997). The overall oxygen mass transfer coefficient $K_L a$ is usually determined in test or full-scale facilities. If pilot-scale facilities are used to determine $K_L a$ values, scale-up must be considered. The mass transfer coefficient $K_L a$ is also a function of temperature, intensity of mixing (and hence of the type of aeration device used and the geometry of the mixing chamber), and constituents in the water (Tchobanoglous and Schroeder, 1985). The effects of temperature, mixing intensity, tank geometry, and wastewater characteristics and the application of correction factors are discussed below. Determination of $K_L a$ is illustrated in Example 5–14.

Effect of Temperature on Oxygen Transfer. Temperature effects are treated in the same manner as they were treated in establishing the BOD rate coefficient (i.e., by using an exponential function to approximate the van't Hoff–Arrhenius relationship):

$$K_L a_{(T)} = K_L a_{(20°\text{C})} \theta^{T-20} \tag{5–74}$$

where $K_L a_{(T)}$ = oxygen mass transfer coefficient at temperature T, s^{-1}
$K_L a_{(20°\text{C})}$ = oxygen mass transfer coefficient at 20°C, s^{-1}

Reported values for θ vary with the test conditions. Typical θ values are in the range of 1.015 to 1.040. The θ value of 1.024 is typical for both diffused and mechanical aeration devices.

EXAMPLE 5–14 **Determination of $K_L a$ Value** The following data have been obtained from a surface aeration test. Using the data, determine the $K_L a$ value at 20°C using a linear regression analysis. The temperature of the water was 15°C.

Time, min	DO conc., mg/L
4	0.8
7	1.8
10	3.3
13	4.5
16	5.5
19	6.2
22	7.3

Solution

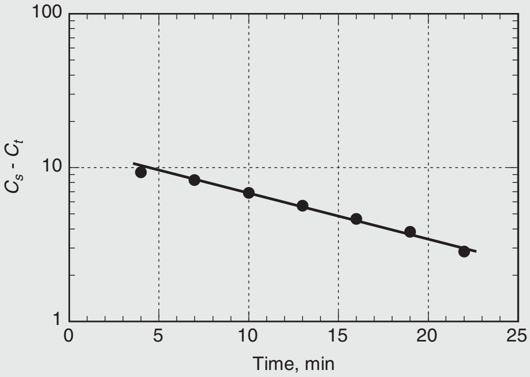
1. To analyze the field data, rewrite Eq. (5–63) in a linear form.

$$\log(C_s - C_t) = \log(C_s - C_o) - \frac{K_L a}{2.303} t$$

2. Determine $C_s - C_t$, and plot $C_s - C_t$ versus t on semilog paper.
   a. $C_{s(15°C)} = 10.08$ (see Appendix E)

Time, min	$C_s - C_t$, mg/L
4	9.28
7	8.28
10	6.78
13	5.58
16	4.58
19	3.88
22	2.78

   b. Plot $C_s - C_t$ versus t. See the following plot:



3. Determine the value of K_La at 20°C.
   a. From the plot, the value of K_La at 15°C is

$$K_La = 2.303 \frac{\log C_{t_1} - \log C_{t_2}}{t_2 - t_1}(60)$$

$$K_La = 2.303 \frac{\log 8.28 - \log 2.78}{22 - 7}(60)$$

$$K_La = 4.37/\text{h}$$

   b. The approximate value of K_La at 20°C is

$$K_La_{20} = (4.37)\ 1.024^{20-15}$$
$$= 4.92/\text{h}$$

Comment The value of K_La determined in this example is approximate because a linear regression analysis was used. To obtain a more accurate value of K_La, the nonlinear method outlined in ASCE (1992) should be used.

Effects of Mixing Intensity and Tank Geometry. Effects of mixing intensity and tank geometry are difficult to deal with on a theoretical basis but must be considered in the design process because aeration devices are often chosen on the basis of efficiency. Efficiency is strongly related to the K_La value associated with a given aeration unit. In most cases an aeration device is rated for a range of operating conditions using tap water having a low TDS concentration. A correction factor is used to estimate the K_La value in the actual system:

$$\alpha = \frac{K_La\,(\text{wastewater})}{K_La\,(\text{tap water})} \tag{5–75}$$

where alpha (α) is the correction factor. Values of α vary with the type of aeration device, the concentration of MLVSS, the basin geometry, the degree of mixing, and other wastewater characteristics, as discussed above. Values of α vary from about 0.3 to 1.2. Typical values for diffused and mechanical aeration equipment, discussed in the following section, are in the range of 0.4 to 0.8 and 0.6 to 1.2, respectively. EPA's Design Manual – Fine Pore Aeration Systems (U.S. EPA, 1989) includes α values collected during full-scale tests on fine pore aeration systems. If the basin geometry in which the aeration device is to be used is significantly different from that used to test the device, great care must be exercised in selecting an appropriate α value.

Evaluation of Beta (β) Correction Factor. The correction factor β is used to correct the test system oxygen transfer rate for differences in oxygen solubility due to constituents in the water such as salts, particulates, and surface-active substances:

$$\beta = \frac{C_s\,(\text{wastewater})}{C_s\,(\text{tap water})} \tag{5–76}$$

The ratio can vary from approximately 0.8 to 1.0 and is generally close to 1.0 for municipal wastewater. Because the ratio cannot be measured by a membrane probe and because many wastewaters contain substances that interfere with wet methods (Winkler method), it is difficult to measure accurately. For this reason the value of β is calculated as the ratio of the surface saturation DO concentration in the process water to the surface saturation DO concentration in clean water. The values given in Appendix E can be used for C_s in clean water with varying amounts of salinity and at various elevations.

Types of Aeration Systems

The various types of aeration systems used and their applications are described in Table 5–26. The principal types, diffused-air systems, mechanical aeration, and high-purity oxygen systems, are discussed in the following paragraphs. Postaeration, which is a special application for aeration, is also discussed in the latter part of this section.

Diffused-Air Aeration

The two basic methods of aerating wastewater are (1) to introduce air or pure oxygen into the wastewater with submerged diffusers or other aeration devices, or (2) to agitate the wastewater mechanically so as to promote solution of air from the atmosphere. A diffused-air system consists of diffusers that are submerged in the wastewater, header pipes, air mains, and the blowers and appurtenances through which the air passes. The following discussion covers the selection of diffusers, the design of blowers, and air piping design.

Diffusers. In the past, the various diffusion devices have been classified as either fine bubble or coarse bubble, with the connotation that fine bubbles are more efficient in transferring oxygen. The definition of terms and the demarcation between fine and coarse bubbles, however, have not been clear, but they continue to be used. The current preference is to categorize the diffused aeration systems by the physical characteristics of the

Table 5–26
Description of commonly used devices for wastewater aeration

Classification	Description	Use or application
Submerged:		
Diffused air		
Fine bubble (fine-pore system	Bubbles generated with ceramic, plastic, or flexible membranes (domes, tubes , disks, plates, or panel configurations)	All types of activated sludge processes
Coarse bubble (non-porous) system	Bubbles generated with orifices, injectors and nozzles, or shear plates	All types of activated sludge processes, channel and grit chamber aeration, and aerobic digestion
Sparger turbine	Low-speed turbine and compressed air injection	All types of activated sludge processes and aerobic digestion
Mixer/Aerator	Hyperboloid mixer rotation mixes the air in the dispersing tunnels turning it into fine bubbles by special shear fins	All types of activated sludge processes and channel aeration
Static tube mixer	Short tubes with internal baffles designed to retain air injected at bottom of tube in contact with liquid	Aerated lagoons and activated sludge processes
Jet	Compressed air injected into mixed liquor as it is pumped under pressure through jet device	All types of activated sludge processes, equalization tank mixing and aeration, and deep tank aeration
Surface:		
Low-speed turbine aerator	Large diameter turbine used to expose liquid droplets to the atmosphere	Conventional activated sludge processes, aerated lagoons, and aerobic digestion
High-speed floating aerator	Small diameter propeller used to expose liquid droplets to the atmosphere	Aerated lagoons and aerobic digestion
Aspirating	Inclined propeller assembly	Aerated lagoons
Rotor-brush or rotating disk assembly	Blades or disks mounted on a horizontal central shaft are rotated through the liquid. Oxygen is induced into the liquid by the splashing action of the rotor and by exposure of liquid droplets to the atmosphere	Oxidation ditch, channel aeration, and aerated lagoons
Cascade	Wastewater flows over a series of steps in sheet flow	Post aeration

equipment. Three categories are defined: (1) porous or fine-pore diffusers, (2) nonporous diffusers, and (3) other diffusion devices such as jet aerators, aspirating aerators, and U-tube aerators. The various types of diffused-air devices are described in Table 5–27.

Porous Diffusers. Porous diffusers are made in many shapes, the most common being discs, domes, plates, tubes, and membranes. Tubes are also used. Ceramic plates were once the most popular but are costly to install and difficult to maintain. Porous ceramic domes and discs, and membranes, discs, and tubes have largely supplanted ceramic plates in

Table 5–27

Description of commonly used air diffusion devices

Type of diffuser or device	Transfer efficiency	Description	See Fig. No.
Porous			
Disk	High	Rigid ceramic discs mounted on air distribution pipes near the tank floor	5–65(a), (c)
Dome	High	Dome-shaped ceramic diffusers mounted on air distribution pipes near the tank floor	5–65(b)
Membrane	High	Flexible porous membrane supported on disk mounted on an air distribution grid	5–65(d)
Panel	Very high	Rectangular panel with a flexible plastic perforated membrane	5–67
Nonporous			
Fixed orifice			
Orifice	Low	Devices usually constructed of molded plastic and mounted on air distribution pipes	5–68(a)
Slotted tube	Low	Stainless steel tubing containing perforations and slots to provide a wide band of diffused air	5–68(b)
Static tube	Low	Stationary vertical tube mounted on basin bottom and functions like an air lift pump	5–69(a)

newer installations (see Fig. 5–65). Several manufacturers of plate diffusers using membrane media are currently on the market.

Domes, discs, or tube diffusers are mounted on or screwed into air manifolds, which may run the length of the tank close to the bottom and along one or two sides, or short manifold headers may be mounted on movable drop pipes on one side of the tank. Dome and disc diffusers may also be installed in a grid pattern on the bottom of the aeration tank to provide uniform aeration throughout the tank (see Fig. 5–66).

Numerous materials have been used in the manufacture of porous diffusers. These materials generally fall into the categories of rigid ceramic and plastic materials and flexible plastic, rubber, or cloth sheaths. The ceramic materials consist of rounded or irregular-shaped mineral particles bonded together to produce a network of interconnecting passageways through which compressed air flows. As the air emerges from the surface pores, pore size, surface tension, and air flowrate interact to produce the bubble size. Rigid porous plastic materials are similar to the ceramic materials in that the plastics contain a number of interconnecting channels or pores through which the compressed air can pass. Thin, flexible sheaths made from soft plastic or synthetic rubber have also been developed and adapted to discs, tubes, and plates. Air passages are created by punching minute holes in the sheath material. When the air is turned on, the sheath expands and each slot acts as a variable aperture opening; the higher the air flowrate, the greater the opening.

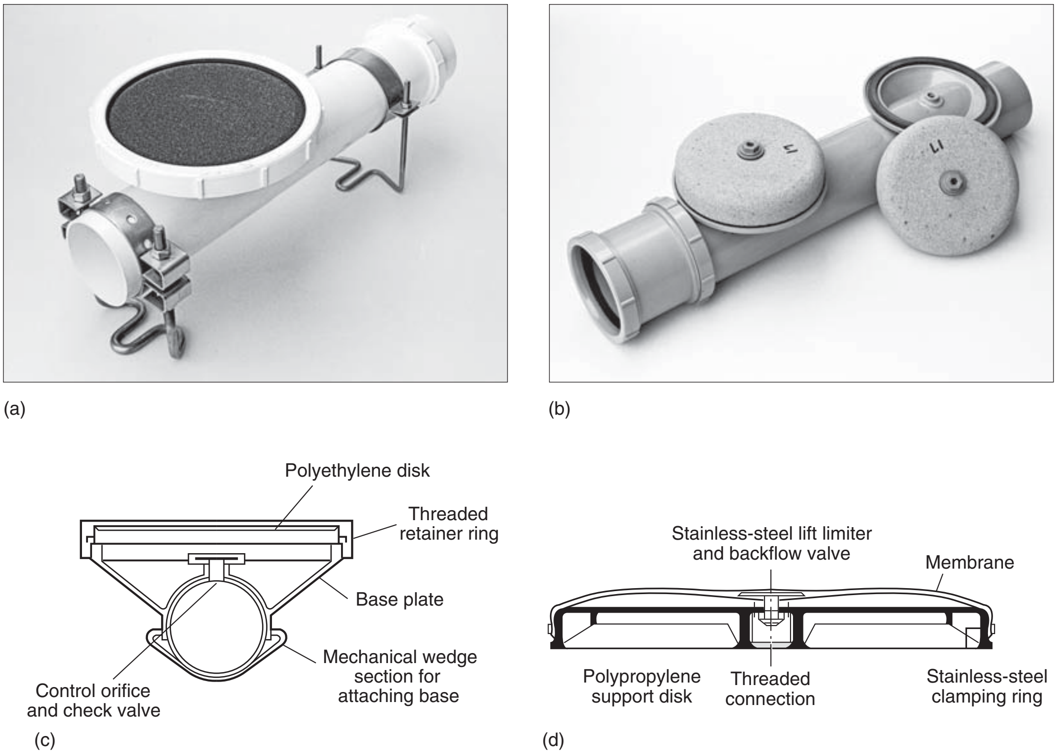


Figure 5–65

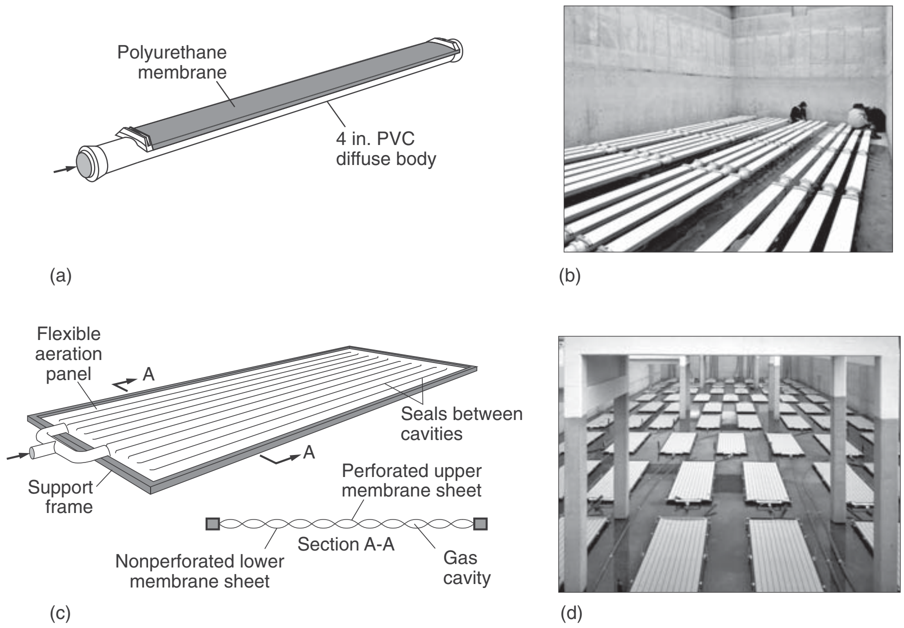
Figure 5–67

Ultra-fine pore membrane aeration devices: (a) schematic of aeration panel (adapted from Xylem Water Solutions), (b) view of aeration panels in bottom of an activated sludge reactor aeration (courtesy Xylem Water Solutions), (c) schematic of aeration panel (adapted from Parkson), and (d) view of aeration panels placed in bottom of an activated sludge reactor (courtesy of Parkson).



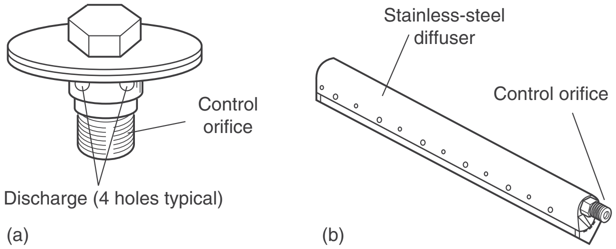
Rectangular panels or strips that use a flexible polyurethane sheet (see Fig. 5–67) are also used in activated-sludge aeration. The panels are constructed with a stainless-steel frame and are placed on or close to the bottom of the tank and anchored. Advantages cited for aeration panels are (1) ultra-fine bubbles are produced that significantly improve oxygen transfer and system energy efficiency, (2) large areas of the tank floor can be covered, which facilitates mixing and oxygen transfer, and (3) foulants can be dislodged by "bumping," i.e., increasing the airflow to flex the membrane. Disadvantages are (1) the membrane has a higher headloss, which may affect blower performance in retrofit applications, and (2) increased blower air filtration is required to prevent internal fouling.

With all porous diffusers, it is essential that the air supplied be clean and free of dust particles that might clog the diffusers. Air filters, often consisting of viscous-impingement and dry-barrier types, are commonly used. Precoated bag filters and electrostatic filters have also been used. The filters should be installed on the blower inlet.

Nonporous Diffusers. Several types of nonporous diffusers are available (see Figs. 5–68 and 5–69). Nonporous diffusers, also known as coarse bubble diffusers, produce larger bubbles than porous diffusers and consequently have lower aeration efficiency; but the advantages of lower cost, less maintenance, and the absence of stringent air-purity

Figure 5–68

Nonporous coarse bubble diffusers: (a) orifice and (b) tube.



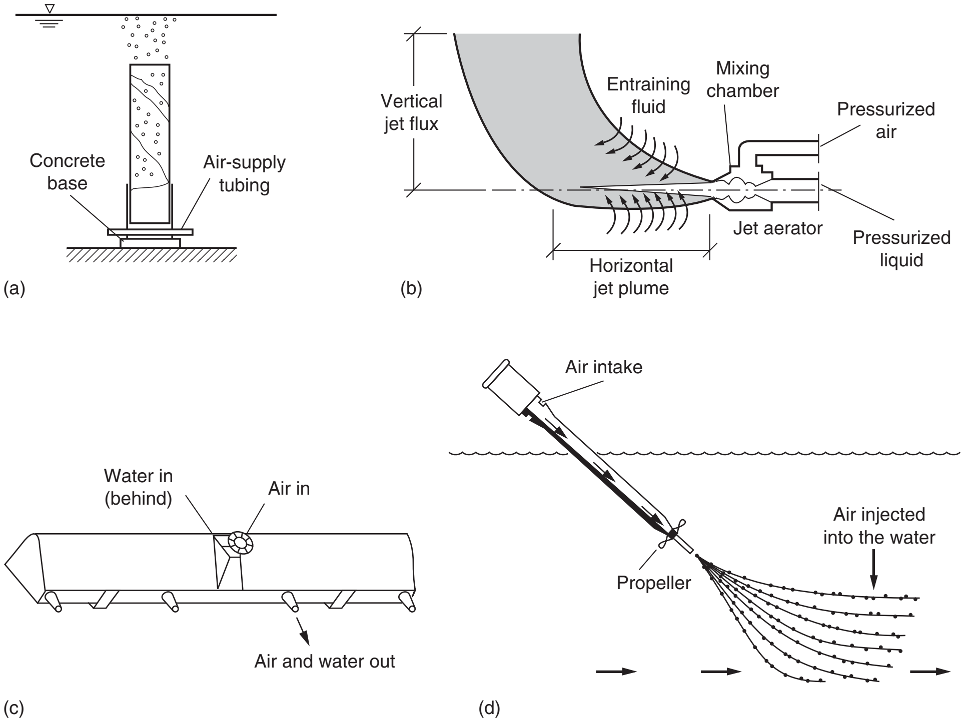


Figure 5–69

Other devices used for the transfer of oxygen: (a) static tube mixer where air is introduced at the base of the aerator that contains mixing elements, (b) jet reactor in which pressurized air and liquid are combined in a mixing chamber (as the jet is emitted, the surrounding liquid is entrained to enhance oxygen transfer), (c) jet aerator in a manifold arrangement, and (d) aspirating aerator.

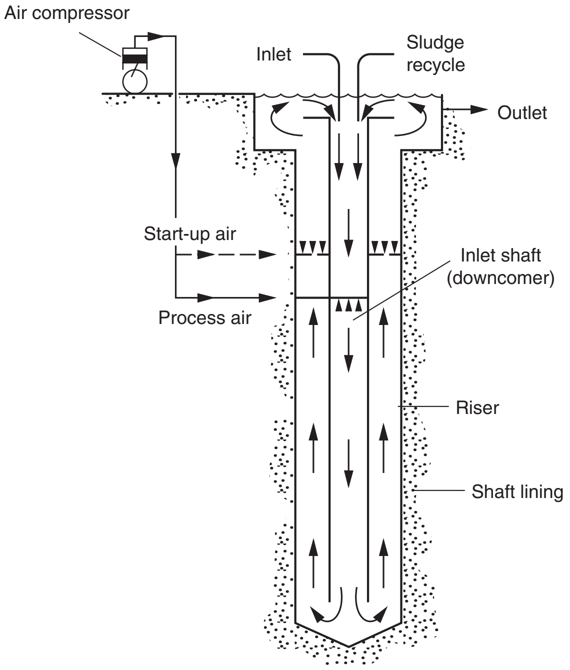
requirements may offset the lower oxygen transfer efficiency and energy cost. Typical system layouts for orifice diffusers closely parallel the layouts for porous dome and disk diffusers; however, single- and dual-roll spiral patterns using narrow- or wide-band diffuser placement are the most common. Applications for orifice and tube diffusers include aerated grit chambers, channel aeration, flocculation basin mixing, aerobic digestion, and industrial waste treatment (WEF, 1998b).

In the static tube aerator [see Fig. 5–69(a)], air is introduced at the bottom of a circular tube that can vary in height from 0.5 to 1.25 m (1.5 to 4.0 ft). Internally, the tubes are fitted with alternately placed deflection plates to increase the contact of the air with the wastewater. Mixing is accomplished because the tube aerator acts as an airlift pump. Static tubes are normally installed in a grid-type floor coverage pattern.

Other Air-Diffusion Devices. Jet aeration [see Figs. 5–69(b) and (c)] combines liquid pumping with air diffusion. The pumping system recirculates liquid in the aeration basin, ejecting it with compressed air through a nozzle assembly. This system is particularly suited for deep (8 m) tanks. Aspirating aeration [see Fig. 5–69(d)] consists of a motor-driven aspirator pump. The pump draws air in through a hollow tube and injects it underwater where both high velocity and propeller action create turbulence and diffuse the air bubbles. The aspirating device can be mounted on a fixed structure or on pontoons. U-tube aeration consists of a deep shaft that is divided into two zones (see Fig. 5–70). Air is added to the influent wastewater in the downcomer under high pressure; the mixture travels to the bottom of the tube and then back to the surface. The great depth to which the air-water mixture is subjected results in high oxygen transfer efficiencies because the high pressure forces all the oxygen into solution. U-tube aeration has particular application for high-strength wastes.

Figure 5–70

Typical schematic of a U-tube aerator.



Diffuser Performance. The efficiency of oxygen transfer depends on many factors, including the type, size, and shape of the diffuser; the air flowrate; the depth of submersion; tank geometry including the header and diffuser location; and wastewater characteristics. Aeration devices are conventionally evaluated in clean water and the results adjusted to process operating conditions through widely used conversion factors. Typical clean water transfer efficiencies and air flowrates for various diffused-air devices are reported in Table 5–28. Typically, the standard oxygen transfer efficiency (SOTE) increases with depth; the transfer efficiencies in Table 5–28 are shown for the 4.5-m (15-ft) depth, the most common depth of submergence. Data on the variation of SOTE with water depth for various diffuser types can be found in WPCF (1988). The variation of oxygen transfer efficiencies with the type of diffuser and diffuser arrangement are also illustrated in Table 5–28. Additional data on the effects of diffuser arrangement on transfer efficiency are reported in U.S. EPA (1989).

Oxygen transfer efficiency (OTE) of porous diffusers may also decrease with use due to internal clogging or exterior fouling. Internal clogging may be due to impurities in the compressed air that have not been removed by the air filters. External fouling may be due to the formation of biological slimes or inorganic precipitants. The effect of fouling on OTE is described by the term F in Eq. (5–70). The rate at which F decreases with time is designated f_F, which is expressed as the decimal fraction of OTE lost per unit time. The rate of fouling will depend on the operating conditions, changes in wastewater characteristics, and the time in service. The fouling rates are important in determining the loss of OTE and the expected frequency of diffuser cleaning. Fouling and the rate of fouling can be estimated by (1) conducting full-scale OTE tests over a period of time, (2) monitoring aeration system efficiency (see Fig. 5–71), and (3) conducting OTE tests of fouled and new diffusers.

Blowers. There are four types of blowers commonly used for wastewater aeration: single-stage centrifugal, multi-stage centrifugal, high speed turbo, and positive displacement. Centrifugal blowers [see Figs. 5–72(a) and (b)] are almost universally used where the

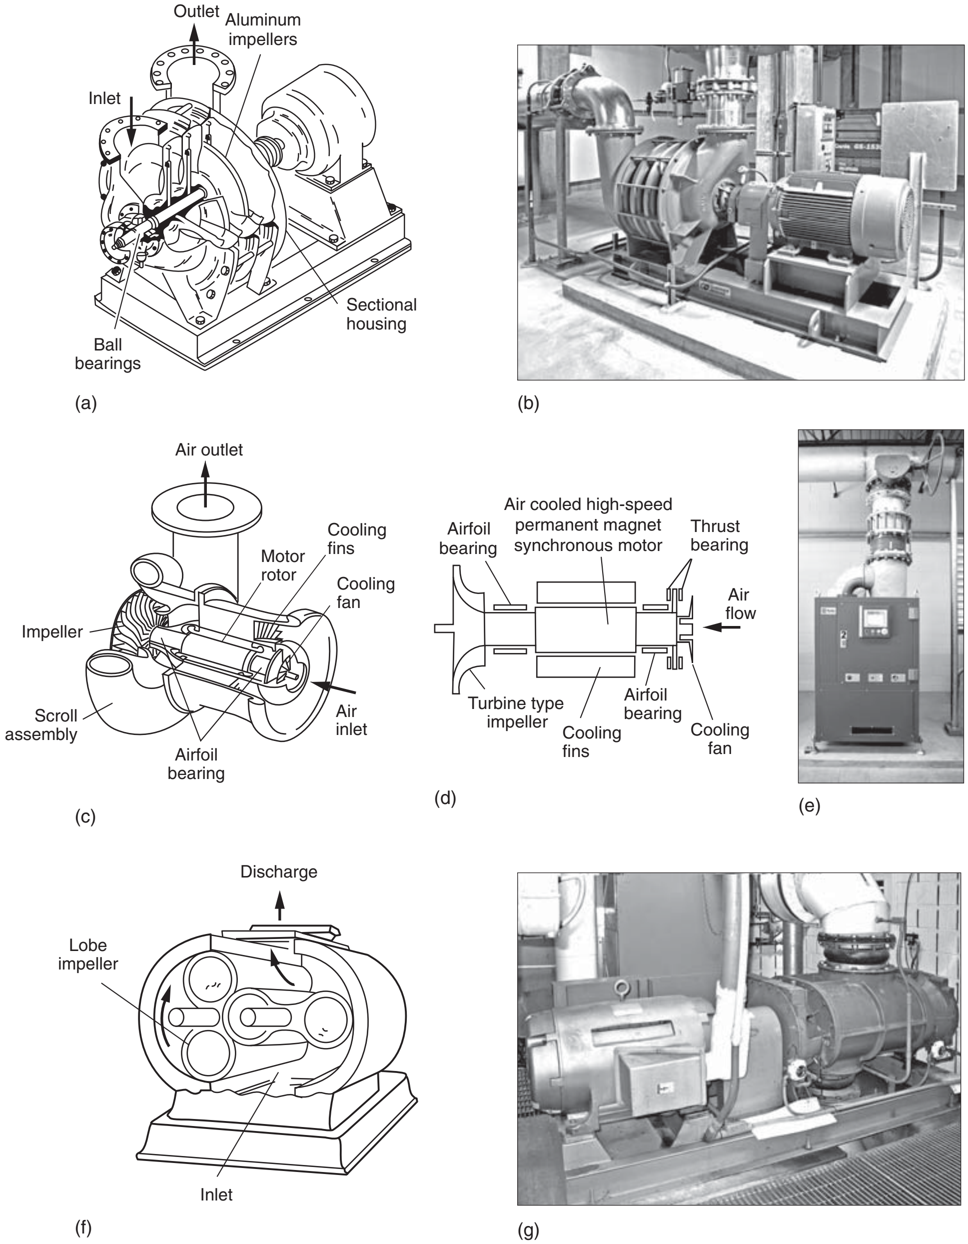
The composition of the gases trapped in the hood is analyzed to assess aeration system performance (adapted from Rosso et al., 2011) and (b) hood is moved to multiple locations in each basin to obtain average performance data.

Figure 5–72

Typical blowers used for diffused-air aeration: (a) schematic of multistage centrifugal blower, (b) view of multi-stage centrifugal blower, (c) schematic of high speed turbo blower (adapted from APG Neuros), (d) schematic cross section through high speed turbo blower (adapted from APG Neuros), (e) view of high speed turbo blower installation in self contained sound-dampening enclosure, (f) schematic of rotary-lobe positive displacement blower, and (g) view of rotary-lobe positive displacement blower.



unit capacity is greater than 425 m^3/min (15,000 ft^3/min) of free air. Rated discharge pressures range normally from 48 to 62 kN/m^2 (7 to 9 lb$_f$/in.^{2}) for single stage centrifugal blowers and as high as 138 kN/m^2 (20 lb$_f$/in.^{2}) for multistage centrifugal blowers. Centrifugal blowers have operating characteristics similar to a low-specific-speed centrifugal pump. The discharge pressure rises from shutoff to a maximum at about 50 percent of capacity and then drops off. The operating point of the blower is determined, similar to a centrifugal pump, by the intersection of the head-capacity curve and the system curve.

In wastewater treatment plants, the blowers must supply a wide range of air flowrates with a relatively narrow pressure range under varied environmental conditions. A blower usually can only meet one particular set of operating conditions efficiently. Because it is necessary to meet a wide range of air flowrates and pressures at a wastewater treatment plant, provisions have to be included in the blower system design to regulate or turn down the blowers. Methods to achieve regulation or turndown are (1) flow blowoff or bypassing, (2) inlet throttling, (3) adjustable discharge diffuser, (4) variable-speed driver, and (5) parallel operation of multiple units. Inlet throttling and an adjustable discharge diffuser are applicable only to centrifugal blowers; variable-speed drivers are more commonly used on positive-displacement blowers. Flow blowoff and bypassing is also an effective method of controlling surging of a centrifugal blower, a phenomenon that occurs when the blower operates alternately at zero capacity and full capacity, resulting in vibration and overheating. Surging occurs when the blower operates in a low volumetric range.

With greater emphasis on energy efficiency, high speed turbo blowers [see Figs. 5–72(c), (d), and (e)] are now being used for wastewater aeration applications. Using advancements in blower technology (adapted from the aircraft industry), these blowers are provided as complete packages that feature (1) aerodynamically designed impellers using turbine engine technology, (2) high speed direct-drive permanent magnet synchronous motors (PMSM) capable of speeds up to 75,000 rev/min (both air and water cooled), (3) air foil bearings that eliminate gears and contact between the stator and the drive shaft, and (4) integrated variable frequency drives. As a result, these units can operate efficiently over a wider range of operating conditions, as compared to conventional blower technologies. High speed turbo blowers are provided for capacities of up to 567 m^3/min (20,000 ft^3/min) and pressures of 103 kN/m^2 (15 lb_f/in.^{2}). Energy savings as high as 40 percent have been reported.

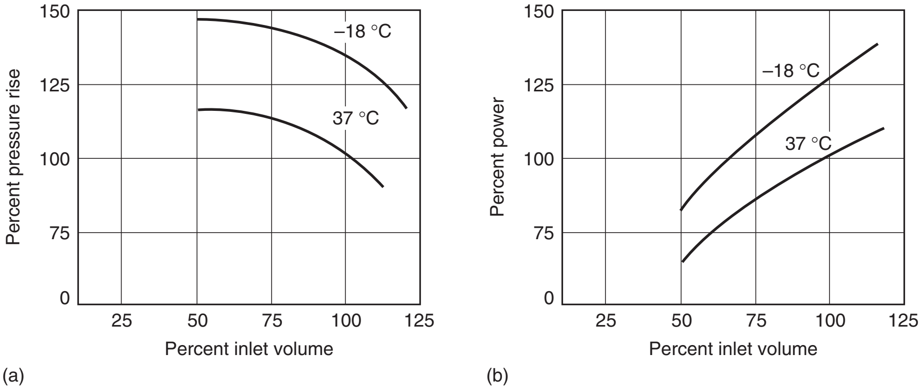
For discharge pressure applications above 55 kN/m^2 (8 lb_f/in.^{2}), for variable discharge pressure applications (such as sequencing batch reactors), and for capacities smaller than 425 m^3/min (15,000 ft^3/min) of free air per unit, rotary-lobe positive-displacement blowers are commonly used [see Figs. 5–72(f) and (g)]. The positive-displacement blower is a machine of constant capacity with variable pressure. The units cannot be throttled, but capacity control can be obtained by the use of multiple units or a variable-speed drive. Rugged inlet and discharge silencers are essential.

Blowers with inlet guide vane-variable diffusers mitigate some of the problems and considerations associated with standard centrifugal blowers. The design is based on a centrifugal blower operation that incorporates actuators to position the inlet guide vane and variable diffusers to vary blower flowrate and optimize efficiency. The blowers are especially well suited to applications with medium to high fluctuations in inlet temperature, discharge pressure, and flowrate. Blower capacities range from 85 to 1700 m^3/min (3000 to 60,000 ft^3/min) at pressures up to 170 kN/m^2 (25 lb_f/in.^{2}). Turndown rates of up to 40 percent of maximum capacity are possible without significant reduction in operating efficiency over the range of operation. Principal disadvantages are high initial cost and a sophisticated computer control system to ensure efficient operation.

The performance curve for a centrifugal blower in which pressure is plotted versus inlet air volume resembles the performance curve for a centrifugal pump. The performance curve typically is a falling-head curve where the pressure decreases as the inlet volume increases. Blowers are rated at standard air conditions, defined as a temperature of 20°C (68°F), a pressure of 760 mm Hg (14.7 lb_f/in.^{2}), and a relative humidity of 36 percent. Standard air has a specific weight of 1.20 kg/m^3 (0.0750 lb/ft^3). The air density affects the performance of a centrifugal blower; any change in the inlet air temperature and barometric pressure will change the density of the compressed air. The greater the gas density, the higher the pressure will rise. As a result, greater power is needed for the compression process (see Fig. 5–73). (Typical values for the specific weight of ambient air are presented

Figure 5–73

Characteristic curves for centrifugal blower at various inlet air temperatures: (a) pressure rise as a function inlet volume and (b) power rise as a function inlet volume.



in Appendix B.) Blowers must be selected to have adequate capacity for a hot summer day, and be provided with a driver with adequate power for the coldest winter weather. The power requirement for adiabatic compression is given in Eq. (5–77).

$$P_w = \frac{wRT_1}{28.97\,n\,e}\left[\left(\frac{p_2}{p_1}\right)^n - 1\right] \qquad \text{(SI units)} \qquad (5\text{–}77a)$$

$$P_w = \frac{wRT_1}{550\,n\,e}\left[\left(\frac{p_2}{p_1}\right)^n - 1\right] \qquad \text{(U.S. customary units)} \qquad (5\text{–}77b)$$

where P_w = power requirement of each blower, kW (hp)
w = weight of air flowrate, kg/s (lb/s)
R = universal gas constant for air, 8.314 J/mole·K (SI units)
53.3 ft·lb/(lb air)·°R (U.S. customary units)
T_1 = absolute inlet temperature, K (°R)
p_1 = absolute inlet pressure, atm ($lb_f/in.^2$)
p_2 = absolute outlet pressure, atm ($lb_f/in.^2$)
n = $(k - 1)/k$ where k is the specific heat ratio. For single-stage centrifugal blower power calculations a value of 1.395 is used for k for dry air and $n = 0.283$.
28.97 = molecular weight of dry air
550 = conversion factor from ft·lb/s to hp
e = efficiency (usual range for compressors is 0.70 to 0.90)

Air Piping. Air piping consists of mains, valves, meters, and other fittings that transport compressed air from the blowers to the air diffusers. Because the pressures are low [less than 70 kN/m^2 (10 $lb_f/in.^2$)], lightweight piping can be used.

The piping should be sized so that losses in air headers and diffuser manifolds are small in comparison to the losses in the diffusers. Typically, if headlosses in the air piping between the last flow-split device and the farthest diffuser are less than 10 percent of the headloss across the diffusers, good air distribution through the aeration basin can be maintained. Valves and control orifices are an important consideration in piping design (WEF, 1998b). Typical velocities in air piping are given in Table 5–29.

Friction losses in air piping can be calculated using the Darcy-Weisbach equation written in the following form:

$$h_L = f\frac{L}{D}h_i \qquad (5\text{–}78)$$

Table 5–29

Typical air velocities in aeration header pipes

Pipe diameter		Velocity[a]	
in.	mm	ft/min	m/min
1–3	75–225	1200–1800	360–540
4–10	100–250	1800–3000	540–900
12–24	300–600	2700–4000	800–1200
30–60	750–1500	3800–6500	1100–2000

[a] At standard conditions.

where h_L = friction loss, mm (in.) of water
f = dimensionless friction factor obtained from Moody diagram (see Appendix G) based on relative roughness. It is recommended that f be increased by at least 10 percent to allow for an increase in friction factor as the pipe ages.
L = equivalent length of pipe, m (ft)
D = pipe diameter, m (ft)
h_i = velocity head of air, mm (in.) of water

The friction factor for steel pipes carrying air can be approximated by Eq. (5–79) (McGhee, 1991).

$$f = \frac{0.029(D)^{0.027}}{Q^{0.148}} \tag{5–79}$$

where Q = airflow, m^3/min under prevailing pressure and temperature conditions
D = pipe diameter, m

Headloss in a straight pipe can be computed by substituting Eq. (5–79) in Eq. (5–78), which yields

$$h_L = 9.82 \times 10^{-8}\left(\frac{fLTQ^2}{PD}\right) \tag{5–80}$$

where P = air discharge pressure, atm
T = temperature in pipe, K [from Eq. (5–81)]

$$T = T_o(P/P_o)^n \tag{5–81}$$

where T_o = ambient air temperature, K (maximum summer air temperature)
P_o = ambient barometric pressure, atm

Losses in elbows, tees, valves, etc., can be computed as a fraction of velocity head using headloss coefficient K values given in the companion volume to this text (Metcalf & Eddy, 1981) or in standard hydraulic texts. Minor losses can also be computed as equivalent lengths of straight pipe, as follows:

$$L = 55.4\ CD^{1.2} \tag{5–82}$$

where L = equivalent length of pipe, L (m)
D = pipe diameter, L (m)
C = resistance factor (see Table 5–30)

Meter losses can be estimated as a fraction of the differential velocity head across the meter, depending on the type of meter. Losses in air filters, blower silencers, and check

Table 5–30

Resistance factors for fittings in aeration piping systems

Fitting	*C* factor
Long radius ell or run of standard tee	0.33
Medium radius ell or run of tee reduced by 25 percent	0.42
Standard ell or run of tee reduced 50 percent	0.67
Tee through side outlet	1.33
Gate valves	0.25
Globe valve	2.00
Angle valve	0.90

valves should be obtained from equipment manufacturers, but approximate values given in Table 5–31 can be used as a guide (Qasim, 1999).

The discharge pressure at the blowers will be the sum of the above losses, the depth of water over the air diffusers, and the loss through the diffusers.

Because of the high temperature of the air discharged by blowers [60 to 80°C (140 to 180°F)], condensation in the air piping is not a problem, except where piping is submerged in the wastewater. It is essential, however, that provisions be made for pipe expansion and contraction. Where porous diffusers are used, pipes must be made of nonscaling materials or must be lined with material that will not corrode. Pipe materials are often stainless steel, fiberglass, or plastics suitable for higher temperatures. Other materials used include mild steel or cast iron with external coatings (e.g., coal-tar epoxy or vinyl). Interior surfaces include cement lining or coal tar or vinyl coatings.

Mechanical Aerators

Mechanical aerators are commonly divided into two groups based on major design and operating features: aerators with vertical axis and aerators with horizontal axis. Both groups are further subdivided into surface and submerged aerators. In surface aerators, oxygen is entrained from the atmosphere; in submerged aerators, oxygen is entrained from the atmosphere and, for some types, from air or pure oxygen introduced in the tank bottom. In either case, the pumping or agitating action of the aerators helps to keep the contents of the aeration tank or basin mixed. In the following discussion, the various types of aerators will be described, along with aerator performance and the energy requirement for mixing.

Surface Mechanical Aerators with Vertical Axis. Surface mechanical aerators with a vertical axis are designed to induce either updraft or downdraft flows through

Table 5–31

Typical headlosses through air filters, blower silences, and check valves[a]

Device	Headloss	
	in.	mm
Air filter	0.5–3	13–76
Silencer		
Centrifugal blower	0.5–1.5	13–38
Positive displacement blower	6–8.5	152–216
Check valve	0.8–8	20–203

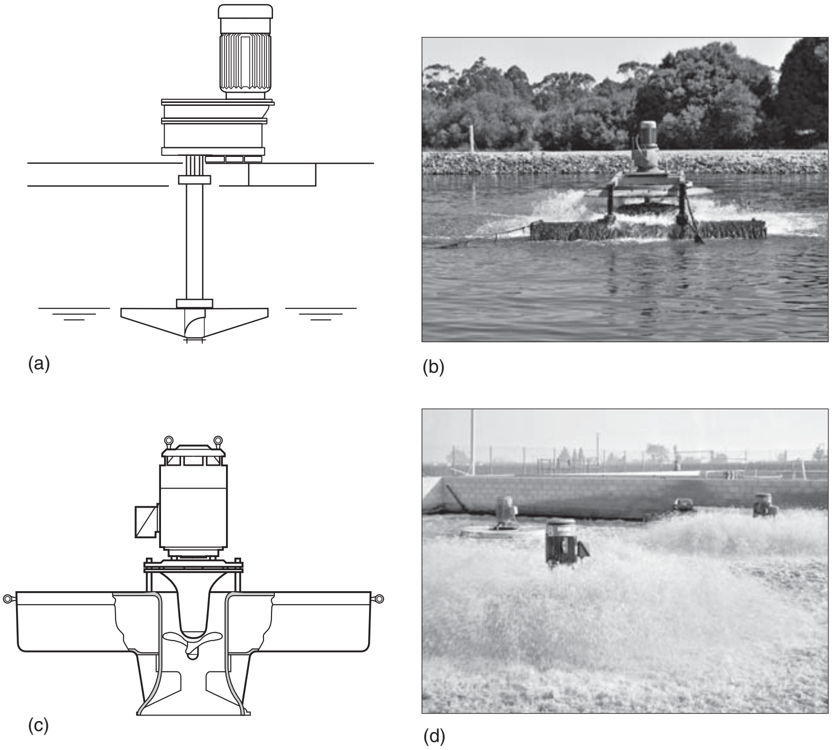
Figure 5–74

Typical mechanical aerators: (a) schematic low-speed surface aerator, (b) view of low-speed surface aerator mounted on floats used in biological treatment system, (c) schematic high-speed surface aerator, and (d) view of high-speed surface aerators in a lined earthen aerobic digester.



a pumping action (see Fig. 5–74). Surface aerators consist of submerged or partially submerged impellers that are attached to motors mounted on floats or on fixed structures. The impellers are fabricated from steel, cast iron, noncorrosive alloys, and fiberglass-reinforced plastic and are used to agitate the wastewater vigorously, entraining air in the wastewater and causing a rapid change in the air-water interface to facilitate dissolution of the air. Surface aerators may be classified according to the type of impeller used—centrifugal, radial-axial, or axial—or the speed of rotation of the impeller: low and high speed. Centrifugal impellers belong to the low-speed category; the axial-flow impeller type aerators operate at high speed. In low-speed aerators, the impeller is driven through a reduction gear by an electric motor [see Fig. 5–74(a)]. The motor and gearbox are usually mounted on a platform that is supported either by piers extending to the bottom of the tank or by beams that span the tank. Low-speed aerators may also be mounted on floats. In high-speed aerators, the impeller is coupled directly to the rotating element of the electric motor [see Fig. 5–74(c)]. High-speed aerators are almost always mounted on floats. These units were originally developed for use in ponds or lagoons where the water surface elevation fluctuates, or where a rigid support would be impractical. Surface aerators may be obtained in sizes from 0.75 to 100 kW (1 to150 hp).

Submerged Mechanical Aerators with Vertical Axis. Most surface mechanical aerators are upflow types that rely on violent agitation of the surface and air entrainment for their efficiency. With submerged mechanical aerators, however, air or pure oxygen may also be introduced by diffusion into the wastewater beneath the impeller or downflow of radial aerators [see Fig. 5–75(a)]. The impeller is used to disperse the air bubbles and mix the tank contents. A draft tube may be used with either upflow or downflow models to control the flow pattern of the circulating liquid within the aeration tank [see Fig. 5–75(b)]. The draft tube is a cylinder, usually with flared ends, mounted

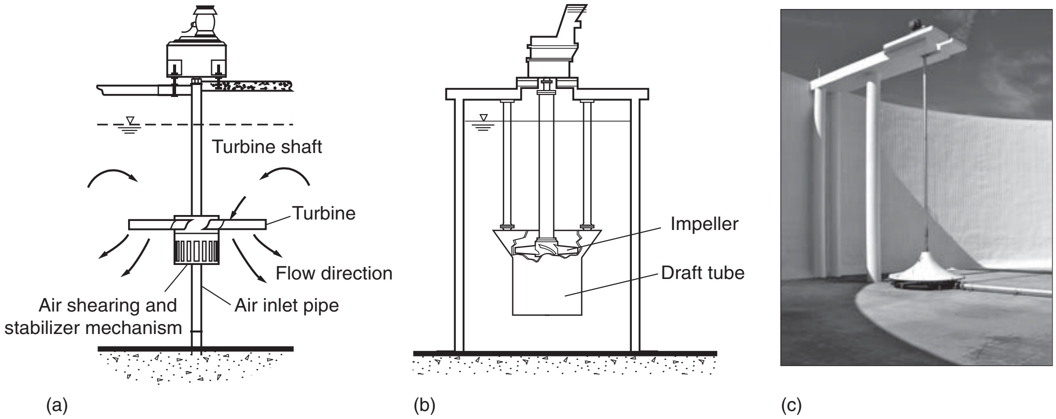


Figure 5–75

Typical submerged mechanical aerators: (a) turbine type with supplementary air or oxygen feed introduced below the turbine, (b) draft tube turbine aerator equipped with an air sparger (adapted from Philadelphia Mixer), and (c) hyperboloid mixer/aerator (courtesy of INVENT Env. Technologies, Inc.).

concentrically with the impeller. The length of the draft tube depends upon the aerator manufacturer. Submerged mechanical aerators of such type may be obtained in sizes from 0.75 to 100kW (1 to 150 hp).

The hyperboloid mixer/aerator [see Fig. 5–75(c)] is a downflow impeller with separate air or gas supply via blower or system pressure. The separation from mixing, gas dispersion and gas feed results in significantly higher efficiencies compared to self-inducing aerators. Hyperboloid mixer/aerators are available in sizes from 7.5 to 37 kW (10 to 50 hp).

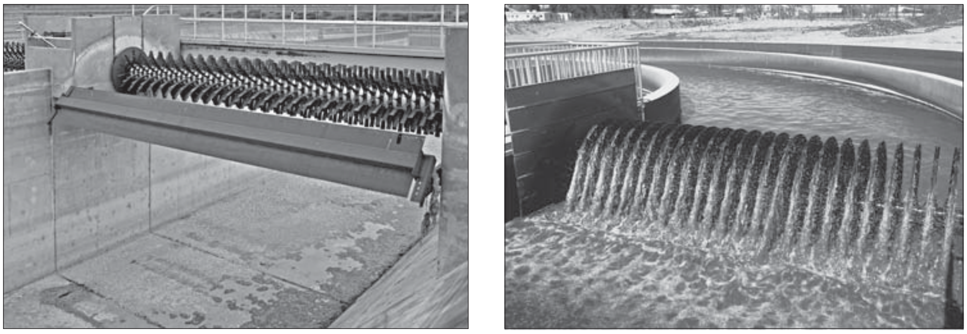
Mechanical Aerators with Horizontal Axis. Mechanical aerators with horizontal axis are divided into two groups: surface and submerged aerators. The surface aerator is patterned after the original Kessener brush aerator, a device used to provide both aeration and circulation in oxidation ditches. The brush-type aerator had a horizontal cylinder with bristles mounted just above the water surface. The bristles were submerged in the water and the cylinder was rotated rapidly by an electric motor drive, spraying wastewater across the tank, promoting circulation, and entraining air in the wastewater. Angle steel, steel of other shapes, or plastic bars or blades are now used instead of bristles. A typical horizontal-axis surface aerator is shown on Fig. 5–76.

Submerged horizontal-axis aerators are similar in principle to surface aerators except disks or paddles attached to rotating shafts are used to agitate the water. The disk aerator has been used in numerous applications for channel and oxidation ditch aeration. The disks are submerged in the wastewater for approximately one-eighth to three-eighths of the diameter and enter the water in a continuous, nonpulsating manner. Recesses in the disks introduce entrapped air beneath the surface as the disk turns. Spacing of the disks can vary depending on the oxygen and mixing requirements of the process. Typical power requirements are reported as 0.1 to 0.75 kW/disk (0.15 to 1.00 hp/disk) (WPCF, 1988).

Aerator Performance. Mechanical aerators are rated in terms of their oxygen transfer rate expressed as kilograms of oxygen per kilowatt-hour (pounds of oxygen per

Figure 5–76

Horizontal axis aerators: (a) rotary brush (also known as a Kessener brush) and (b) disk aerators.



(a) (b)

horsepower-hour) at standard conditions. Standard conditions exist when the temperature is 20°C, the dissolved oxygen is 0.0 mg/L, and the test liquid is tap water. Testing and rating are normally done under non-steady-state conditions using fresh water, deaerated with sodium sulfite. Commercial-size surface aerators range in efficiency from 1.20 to 2.4 kg O_2/kW·h (2 to 4 lb O_2/hp·h). Oxygen transfer data for various types of mechanical aerators are reported in Table 5–32. Efficiency claims for aerator performance should be accepted by the design engineer only when they are supported by actual test data for the actual model and size of aerator under consideration.

Energy Requirement for Mixing in Aeration Systems

As with diffused-air systems, the size and shape of the aeration tank are very important if good mixing is to be achieved. Aeration tanks may be square or rectangular and may contain one or more aerators. The depth and width of the aeration tanks for mechanical surface aerators are dependent on aerator size, and typical values are given in Table 5–33. Depths up to 11 m (35 ft) have been used with submerged-draft tube and hyperboloid mixers.

Table 5–32

Typical ranges of oxygen transfer capabilities for various types of mechanical aerators

	Transfer rate, lb O_2/hp·h		Transfer rate, kg O_2/kW·h	
Aeration system	**Standard**[a]	**Field**[b]	**Standard**[a]	**Field**[b]
Surface low speed	2.5–3.5	1.2–2.4	1.5–2.1	0.7–1.5
Surface low speed with draft tube	2.0–4.6	1.2–2.1	1.2–2.8	0.7–1.3
Surface high speed	1.8–2.3	1.2–2.0	1.1–1.4	0.7–1.2
Submerged turbine with draft tube	2.0–3.3	1.2–1.8[c]	1.2–2.0	0.6–1.1
Submerged turbine	1.8–3.5		1.1–2.1	
Submerged turbine with sparger	2.0–3.3	1.2–1.8[c]	1.2–2.0	0.7–1.0
Horizontal rotor	1.5–3.6	0.8–1.8	1.5–2.1	0.5–1.1

[a] Standard conditions: tap water 20°C (68°F); at 101.325 kN/m^2 (14.7 lb$_f$/in.^{2}); and initial dissolved oxygen = 0 mg/L.
[b] Field conditions: wastewater, 15°C (59°F); altitude 150 m (500 ft), $\alpha = 0.85$, $\beta = 0.9$; operating dissolved oxygen = 2 mg/L.
[c] The α values may be lower than 0.85; reported ranges vary from 0.3 to 1.1.

Table 5–33

Typical aeration tank dimensions for mechanical surface aerators

Aerator size		Tank dimensions			
		U.S. customary units		SI units	
hp	kW	Depth, ft	Width, ft	Depth, m	Width, m
10	7.5	10–12	30–40	3–3.5	9–12
20	15	12–14	35–50	3.5–4	10–15
30	22.5	13–15	40–60	4–4.5	12–18
40	30	12–17	45–65	3.5–5	14–20
50	37.5	15–18	45–75	4.5–5.5	14–23
75	55	15–20	50–85	4.5–6	15–26
100	75	15–20	60–90	4.5–6	18–27

In diffused-air systems, the air requirement to ensure good mixing varies from 20 to 30 $m^3/10^3\ m^3\cdot min$ (20 to 30 $ft^3/10^3\ ft^3\cdot min$) of tank volume, for a spiral-roll aeration pattern. For a grid system of aeration in which the diffusers are installed uniformly along the aeration basin bottom, mixing rates of 10 to 15 $m^3/10^3\ m^3\cdot min$ (10 to 15 $ft^3/10^3\ ft^3\cdot min$) have been suggested (WPCF, 1988). Fine pore diffusers installed in a grid Pattern typically require a minimum aeration rate of 0.12 scfm/square foot for mixing (U.S. EPA, 1989). Typical power requirements for maintaining a completely mixed flow regime with mechanical aerators vary from 20 to 40 $kW/10^3\ m^3$ (0.75 to 1.50 $hp/10^3\ ft^3$), depending on the type and design of the aerator, the nature and concentration of the suspended solids, the temperature, and the geometry of the aeration tank, lagoon, or basin. In the design of aerated lagoons for the treatment of domestic wastewater, it is extremely important that the mixing power requirement be checked because, in most instances, it will be the controlling factor.

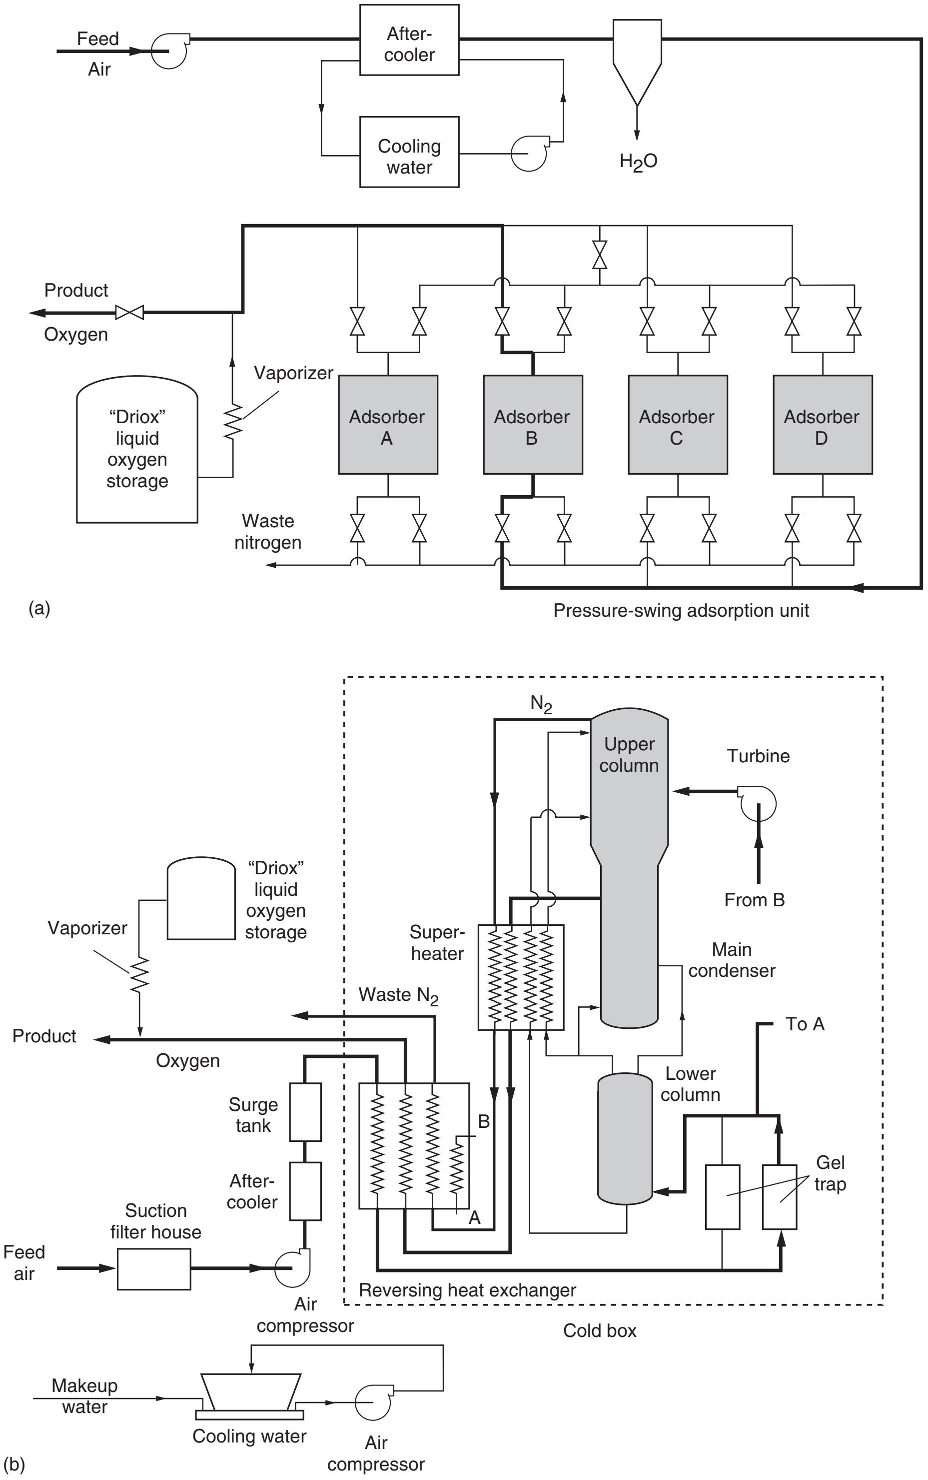
Generation and Dissolution of High-Purity Oxygen

After the quantity of oxygen required is determined, it is necessary, where high-purity oxygen is to be used, to specify the type of oxygen generator that will best serve the needs of the plant. There are two basic oxygen generator designs: (1) a pressure swing adsorption (PSA) system for smaller and more common plant sizes (less than 150,000 m^3/d (40 Mgal/d)), and (2) the traditional cryogenic air-separation process for large applications. Liquid oxygen can also be trucked in and stored onsite in a liquid form.

Pressure-Swing Adsorption. The pressure-swing adsorption system uses a multibed adsorption process to provide a continuous flow of oxygen gas (U.S. EPA, 1974). A schematic diagram of the four-bed system is shown on Fig. 5–77(a). The operating principle of the pressure-swing adsorption generator is that the oxygen is separated from the feed air by adsorption at high pressure, and the adsorbent is regenerated by "blowdown" to low pressure. The process operates on a repeated cycle having two basic steps, adsorption and regeneration. During the adsorption step, feed air flows through one of the adsorber vessels until the adsorbent is partially loaded with impurity. At that time the feed-air flow is switched to another adsorber, and the first adsorber is regenerated. During regeneration, the impurities are cleaned from the adsorbent so that the bed will be available again for the adsorption step. Regeneration is carried out by depressurizing to atmospheric pressure, purging with some of the oxygen, and repressurizing back to the pressure of the feed air.

Figure 5–77

Schematic diagrams for the generation of oxygen used in high-purity oxygen activated sludge process: (a) pressure-swing adsorption and (b) cryogenic air separation.



Cryogenic Air Separation. The cryogenic air separation process involves the liquefaction of air, followed by fractional distillation to separate it into its components (mainly nitrogen and oxygen). A schematic diagram of this process is shown on Fig. 5–77(b). First, the entering air is filtered and compressed, and then it is fed to the reversing heat exchangers, which perform the dual function of cooling and removing the water vapor and carbon dioxide by freezing these mixtures out into the exchanger surfaces. Periodically switching or reversing the feed air and the waste nitrogen streams through identical passes of the exchangers to regenerate their water vapor and carbon dioxide removal capacity accomplishes this process.

Next, the air is processed through "cold and gel traps," which are adsorbent beds that remove the final traces of carbon dioxide as well as most hydrocarbons from the feed air. The processed air is then divided into two streams. The first stream is fed directly to the lower column of the distillation unit. The second stream is returned to the reversing heat exchangers and partially warmed to provide the required temperature difference across the exchanger. This stream is then passed through an expansion turbine and fed into the upper column of the distillation unit. An oxygen-rich liquid exits from the bottom of the lower column and the liquid nitrogen exits from the top. Both streams are then subcooled and transferred to the upper column. In this column, the descending liquid phase becomes progressively richer in oxygen, and the liquid that subsequently collects in the condenser reboiler is the oxygen product stream. This oxygen is recirculated continually through an adsorption trap to remove all possible residual traces of hydrocarbons. The waste nitrogen exits from the top portion of the upper column and is heat exchanged along with the oxygen product to recover all available refrigeration and to regenerate the reversing heat exchangers.

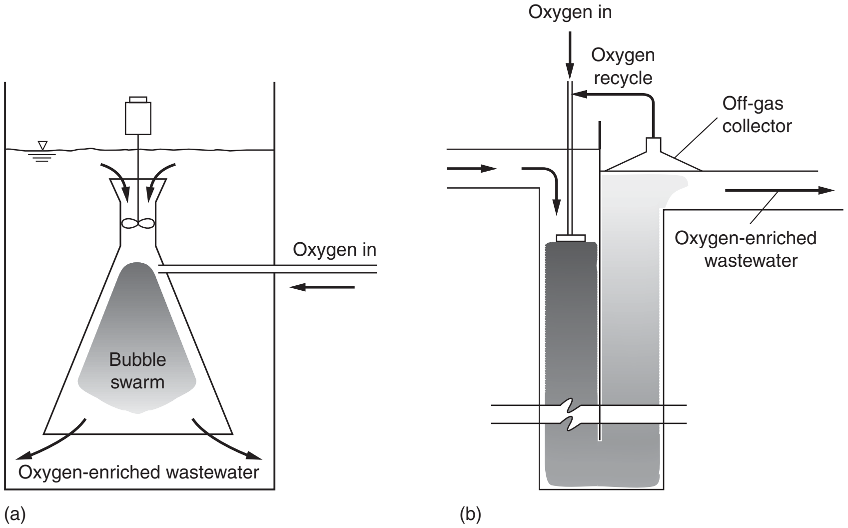
Dissolution of Commercial Oxygen. Oxygen is very insoluble in water—even pure oxygen—and requires special considerations to ensure high absorption efficiency. Oxygen dissolution equipment designed for air only optimizes energy consumption because the air is free and efficient oxygen absorption is not relevant. However, because of the cost of commercial oxygen, the facilities used for its dissolution must be designed to both efficiently absorb the commercial oxygen as well as minimize the unit energy consumption. These requirements rule out the more common aeration equipment alternatives.

Dissolution Time. A key feature that must be incorporated into a commercial oxygen dissolution system is oxygen retention time. To optimize the absorption of pure oxygen it has been found that a detention time of about 100 s is required. Further, two-phase flow must be maintained to avoid the coalescence of the oxygen bubbles to maintain absorption efficiency. Unfortunately, some pure oxygen dissolution systems consume as much energy to dissolve a ton of pure oxygen as standard surface aerators consume in dissolving a ton of oxygen from air.

Speece Cone (Downflow Bubble Contactor). A system that incorporates prolonged oxygen bubble contact time and high rates of oxygen transfer is a cone-shaped chamber, downflow bubble contact aerator termed the Speece cone [see Fig. 5–78(a)]. Water enters the chamber at the apex with a velocity of approximately 3 m/s (10 ft/s). This inlet velocity provides the energy to maintain a two-phase bubble swarm in the cone, ensuring a very high bubble/water interface, resulting in a proportionately high gas transfer rate. The expanding horizontal cross section of the cone reduces the downward flow velocity of the water to less than 0.3 m/s (1 ft/s). Because the bubbles have a nominal buoyant velocity of about 0.3 m/s, if the downflow velocity of the water is reduced below the buoyant velocity of the bubbles, they will remain indefinitely in the cone, thus satisfying the required bubble residence time. The water, however, has a residence time of about 10 s,

Figure 5–78

Pure oxygen dissolution systems: (a) Speece cone (downflow bubble contactor) and (b) U-tube contactor (Speece and Tchobanoglous, 1990).



reflecting a relatively small volume of reactor cone. This system incorporates the desired features of relatively small size, high rate of oxygen transfer, and more than adequate bubble residence time (Speece and Tchobanoglous, 1990).

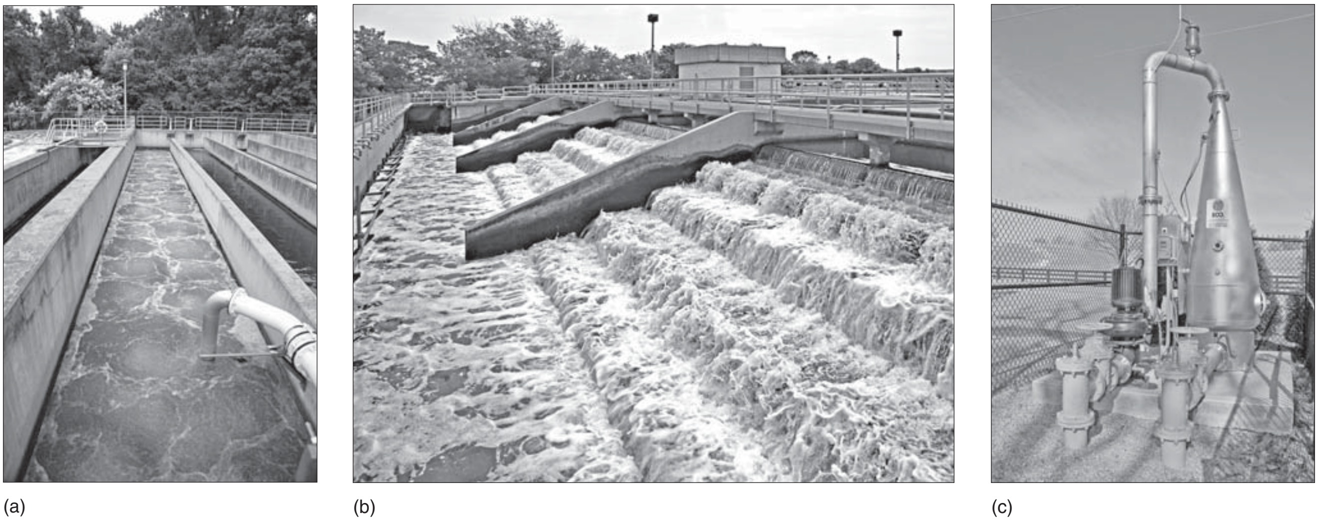
U-Tube Contactor. Another oxygen transfer system that incorporates desirable features for efficient dissolution of commercial oxygen with low unit energy consumption is the U-tube [see Fig. 5–78(b)]. At a depth of 30 m (100 ft) and a throughput velocity of 2.5 m/s (8 ft/s), the residence time is 25 s. Because a contact time of 25 s is low, off-gas recycle back through the system can be used to increase the contact time to about 100 s where efficient absorption occurs. The energy requirements are low because the bubble/water mixture is pumped through a filled U-tube pipe that is hydrostatically pressurized by its vertical configuration. Use of the U-tube enhances gas transfer significantly. Energy consumption is about 54 kWh/Mg O_2 (60 kWh/ton) while producing an effluent dissolved oxygen of 60 mg/L (Speece and Tchobanoglous, 1990).

Conventional Diffused Aeration. Conventional diffused aeration or surface aerators must operate in a closed headspace to absorb commercial oxygen efficiently. A concrete cover usually is placed over the aeration tank to enclose the headspace.

Postaeration

The requirement for postaeration systems has developed in recent years with the introduction of effluent standards and permits that include high dissolved oxygen levels (5 to 8 mg/L). Dissolved oxygen levels have become standard for discharge to water-quality-limited stream sections and to effluent dominated waters. The regulatory intent is to ensure that low dissolved oxygen levels in the treated effluent do not cause immediate depression after mixture with the waters of the receiving stream. To meet postaeration requirements, three methods are most commonly used: (1) diffused air, (2) mechanical aeration, (3) cascade aeration, and (4) The Speece cone, described above, can also be used for postaeration and for reaerating reclaimed water-storage reservoirs.

Diffused-Air Aeration. In larger treatment plants, diffused aeration systems may be more appropriate [see Fig. 5–79(a)]. Coarse- or fine-bubble diffusers may be used. Depending



(a) (b) (c)

Figure 5–79

Postaeration aeration systems: (a) diffused air, (b) cascade step aeration, and (c) Speece cone.

on the depth of submergence, transfer efficiencies of 5 to 8 percent may be attained with non-porous diffusers, and 15 to 25 percent with fine-pore diffusers. After secondary treatment, the alpha factors should range from 0.85 to 0.95 for nonporous systems, and from 0.70 to 0.85 for fine-pore systems.

EXAMPLE 5–15 **Derivation of Equation for Estimating Diffused-Air Requirements for Post-aeration** Develop an expression that can be used to estimate the diffused-air requirement for the postaeration of effluent following chlorination. Assume that aeration will be accomplished in a plug-flow reactor. Using the expression developed, estimate the amount of air in m^3/s to increase the DO from 1.5 to 5 g/m^3 at 20°C. The wastewater flowrate is 3800 m^3/d (1.0 Mgal/d). Assume the oxygen transfer efficiency is 6 percent and that C_s at 20°C is equal to 9.09 g/m^3 (from Appendix E).

Solution—Part 1 Expression Development

1. Write an equation for the oxygen-solution rate. The appropriate expression, similar to Eq. (5–57), is

$$r_m = \frac{dm}{dt} = K'_T(C_s - C)$$

where K'_T = overall mass transfer coefficient for the given conditions
$K'_T = K'_{20} \times (1.024)^{T-20}$

2. Write an expression for the oxygen-transfer efficiency. The efficiency may be defined as

$$E = \frac{(dm/dt)_{20°\text{C},C=0}}{M}$$

where E = oxygen transfer efficiency
$(dm/dt)_{20°C,C=0}$ = oxygen-solution rate at 20°C and zero dissolved oxygen
M = mass rate at which oxygen is introduced

3. Develop a differential expression for the mass rate at which oxygen is introduced. The mass rate at which oxygen is introduced is given by

$$M = \frac{1}{E}\left(\frac{dm}{dt}\right)_{20°\mathrm{C},C=0}$$
$$= \frac{1}{E}\left(\frac{dm}{dt}\right)_T \frac{(dm/dt)_{20°\mathrm{C},C=0}}{(dm/dt)_T}$$

Substituting for $(dm/dt)_{20,\,C=0}$ and $(dm/dt)_T$ yields

$$M = \frac{1}{E}\left(\frac{dm}{dt}\right)_T \frac{(C_s)_{20°\mathrm{C}}}{(C_s - C)_T\,(1.024)^{T-20}}$$

If the expression is applied to an infinitesimal transverse segment of the tank and QdC is substituted for dm/dt (note that $V(dC/dt) = dm/dt$ and $Q = V/dt$), then the differential form of the above expression can be rewritten as

$$dm = \frac{Q(C_s)_{20°\mathrm{C}}}{E(1.024)^{T-20}}\left(\frac{dC}{C_s - C}\right)_T$$

4. Integrate the differential expression derived in step 3. Integrating the expression from the inlet of the tank where $C = C_i$ to the outlet of the tank where $C = C_o$ and $M = 0$ to $M = M$:

$$\int_0^M dM = \frac{Q(C_s)_{20°\mathrm{C}}}{E(1.024)^{T-20}}\int_{C_i}^{C_o}\frac{dC}{C_s - C}$$

$$M = \frac{Q(C_s)_{20°\mathrm{C}}}{E(1.024)^{T-20}}\left[\ln\left(\frac{C_s - C_i}{C_s - C_o}\right)_T\right]$$

5. Rewrite the equation derived in step 4 in a more practical format. Note that the density of air is 1.23 kg/m³ and air contains about 23 percent oxygen by weight. The mass rate at which oxygen is introduced, expressed as g/s, is

$$M,\ \mathrm{g/s} = \left(Q, \frac{\mathrm{m^3\ air}}{\mathrm{s}}\right)\left(\frac{1.23\ \mathrm{kg}}{\mathrm{m^3\ O_2}}\right)\left(\frac{0.23\ \mathrm{kg\ O_2}}{\mathrm{kg\ air}}\right)\left(\frac{10^3\ \mathrm{g}}{1\ \mathrm{kg}}\right)$$

Thus, the rate of oxygen input, in terms of the equivalent air flowrate, expressed in m³/s, is equal to

$$Q_a = (3.53 \times 10^{-3})\frac{Q(C_s)_{20°\mathrm{C}}}{E(1.024)^{T-20}}\left[\ln\left(\frac{C_s - C_i}{C_s - C_o}\right)\right]$$

where Q_a = required air flowrate, m³/s
Q = wastewater flowrate, m³/s
C_s = saturation concentration of oxygen at 20°C, g/m³

Solution—Part 2 Estimate the mass air flowrate

6. Estimate the amount of air required using the expression developed in Step 5 above.

$$Q_a = (3.53 \times 10^{-3})\frac{Q(C_s)_{20°\mathrm{C}}}{E(1.024)^{T-20}}\left[\ln\left(\frac{C_s - C_i}{C_s - C_o}\right)\right]$$

a. Summarize known values
Q = 3800 m³/d = 0.044 m³/s
C_s = 9.09 g/m³
C_i = 1.5 g/m³

$C_o = 5.0\ \text{g/m}^3$
$E = 0.06$

b. Substitute known values and solve for Q_a.

$$Q_a = (3.53 \times 10^{-3})\frac{(0.044\ \text{m}^3/\text{s})(9.09)}{0.06(1.024)^{20-20}}\left[\ln\left(\frac{9.09 - 1.5}{9.09 - 5.0}\right)\right] = 1.30\ \text{m}^3/\text{s}$$

$$= 78\ \text{m}^3/\text{min}$$

Comment The value of Q_a is usually multiplied by a factor of 1.1 to account for the fact that the saturation value of oxygen in wastewater is about 95 percent of that in distilled water, and to account for the difference in the transfer rates.

Cascade Aeration. If site constraints and hydraulic conditions permit gravity flow, the least costly method to raise dissolved oxygen levels is with the use of cascade aeration [see Fig. 5–79(b)]. Cascade aeration consists of using the available discharge head to create turbulence as the wastewater falls in a thin film over a series of concrete steps. Performance depends on the initial dissolved oxygen level, required discharge dissolved oxygen, and wastewater temperature. Typical design information is given in Table 5–34. Where the cascade aeration facility joins the chlorine contact basin, the postaeration structure may be made equal to the chlorine contact basin width for ease of construction.

The most commonly used method for determining required cascade height is based on the following equations developed by Barrett (1960).

$$H = \frac{R - 1}{0.361\,ab(1 + 0.046 \times T)} \quad \text{SI units} \tag{5–83a}$$

$$H = \frac{R - 1}{0.11\,ab(1 + 0.046 \times T)} \quad \text{U.S. customary units} \tag{5–83b}$$

where R = deficit ratio = $\dfrac{C_s - C_o}{C_s - C}$

C_s = dissolved oxygen saturation concentration of the wastewater at temperature T, mg/L
C_o = dissolved oxygen concentration of the postaeration influent, mg/L
C = required final dissolved oxygen level after postaeration, mg/L
a = water-quality parameter equal to 0.8 for a wastewater-treatment plant effluent
b = weir geometry parameter for a weir, $b = 1.0$; for steps, $b = 1.1$; for step weir, $b = 1.3$

Table 5–34
Typical design information for a cascade type post aeration system

	U.S. customary units			SI units		
Parameter	**Units**	**Range**	**Typical**	**Units**	**Range**	**Typical**
Hydraulic loading rate at average design flow	gal/ft of width·d	100,000–500,000	240,000	m^3/m of width·d	1240–6200	3000
Step dimensions						
Height	in.	6–12	8	mm	150–300	200
Length	in.	12–24	18	mm	300–600	450
Cascade height	ft	6–16		m	2–5	

T = water temperature, °C
H = height through which water falls, m (ft)

A key element is the proper selection of the critical wastewater temperature, which affects the dissolved oxygen saturation concentration C_s. The effect of temperature is illustrated in Example 5–16.

EXAMPLE 5–16 **Calculation of Cascade Aeration Height** Calculate the height of a step cascade aeration system for a wastewater treatment plant in a warm climate where the wastewater temperature averages 20°C in the winter and 25°C in the summer. The dissolved oxygen in the influent to the postaeration system C_o is 1.0 mg/L and the required final dissolved oxygen concentration C is 6.0 mg/L.

Solution

1. Determine the dissolved oxygen saturation concentration C_s at the wastewater temperatures.
    a. From Appendix E, the dissolved oxygen at 20°C = 9.09 mg/L; and 8.26 mg/L at 25°C.
2. Calculate the cascade height for T = 20°C using Eq. (5–83a).
    a. Calculate the deficit ratio.

$$R = \text{deficit ratio} = \frac{C_s - C_o}{C_s - C} = \frac{9.09 - 1.0}{9.09 - 6.0} = 2.62$$

    b. Calculate the cascade height, assuming steps ($b = 1.1$).

$$H = \frac{R - 1}{0.361\,ab\,(1 + 0.046T)}$$

$$H = \frac{2.62 - 1}{0.361\,(0.8)(1.1)\,(1 + 0.046 \times 20)}$$

$$H = 2.66\ \text{m}\ (8.73\ \text{ft})$$

3. Calculate the cascade height for T = 25°C.
    a. Calculate the deficit ratio

$$R = \frac{8.26 - 1.0}{8.26 - 6.0} = 3.21$$

    b. Calculate the cascade height, assuming steps and using the same computation procedure as in 2b above.

$$H = 3.62\ \text{m}\ (11.9\ \text{ft})$$

Comment The increased wastewater temperature increases the dissolved oxygen deficit ratio and therefore affects the height of the cascade. The maximum wastewater temperatures should be checked to ensure the cascade height is not underdesigned. The physical dimensions of each step will depend on the site conditions and should be configured relative to the typical values given in Table 5–34. If a step height of 300 mm (12 in.) is selected, the required number of steps would be 12.

Mechanical Aeration. Two major types of mechanical aeration equipment are commonly used for postaeration systems: low-speed surface aerators and submerged turbine aerators. Low-speed surface aerators are preferred because they are usually the most economical, except where high oxygen transfer rates are required. For high oxygen transfer rates, submerged turbine units are preferred. Most installations consist of two or more aerators in rectangular basins. Detention times for postaeration using either mechanical or diffused-air aeration are usually 10 to 20 min at peak flowrates.

Aeration Using the Speece Cone. In postaeration with a Speece cone, a sidestream of the main flow is oxygenated and then reblended with the main flow before discharge. In open reservoirs used for storing reclaimed water, problems occur due to temperature stratification, low dissolved oxygen, and release of odors, principally hydrogen sulfide (see Sec. 13–4). The Speece cone, which has a very high oxygen transfer rate and is shown on Fig. 5–79(c), is ideally suited for reservoir aeration and temperature destratification. For reservoir aeration applications, compressed air can be used instead of high-purity oxygen.

PROBLEMS AND DISCUSSION TOPICS

5–1 A vertical bar screen is constructed of 20-mm diameter bars that have a clear spacing of 25 mm. Determine the headloss and velocity through a clean screen when the channel approach velocity is 1.0 m/s. If the screen is inclined at a 50, 55, and 60° angle from the horizontal (angle to be selected by instructor), how will the headloss and velocity through the clean screen be impacted?

5–2 Size the channel for a mechanically cleaned coarse bar rack for a flowrate of 40,000 m^3/d. The bar rack will be set at an angle of 75 degrees from horizontal and will have clear bar spacing of 12 mm. The bar rack uses 12-mm-wide by 25-mm deep bars. The upstream channel velocity should be greater than 0.4 m/s. Determine the headloss through the bar rack for the clean screen and for a screen that is 50 percent clogged.

5–3 The contents of a tank are to be mixed with a turbine impeller that has six flat blades. The diameter of the impeller is 3 m, and the impeller is installed 1.25 m above the bottom of a 6-m deep tank. If the temperature is 30°C and the impeller is rotated at 30 rev/min, what will be the power consumption? Find the Reynolds number using Eq. (5–11).

5–4 It is desired to flash-mix some chemicals with incoming wastewater that is to be treated. Mixing is to be accomplished using a flat-paddle mixer 500 mm in diameter having six blades. If the temperature of the incoming water is 10°C and the mixing chamber power number is 1.70, determine, (a) the speed of rotation when the Reynolds number is approximately 100,000, (b) why it is desirable to have a high Reynolds number in most mixing operations, (c) the required mixer motor size, assuming an efficiency factor of 20 percent.

5–5 Assuming that a given flocculation process can be defined by a first-order reaction ($r_N = -kN$), complete the following table (instructor to select data set) assuming the process is occurring in a plug-flow reactor with a detention time of 10 min. What would the value be after 5 min if a batch reactor were used instead, assuming the rate constant is the same?

	Particles, no/unit volume		
Time, min	Data set 1	Data set 2	Data set 3
0	10	40	20
5	?	?	?
10	3	5	2

5–6 If the steady-state effluent from a complete-mix reactor used as a flocculator contained 3 particles/unit volume, determine the concentration of particles in the effluent 5 min after the process started before steady-state conditions are reached. Assume that the influent contains 10 particles/unit volume, the detention time in the reactor is equal to 10 min, and that first-order kinetics apply ($r_N = -kN$).

5–7 An air flocculation system is to be designed. If a G value of 60 s^{-1} is to be used, estimate the air flowrate that will be necessary for a 200 m^3 flocculation chamber. Assume the depth of the flocculation basin is to be 4 m and that the air is released 0.25 m above the tank bottom.

5–8 Determine the required air flowrate to accomplish the flocculation operation in Example 5–3 pneumatically. Assume the air will be released at a depth of 3 m.

5–9 Derive Stokes' law by equating Eq. (5–23) to the particle mass.

5–10 Determine the settling velocity in m/s of a sand particle with a specific gravity of 2.65 and a diameter of 1 mm. Assume that the Reynolds number is 275.

5–11 Prepare a spreadsheet for computing the settling velocity of a spherical particle for the data given in Example 5–4. What are the values of Reynolds number and coefficient of drag necessary to have the assumed velocities agree with the calculated velocities?

5–12 Design a vortex type grit removal facility to handle a peak flowrate of 40,000 m^3/d. No grit sampling program has been conducted, and the design is to be based on removal of grit particles with an assumed SES of 106 μm. If this facility is located in an area that is known to have fine grit, what would be the expected percent grit removed? To achieve 90 percent grit removal, what adjustments would be necessary in the design of the facility.

5–13 Design an aerated grit chamber for a plant with an average flowrate of 15,000 m^3/d and a peak hourly flowrate of 40,000 m^3/d. Determine the amount of air required and the pressure at the discharge of the blowers. Allow a 250-mm loss in the diffusers, and add the submergence plus 400-mm for loss in piping and valves. Determine the power required. Use a blower efficiency of 70 percent. Determine the monthly power bill, assuming a motor efficiency of 90 percent and a power cost of \$0.12/kWh.

5–14 Design an aerated grit chamber installation for an average wastewater flowrate of 0.3 m^3/s and a peak flowrate of 1.0 m^3/s. Assume that the detention time at peak = 3.0 min, 4.0 min, and 5.0 min (detention time to be selected by instructor). Determine the dimensions of the grit chambers and the total air required.

5–15 Discuss the advantages and disadvantages of aerated grit chambers versus vortex-type grit chambers. Cite three references.

5–16 Determine the removal efficiency for a sedimentation basin with a critical velocity V_o of 2 m/h in treating a wastewater containing particles whose settling velocities are distributed as given in the table below (sample number to be selected by instructor). Plot the particle histogram for the influent and effluent wastewater.

	No. of particles		
	Sample		
V_{avg}, m/h	1	2	3
0.0–0.5	10	20	20
0.5–1.0	29	100	40
1.0–1.5	47	130	80
1.5–2.0	65	100	120
2.0–2.5	74	70	100
2.5–3.0	60	45	70
3.0–3.5	28	28	20
3.5–4.0	13	16	10
4.0–4.5	5	7	3

5–17 The rate of flow through an ideal clarifier is 8000 m^3/d, the detention time is 1 h, the depth is 3 m. If a full-length movable horizontal tray is set 1 m below the surface of the water, determine the percent removal of particles having a settling velocity of 1 m/h. Could the removal efficiency of the clarifier be improved by moving the tray? If so, where should the tray be located and what would be the maximum removal efficiency? What effect would moving the tray have if the particle settling velocity were equal to 0.3 m/h?

5–18 In Example 5–4, the assumed and calculated particle settling velocities did not reach closure. Continue the calculation iterations to find the actual settling velocity.

5–19 For a flocculent suspension, determine the removal efficiency for a basin 3 m deep with an overflow rate V_o equal to 3 m/h using the laboratory settling data presented in the following table.

	Percent suspended solids removed at indicated depth, m				
Time, min	0.5	1.0	1.5	2	2.5
20	61				
30	71	63	55		
40	81	72	63	61	57
50	90	81	73	67	63
60		90	80	74	68
70			86	80	75
80				86	81

5–20 A sedimentation basin has been retrofitted with 2.0-m (6.6-ft) square inclined plates spaced 75 mm (3.0 in.) apart. The angle of inclination of the plates can be set from 40, 50, or 60°. Assuming that the operation of the sedimentation basin can be either countercurrent or cocurrent, determine which arrangement is most efficient.

5–21 The following data were obtained from a settling test in a 3 m cylinder. The initial solids concentration was 3600 mg/L. Determine the thickener area required for sample (to be selected by instructor) for a concentration C_u of 11,000 or 12,000 mg/L (to be selected by instructor) with a flowrate of 1500 m^3/d.

	Height of interface, m		
	Sample		
Time, min	1	2	3
0	3.0	3.0	3.0
5	2.0	2.2	2.3
10	1.35	1.6	1.75
20	0.75	1.0	1.25
30	0.5	0.7	0.9
40	0.35	0.5	0.7
50	0.25	0.4	0.6
60	0.2	0.32	0.5

5–22 Design a circular radial-flow sedimentation tank for a town with a projected population of 45,000. Assume that the wastewater flowrate is 400 L/capita·d. Design for 2 h detention at the average flow. Determine the tank depth and diameter to produce an overflow rate of 36 $m^3/m^2 \cdot d$ for average flow. Assume standard tank dimensions to fit mechanisms made in diameters with increments of 1.0 m and in depth increments of 0.5 m.

5–23 A rectangular settling tank has an overflow rate of 30 $m^3/m^2 \cdot d$ and dimensions of 2.75 m deep by 6 m wide by 15 m long. Determine whether or not particles with a diameter of

0.1 mm and a specific gravity of 2.5 will be scoured from the bottom. Use $f = 0.03$ and $k = 0.04$.

5–24 Determine the percentage increase in the hydraulic and solids loading rates of the primary settling facilities of a treatment plant when 200 m^3/d of settled waste activated sludge containing 2000 mg/L of suspended solids is discharged to the existing primary facilities for thickening. The average plant flowrate is 20,000 m^3/d and the influent suspended solids concentration is about 350 mg/L. The design overflow rate for the primary settling tanks without the waste solids is 32 $m^3/m^2 \cdot d$ and the detention time is 2.8 h. Will the added incremental loading rate affect the performance of the primary settling facilities? Document the basis for your answer.

5–25 Prepare a table and compare the data from a minimum of three references with regard to the following primary sedimentation tank design parameters: (1) detention time (with and without preaeration); (2) expected BOD removal; (3) expected suspended-solids removal; (4) mean horizontal velocity; (5) surface loading rate in $m^3/m^2 \cdot d$; (6) effluent weir overflow rate per unit length; (7) size of organic particle removed; (8) length-to-width ratio (rectangular tanks); (9) average depth. List all references.

5–26 A medium-size treatment plant is being designed, and circular and rectangular primary sedimentation tanks are being considered. What factors should be considered in the evaluation and selection of the type of tank? List the advantages and disadvantages for each type. Cite at least three recent references (since 2000).

5–27 Contrast dissolved-air flotation with sedimentation discussing the following parameters: (a) detention time, (b) surface-loading rate, (c) power input, (d) efficiency, and (e) most favorable application for each type.

5–28 Using one of the following three data sets (to be selected by instructor), design a dissolved air flotation thickening system to thicken the solids to a 4 percent solids concentration.

		Data set		
		1	2	3
Item	Unit	Mixed liquor	Settled activated sludge	Primary + activated sludge
Solids conc.	mg/L	2500	7500	10,000
Optimum A/S ratio	ratio	0.02	0.03	0.03
Temperature	°C	20	20	20
Surface loading rate	$L/m^2 \cdot min$	10	15	8
Flowrate	m^3/d	1200	400	800

5–29 The following data were obtained from a test program designed to evaluate a new diffused-air aeration system. Using these data, determine the value of K_La at 20°C and the equilibrium dissolved-oxygen concentration in the test tank. The test program was conducted using tap water at a temperature of 24°C.

C, mg/L	dC/dt, mg/L·h
1.5	8.4
2.7	7.5
3.9	5.3
4.8	4.9
6.0	4.2
7.0	2.8
8.2	2.0

5–30 If the volume of the test tank used to evaluate the aeration system in Prob. 5–29 were equal to 100 m^3 and the air flowrate were equal to 2 m^3/min, determine the maximum oxygen-transfer efficiency at 20°C and 1.0 atmosphere.

5–31 Using the equation developed in Example 5–15, estimate the air flowrate in m^3/min required to increase the oxygen content of chlorinated effluent from zero to 4 mg/L. The effluent flowrate is equal to 20,000 m^3/d. Assume that the transfer efficiency is 6 percent and the temperature is 15°C. What is the air requirement when the temperature is 25°C?

5–32 Alternative diffused-air aeration devices are being considered for installation with a submergence of 4.5 m in an aeration tank at an activated-sludge treatment plant. The oxygen required for biological treatment is 7000 kg/d. Determine the standard oxygen transfer rate and theoretical air requirements for ceramic dome diffusers installed in a grid pattern as compared to nonporous diffusers installed for a dual-spiral roll. The wastewater temperature is 20°C and the α factors are 0.64 for ceramic domes and 0.75 for the nonporous diffusers, respectively.

5–33 Using the data in Prob. 5–29 and a wintertime wastewater temperature of 10°C, determine the theoretical air requirements for cold-weather operation. How will equipment selection be affected in meeting both summer and winter operation?

Chemical Unit Processes

WORKING TERMINOLOGY

Term	Definition
Absorption	The process by which atoms, ions, molecules, and other constituents are transferred from one phase and are distributed uniformly in another phase (see also adsorption).
Activated carbon	A substance used commonly in adsorption processes for the removal of various constituents from water and air. Activated carbon is derived from an organic base material, prepared (activated) using a high temperature and pressure pyrolysis process, resulting in properties conducive to mass transfer.
Adsorption	The process by which atoms, ions, molecules, and other constituents are transferred from one phase and accumulate on the surface of another phase (see also absorption). Substances accumulate on the solid phase due to a number of physical attraction and chemical bonding forces.
Adsorbate	The compound in a liquid or gas phase suspension that is deposited onto the surface of an adsorbent material.
Adsorbent	The solid material onto which adsorption takes place.
Advanced oxidation	A chemical oxidation process that relies upon the hydroxyl radical (HO•) for the destruction of trace organic constituents found in water. A number of processes have been identified that are able to produce HO•, including combinations of ozone, hydrogen peroxide and ultraviolet light.

Term	Definition
Desorption	The release of a volatile gas phase from a liquid phase as in gas stripping or the release of a previously adsorbed compound from an adsorbent material.
Electrical potential	The driving force for the exchange of electrons between constituents during a redox reaction, reported in volts with respect to the standard hydrogen electrode.
Extinction coefficient	The fractional amount of UV radiation attenuated as UV light passes through water that contains dissolved substances that absorb the energy. The extinction coefficient is also known as the molar absorptivity.
Gas stripping	A process to remove a volatile constituent from a liquid phase, such as the removal of ammonia from water in a packed column using air as the gas phase.
Ion exchange	A process used for the removal of dissolved ionic constituents where ions of a given species are displaced from a solid phase material by ions of a different species from solution.
Isotherm	A mathematical function used to relate the amount of a given constituent adsorbed from water per concentration of adsorbent at a given temperature.
Mineralization	The complete oxidation and conversion of organic substances into inorganic forms, such as carbon dioxide, water, and mineral acids, through the action of chemically and biologically mediated redox reactions.
Natural organic matter (NOM)	A bulk parameter used to describe the complex matrix of organic constituents of biological origin found in water, quantified typically as total organic carbon (TOC). See also Chap. 2.
Oxidation reactions	The component of a redox reaction involving the loss of electrons. The oxidation reaction can be obtained from tabulated half reactions (by convention, half reactions are reported as reduction reactions) by reversing the direction of the half reaction and multiplying the electrical potential by -1.
Photolysis	A process used for the treatment of trace organic constituents, where a UV light source is used to supply photons that are absorbed by the constituent and subsequently become unstable and react or split apart.
Quantum yield	A quantity used to describe the frequency at which photon absorption results in a photolysis reaction and is specific to the compound and the wavelength.
Quenching	The use of physical or chemical means to stop a chemical reaction.
Redox reaction	The overall reaction resulting from the combination of a reduction and oxidation reaction.
Reduction reactions	The component of a redox reaction involving the gain of electrons. The reduction reaction can be obtained directly from tabulated half reactions.
Reactivation	The desorption of constituents from an adsorbent material followed by the combustion of the remaining sorbed constituents, resulting in restoration of the adsorptive capacity.
Regeneration	The desorption of constituents from an adsorbent material for the partial restoration of the adsorptive capacity.
Reverse osmosis (RO)	The rejection of dissolved constituents by preferential diffusion using a pressure-driven, semipermeable membrane (see Chap. 11).
Scavengers	In advanced oxidation systems, substances that preferentially react with the oxidant and radical species, typically reducing the degradation rate for the compound of interest and overall efficiency of the process.
Separation processes	Physical and chemical mass transfer processes used in water reclamation that bring about treatment by the isolation of particular constituents. The isolated constituents are concentrated into a waste stream that must be managed (see Chap. 11).

Term	Definition
Synthetic organic compounds (SOCs)	Compounds of synthetic origin used extensively in industrial processes and contained in numerous manufactured consumer products. The presence of SOCs in drinking water as well as reclaimed water is of concern due to toxicity and unknown effects.
Trace constituent	A diverse classification of constituents found at low concentrations in untreated wastewater and not readily removed using conventional secondary treatment, and thus also found in treated effluent and environmental water systems. Trace constituents are of concern due to known or suspected toxicity associated with many of these compounds, which may need to be removed during water reclamation depending on the reuse requirements.
Water matrix	The term used to refer to a given water and all of its constituents that result in the physical, chemical, and biological properties of the solution.

Processes used for the treatment of wastewater in which change is brought about by means of or through chemical reactions are known as *chemical unit processes*. In the field of wastewater treatment, chemical unit processes are used commonly in conjunction with the physical unit processes discussed in Chap. 5, and the biological unit processes discussed in Chaps. 7 through 10, to meet specific treatment objectives. The purpose in this chapter is to present and discuss (1) the role of chemical unit processes in wastewater treatment; (2) fundamentals of chemical coagulation; (3) the precipitation reactions that occur when various chemicals are added to improve the performance of wastewater treatment facilities; (4) the chemical reactions involved in the precipitation of phosphorus from wastewater; (5) precipitation of ammonium and phosphorus; (6) precipitation of heavy metals and dissolved inorganic substances; (7) chemical oxidation; (8) advanced oxidation; (9) photolysis; (10) chemical neutralization, scale control, and stabilization; and (11) chemical storage, feeding, piping, and control systems. Ion exchange and adsorption, sometimes classified as chemical unit processes, but which, more correctly, should be classified as separation processes as they are based on mass transfer, are considered in Chap. 11. Chemical disinfection, an important and much-used chemical unit process, is considered separately in Chap. 12.

6–1 ROLE OF CHEMICAL UNIT PROCESSES IN WASTEWATER TREATMENT

The principal chemical unit processes used for wastewater treatment include (1) chemical coagulation, (2) chemical precipitation, (3) chemical oxidation, (4) advanced oxidation, (5) photolysis, and (6) chemical neutralization, scale control, and stabilization. The applications and the limitations involved in the use of these processes are considered in the following discussion.

Applications of Chemical Unit Processes

Applications of chemical unit processes for the management and treatment of wastewater are reported in Table 6–1. Chemical processes, in conjunction with various physical operations, have been used in nearly all aspects of wastewater treatment, including physical-chemical treatment systems for the complete treatment of untreated (raw) wastewater. In some cases, chemical processes have been developed for the advanced treatment of secondary effluent (see Fig. 6–1). The most important applications of chemical unit processes in

Table 6–1

Applications of chemical unit processes in wastewater treatment

Process	Application	See section or chapter
Advanced oxidation processes	Removal of refractory organic compounds	6–8
Chemical coagulation	The chemical destabilization of particles in wastewater to bring about their aggregation during perikinetic and orthokinetic flocculation	6–2
Chemical disinfection	Disinfection with chlorine, chlorine compounds, bromine, and ozone	Chap. 12
	Control of biofilm growths in sewers	Chap. 12
	Control of odors	Chap. 16
Chemical neutralization	Control of pH	6–10
Chemical oxidation	Removal of BOD, grease, etc.	6–7
	Removal of ammonium	6–7
	Destruction of microorganisms	Chap. 12
	Control of odors in sewers, pump stations, and treatment plants	Chap. 16
	Removal of resistant organic compounds	6–7, 6–8, 6–9
Chemical precipitation	Enhanced removal of total suspended solids and BOD in primary sedimentation facilities (chemically enhanced primary treatment, CEPT).	6–3
	Removal of phosphorus	6–4, 6–5
	Removal of ammonium	6–5
	Removal of heavy metals	6–6
	Physical-chemical treatment	6–3
	Corrosion control in sewers due to H_2S	6–7
Chemical scale control	Control of scaling due to calcium carbonate and related compounds	6–10
Chemical stabilization	Stabilization of treated effluents	6–10
Ion exchange	Removal of ammonium (NH_4^+), heavy metals, total dissolved solids	Chap. 11
	Removal of organic compounds	Chap. 11

modern wastewater treatment have included: (1) the disinfection of wastewater; (2) the removal of phosphorus; (3) the coagulation of particulate matter; (4) pH control, neutralization, and alkalinity supplementation; and (5) water stabilization and stability control, which is increasingly important in wastewater reuse applications, e.g., cooling tower makeup. However, the need to remove trace constituents prior to potable reuse has stimulated the rapid development and implementation of advanced oxidation and photolysis processes. Chemical unit processes are also being implemented to separate wastewater constituents from untreated wastewater for the recovery of energy and agricultural nutrients.

Considerations in the Use of Chemical Unit Processes

In considering the application of chemical unit processes, it is important to remember that one of the inherent disadvantages associated with some chemical unit processes, as compared with the physical unit operations, is that they are additive processes (i.e., something

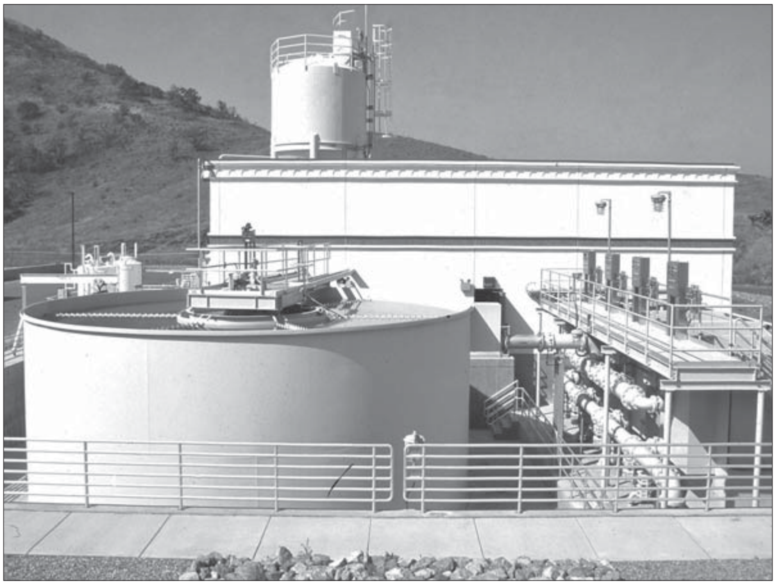

Figure 6–1

Typical lime clarification facilities following secondary treatment used as pretreatment step for advanced treatment of wastewater using reverse osmosis. Lime storage is in the silo shown behind the building that is used to house the lime slaking facilities and the reverse osmosis units used for advanced treatment. Granular medium depth filters are shown to the right of the lime clarifier in the foreground.

is added to the wastewater to achieve the removal of something else). As a result, there is often a net increase in certain dissolved wastewater constituents from a given process. For example, where coagulants are added to enhance the removal efficiency of particulate matter in sedimentation, the total dissolved solids (TDS) concentration of the wastewater is increased generally. Depending on the specific chemicals used, the concentration of aluminum or iron in the process effluent or solids may also be increased. Similarly, when chlorine is added to wastewater, the TDS of the effluent is increased and disinfection byproducts may appear. If the treated wastewater is to be reused or strict discharge limits exist for specific constituents, the increase in dissolved constituents can be a significant factor. This additive aspect is in contrast to the physical unit operations and the biological unit processes, which may be described as being subtractive, in that wastewater constituents are removed from the wastewater without a corresponding increase in the dissolved constituents. A potential disadvantage of chemical precipitation processes is the handling, treatment, and disposal of the sludge that is produced. Another disadvantage of chemical unit processes is that the cost of most chemicals is related to the cost of energy. As a result, the use of chemicals affects the overall wastewater treatment process carbon footprint because of energy inputs required to produce and transport chemicals. The impacts of chemical usage on the carbon footprint and overall process sustainability are considered in Chap. 16. In some cases, such as meeting low discharge limits for nutrients or specific constituents, the use of chemicals will be unavoidable.

6–2 FUNDAMENTALS OF CHEMICAL COAGULATION

Colloidal particles found in wastewater typically have a net negative surface charge. The size of colloids (about 0.001 to 1 μm) is such that the attractive body forces between particles are considerably less than the repelling forces of the electrical charge. Under these stable conditions, Brownian motion keeps the particles in suspension. Brownian motion (i.e., random movement) results from the constant bombardment of the colloidal particles by the relatively small water molecules, driven by random thermal motion that surrounds them. Coagulation is the process of destabilizing colloidal particles so that particle growth can occur as a result of particle collisions. The complete theory of chemical coagulation reactions is beyond the scope of this textbook. The simplified reactions used in this and other textbooks to describe coagulation and chemical precipitation processes can only be considered approximations, as the reactions may not necessarily proceed as indicated.

Coagulation reactions are often incomplete, and numerous side reactions with other substances in wastewater may take place depending on the characteristics of the water matrix, which will vary diurnally as well as seasonally. To introduce the subject of chemical coagulation, the following topics are discussed in this section: (1) basic definitions for coagulation and flocculation, (2) the nature of particles in wastewater, (3) the development and measurement of surface charge, (4) consideration of particle-particle interactions, (5) particle destabilization with potential determining ions and electrolytes, (6) particle destabilization and aggregation with polyelectrolytes, and (7) particle destabilization and removal with hydrolyzed metal ions. The following discussion is meant to serve as an introduction to the nature of the phenomena and processes involved in the coagulation process.

Basic Definitions

The term *chemical coagulation* as used in this text includes all of the reactions and mechanisms involved in the chemical destabilization of particles and in the formation of larger particles through perikinetic flocculation (aggregation of particles in the size range from 0.001 to 1 μm). Coagulant and flocculant are terms that will also be encountered in the literature on coagulation. In general, a coagulant is the chemical that is added to destabilize the colloidal particles in wastewater so that floc formation can result. A flocculant is a chemical, typically organic, added to enhance the flocculation process. Typical coagulants include natural and synthetic organic polymers, metal salts such as alum or ferric chloride, and prehydrolized metal salts such as polyaluminum chloride (PACl), polyiron chloride (PICl), and polydiallyldimethylammonium chloride (polyDADMAC). Flocculants, especially organic polymers, are also used to enhance the performance of granular medium filters and in the dewatering of digested biosolids. In these applications, the flocculant chemicals are often identified as filter aids. Note that inorganic substances, such as bentonite, are used to improve the performance of filtration system in some industrial applications.

The term *flocculation* is used to describe the process whereby the size of particles increases as a result of particle collisions. As noted in Chap. 5, there are two types of flocculation: (1) *microflocculation* (also known as *perikinetic flocculation*) in which particle aggregation is brought about by the random thermal motion of fluid molecules known as Brownian motion or movement, and (2) *macroflocculation* (also known as *orthokinetic flocculation*) in which particle aggregation is brought about by inducing velocity gradients and mixing in the fluid containing the particles to be flocculated. Another form of macroflocculation is brought about by differential settling in which large particles overtake small particles to form larger particles. The purpose of flocculation is to produce particles, by means of aggregation, that can be removed by inexpensive particle-separation procedures such as gravity sedimentation and filtration. Again as noted in Chap. 5, macroflocculation is ineffectual until the colloidal particles reach a size of 1 to 10 μm through contacts produced by Brownian motion and gentle mixing.

Nature of Particles in Wastewater

The particles in wastewater may, for practical purposes, be classified as suspended and colloidal. In practice, the distinction between colloidal and suspended particles is blurred because the particles removed by gravity settling will depend on the design of the sedimentation facilities. Because colloidal particles cannot be removed by sedimentation in a reasonable period of time, chemical methods (i.e., the use of chemical coagulants and flocculant aids) must be used to help bring about the removal of these particles.

To understand the role that chemical coagulants and flocculant aids play in bringing about the removal of colloidal particles, it is important to understand the characteristics of the colloidal particles found in wastewater. Important factors that contribute to the characteristics of colloidal particles in wastewater include: (1) particle size and number, (2) particle shape and flexibility, (3) surface properties including electrical characteristics, (4) particle-particle interactions, and (5) particle-solvent interactions (Shaw, 1966). Particle size, particle shape and flexibility, and particle-solvent interactions are considered below. Because of their importance, the development and measurement of surface charge and particle-particle interactions are considered separately.

Particle Size and Number. The size of colloidal particles in wastewater considered in this text is typically in the range from 0.01 to 1 μm. As noted in Chap. 2, some researchers have classified the size range for colloidal particles as varying from 0.001 to 1 μm. The number of colloidal particles in untreated wastewater and after primary sedimentation is typically in the range from 10^6 to 10^{12}/mL. It is important to note that the number of colloidal particles will vary depending on the location where the sample is taken within a treatment plant. The number of particles, as will be discussed later, is of importance with respect to the method to be used for their removal.

Particle Shape and Flexibility. Particle shapes found in wastewater can be described as: spherical, semi-spherical, ellipsoids of various shapes (e.g., prolate and oblate), rods of various length and diameter (e.g., *E. coli*), disk and disk-like, strings of various lengths, and random coils. Large organic molecules are often found in the form of coils which may be compressed, uncoiled, or almost linear. The shape of some larger floc particles is often described as fractal. The particle shape will vary depending on the location within the treatment process that is being evaluated. The shape of the particles will affect the electrical properties, the particle-particle interactions, and particle-solvent interactions. Because of the many shapes of particles encountered in wastewater, the theoretical treatment of particle-particle interactions is an approximation, at best.

Particle-Solvent Interactions. There are three general types of colloidal particles in liquids: hydrophobic or "water-hating," hydrophilic or "water-loving," and association colloids. The first two types are based on the attraction of the particle surface for water. Hydrophobic particles have relatively little attraction for water while hydrophilic particles have a great attraction for water. It should be noted, however, that water can interact to some extent even with hydrophobic particles. Some water molecules will generally adsorb on the typical hydrophobic surface, but the reaction between water and hydrophilic colloids occurs to a much greater extent. The third type of colloid is known as an association colloid, typically made up of surface-active agents such as soaps, synthetic detergents, and dyestuffs that form organized aggregates known as micelles.

Development and Measurement of Surface Charge

An important factor in the stability of colloids is the presence of a surface charge. Surface charge develops in a number of different ways, depending on the chemical composition of the water matrix (wastewater in this case) and the nature of the colloid. Surface charge develops most commonly through (1) isomorphous replacement, (2) structural imperfections,

(3) preferential adsorption, and (4) ionization, as defined below. Regardless of how it develops, the surface charge, which promotes stability, must be overcome if these particles are to be aggregated (flocculated) into larger particles with enough mass to settle easily.

Isomorphous Replacement. Charge development through isomorphous replacement occurs in clay and other soil particles in which ions in the lattice structure are replaced with ions from solution (e.g., the replacement of Si^{4+} with Al^{3+}).

Structural Imperfections. In clay and similar particles, charge development can occur because of broken bonds on the crystal edge and imperfections in the formation of the crystal.

Preferential Adsorption. When oil droplets, gas bubbles, or other chemically inert substances are dispersed in water, they will acquire a negative charge through the preferential adsorption of anions (particularly hydroxyl ions).

Ionization. In the case of substances such as proteins or microorganisms, surface charge is acquired through the ionization of carboxyl and amino groups (Shaw, 1966). This ionization can be represented as follows, where *R* represents the bulk of the solid (Fair et al., 1968):

$$\underset{\text{at high pH}}{R^{\mathrm{COO^-}}_{\mathrm{NH_2}}} \qquad \underset{\text{at isoelectric point}}{R^{\mathrm{COO^-}}_{\mathrm{NH_3^+}}} \qquad \underset{\text{at low pH}}{R^{\mathrm{COOH}}_{\mathrm{NH_3^+}}} \tag{6–1}$$

The Electrical Double Layer. When the colloid or particle surface becomes charged, some ions of the opposite charge (known as counter-ions) become attached to the surface (see Fig. 6–2). Ions are held there through electrostatic and van der Waals forces of attraction strongly enough to overcome thermal agitation. Surrounding this fixed layer of ions is a diffuse layer of ions, which is prevented from forming a compact double layer by thermal agitation, as illustrated schematically on Fig. 6–2. The electrical double layer consists of a compact layer (Stern) in which the potential drops from ψ_o to ψ_s, and a diffuse layer in which the potential drops from ψ_s to 0 in the bulk solution.

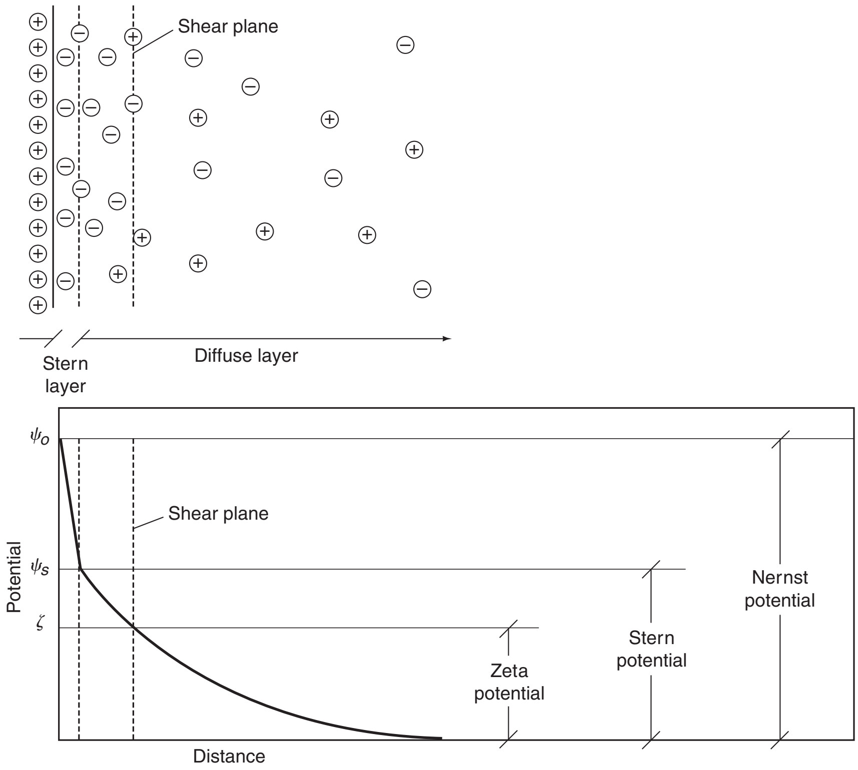
Measurement of Surface Potential. If a particle is placed in an electrolyte solution, and an electric current is passed through the solution, the particle, depending on its surface charge, will be attracted to one or the other of the electrodes, dragging with it a cloud of ions. The potential at the surface of the cloud (called the surface of shear) is sometimes measured in wastewater treatment operations. The measured value is often called the zeta potential. Theoretically, however, the zeta potential should correspond to the potential measured at the surface enclosing the fixed layer of ions attached to the particle, as shown on Fig. 6–2. The use of the measured zeta potential value is limited because it will vary with the nature of the water matrix.

Particle-Particle Interactions

Particle-particle interactions are important in bringing about aggregation by means of Brownian motion. The theory that has been developed to describe particle-particle interactions is based on the consideration of interaction between two charged flat plates and between two charged spheres (Deryagin and Landau, 1941; Verwey and Overbeek, 1948). As neither of these developments is directly applicable to the particles found in wastewater,

Figure 6–2

Stern model of electrical double layer (Shaw, 1966).



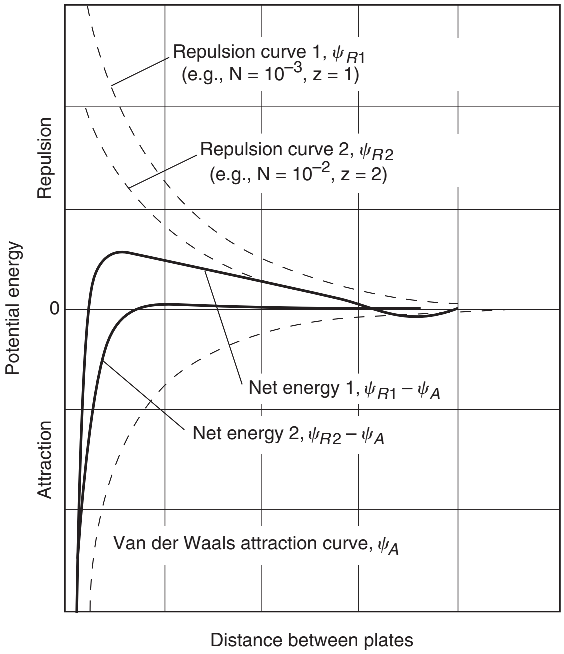
as described previously, the analysis for two charged flat plates will be used for illustrative purposes. The interaction between two plates is illustrated on Fig. 6–3. As shown on Fig. 6–3, the two principal forces involved are the forces of repulsion, due to the electrical properties of the charged plates, and the van der Waals forces of attraction. It should be noted that the van der Waals forces of attraction do not come into play until the two plates are brought together in close proximity to each other.

The net total energy shown on Fig. 6–3 by the solid lines is the difference between the forces of repulsion and attraction. The two conditions, with respect to the forces of repulsion, are illustrated on Fig. 6–3. As shown for condition 1, the forces of attraction will predominate at short and long distances. The net energy curve for condition 1 contains a repulsive maximum that must be overcome if the particles, represented as the two plates, are to be held together by the van der Waals force of attraction. In condition 2, there is no energy barrier to overcome. Clearly, if colloidal particles are to be removed by microflocculation, the repulsive force must be reduced. Although floc particles can form at long distances as shown by the net energy curve for condition 2, the net force holding these particles together is weak and the floc particles that are formed can be ruptured easily.

Particle Destabilization with Potential-Determining Ions and Electrolytes. To bring about particle aggregation through microflocculation, steps must be taken to reduce particle charge or to overcome the effect of this charge. The effect of the charge can be overcome by (1) the addition of potential-determining ions, which will be taken up by or will react with the colloid surface to lessen the surface charge and (2) the addition of electrolytes, which have the effect of reducing the thickness of the diffuse electric layer and, thereby, reduce the zeta potential.

Figure 6–3

Definition sketch for particle-particle interactions based on the repulsion due to particle surface charge and van der Waals forces of attraction. N = concentration, z = charge.



Use of Potential-Determining Ions. The addition of potential-determining ions to promote coagulation can be illustrated by the addition of strong acids or bases to reduce the charge of metal oxides or hydroxides to near zero so that coagulation can occur. The effect of adding potential determining ions in a solution containing charged particles is illustrated on Fig. 6–4. The magnitude of the effect will depend on the concentration of

Figure 6–4

Definition sketch for the effects of the addition of counter-ions and electrolytes to solutions containing charged colloidal particles.

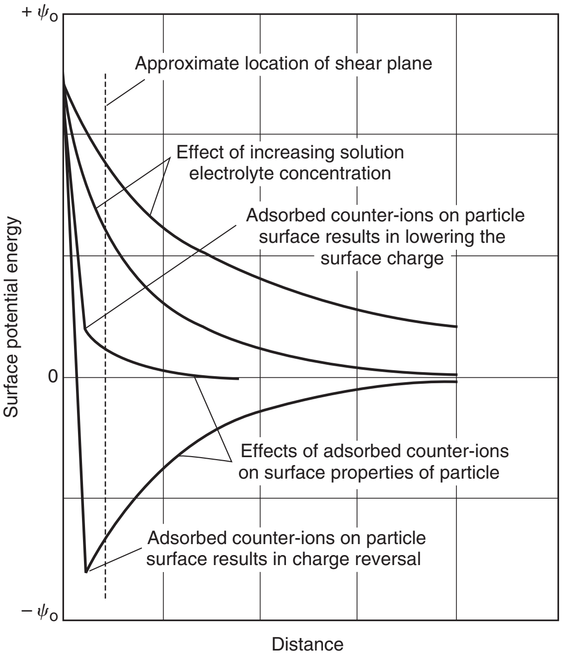


Figure 6–5

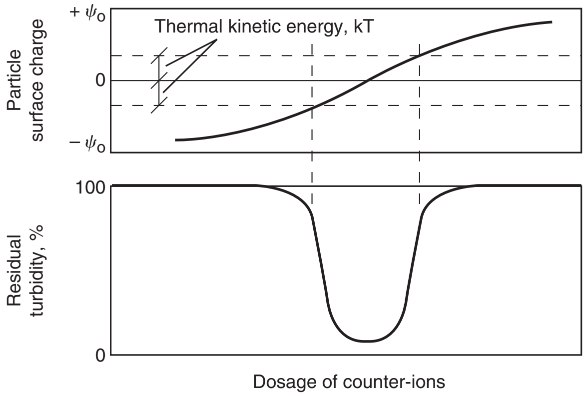
Definition sketch for the reversal of particle surface charge due to the addition of counter-ions.



potential determining ions added. The following ratios, known as the Shultz-Hardy rule, can be used to assess the effectiveness of potential determining or counter-ions:

$$1:\frac{1}{2^6}:\frac{1}{3^6} \quad \text{or} \quad 100:1.6:0.13 \tag{6–2}$$

It is interesting to note that, depending on the concentration and nature of the counter-ions added, it is possible to reverse the charge of the double layer and develop a new stable particle.

The effect of adding counter-ions to a solution containing charged particles is illustrated on Fig. 6–5. The upper curve on Fig. 6–5 represents the surface charge of the particle as a function of the concentration of counter-ions added. The lines designated kT represent the thermal kinetic energy of the particle. The lower diagram is a plot of the turbidity that would result if the particles that have been destabilized and have undergone microflocculation were removed by settling. As shown, when the surface charge (either positive or negative) is greater than the thermal kinetic energy of the particles, the particles will not flocculate and the original turbidity is observed.

Additional details on the use of counter-ions may be found in Shaw (1966). The use of potential determining ions is not feasible in either water or wastewater treatment because of the massive concentration of ions that must be added to bring about sufficient compression of the electrical double layer to effect perikinetic flocculation.

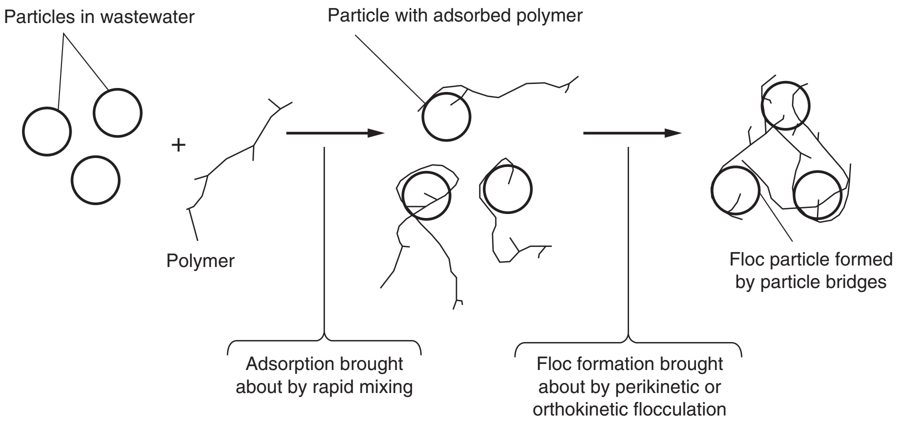
Use of Electrolytes. Electrolytes can also be added to coagulate colloidal suspensions. Increased concentration of a given electrolyte will cause a decrease in zeta potential and a corresponding decrease in repulsive forces as illustrated in condition 2 on Fig. 6–3 and on Fig. 6–4. The concentration of an electrolyte that is needed to destabilize a colloidal suspension is known as the *critical coagulation concentration* (CCC). Increasing the concentration of an indifferent electrolyte will not result in the restabilization of the colloidal particles. As with the addition of potential determining ions, the use of electrolytes is also not feasible in wastewater treatment. As discussed subsequently, a change in the particle charge will occur when chemicals are added to adjust the pH of the wastewater to optimize the performance of hydrolyzed metal ions used as coagulants.

Particle Destabilization and Aggregation with Polyelectrolytes

Polyelectrolytes may be divided into two categories: natural and synthetic. Important natural polyelectrolytes include polymers of biological origin and those derived from starch products such as cellulose derivatives, and alginates. Synthetic polyelectrolytes

Figure 6–6

Definition sketch for inter-particle bridging with organic polymers.



consist of simple monomers that are polymerized into high-molecular-weight substances. Depending on whether their charge, when placed in water, is negative, positive, or neutral, these polyelectrolytes are classified as anionic, cationic, and nonionic, respectively. The action of polyelectrolytes may be divided into the following three general categories.

Charge Neutralization. In the first category, polyelectrolytes act as coagulants that neutralize or lower the charge of the wastewater particles. Because wastewater particles normally are charged negatively, cationic polyeletrolytes are used for this purpose. In this application, the cationic polyelectrolytes are considered to be primary coagulants. To affect charge neutralization, the polyelectrolyte must be adsorbed to the particle. Because of the large number of particles found in wastewater, the mixing intensity must be sufficient to bring about the adsorption of the polymer onto the colloidal particles. With inadequate mixing, the polymer will eventually fold back on itself and its effectiveness in reducing the surface charge will be diminished. Further, if the number of colloidal particles is limited, it will be difficult to remove them with low polyelectrolyte dosages.

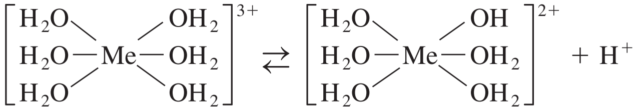
Polymer Bridge Formation. The second mode of action of polyelectrolytes is interparticle bridging (see Fig. 6–6). In this case, polymers that are anionic and nonionic (usually anionic to a slight extent when placed in water) become attached at a number of adsorption sites to the surface of the particles found in the wastewater. A bridge is formed when two or more particles become adsorbed along the length of the polymer. Bridged particles become intertwined with other bridged particles during the flocculation process. The size of the resulting three-dimensional particles grows until they can be removed easily by sedimentation. Where particle removal is to be achieved by the formation of particle-polymer bridges, the initial mixing of the polymer and the wastewater containing the particles to be removed must be accomplished in a matter of seconds. Instantaneous initial mixing is usually not required, as the polymers are already formed, which is not the case with the polymers formed by metal salts (see discussion of hydrolyzed metal ions given below). As noted above, the mixing intensity must be sufficient to bring about the adsorption of the polymer onto the colloidal particles. If inadequate mixing is provided, the polymer will eventually fold back on itself, in which case it is not possible to form polymer bridges.

Charge Neutralization and Polymer Bridge Formation. The third type of polyelectrolyte action may be classified as a charge neutralization and bridging phenomenon, which results from using cationic polyelectrolytes of high molecular weight. Besides lowering the surface charge on the particle, these polyelectrolytes also form particle bridges as described above.

Particle Destabilization and Removal with Hydrolyzed Metal Ions

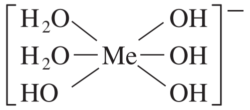
In contrast with the aggregation brought about by the addition of chemicals that act as counter-ions, electrolytes, and polymers, aggregation brought about by the addition of alum or ferric compounds is a more complex process. To understand particle destabilization and the removals achieved with hydrolyzed metal ions, it will be instructive to consider first the formation of metal ion hydrolysis products. Operating ranges for action of metal salts and the importance of initial mixing are also considered in light of the formation of these particles.

Formation of Hydrolysis Products. In the past, it was thought that free Al^{3+} and Fe^{3+} were responsible for the effects observed during particle aggregation; it is now known, however, that their hydrolysis products are responsible (Stumm and Morgan, 1962; Stumm and O'Melia, 1968). Although the effect of these hydrolysis products is only now appreciated, it is interesting to note that their chemistry was first elucidated in the early 1900s by Pfeiffer (1902–1907), Bjerrum (1906–1920), and Werner (1907) (Thomas, 1934). In the early 1900s, Pfeiffer proposed that the hydrolysis of trivalent metal salts, such as chromium, aluminum, and iron, could be represented as



(6–3)

with the extent of the dissociation depending on the anion associated with the metal and on the physical and chemical characteristics of the solution. Further, it was proposed that, upon the addition of sufficient base, the dissociation can proceed to produce a negative ion (Thomas, 1934), such as



(6–4)

It should be noted that the complex compounds given in Eqs. (6–3) and (6–4) are known as a *coordination compounds*, which are defined as a central metal ion (or atom) attached to a group of surrounding molecules or ions by coordinate covalent bonds. The surrounding molecules or ions are known as *ligands*, and the atoms attached directly to the metal ion are called ligand donor atoms (McMurry and Fay, 2011). Ligand compounds of interest in wastewater treatment include: carbonate (CO_3^{2-}), chloride (Cl^-), hydroxide (OH^-), ammonium (NH_4^+), and water (H_2O).

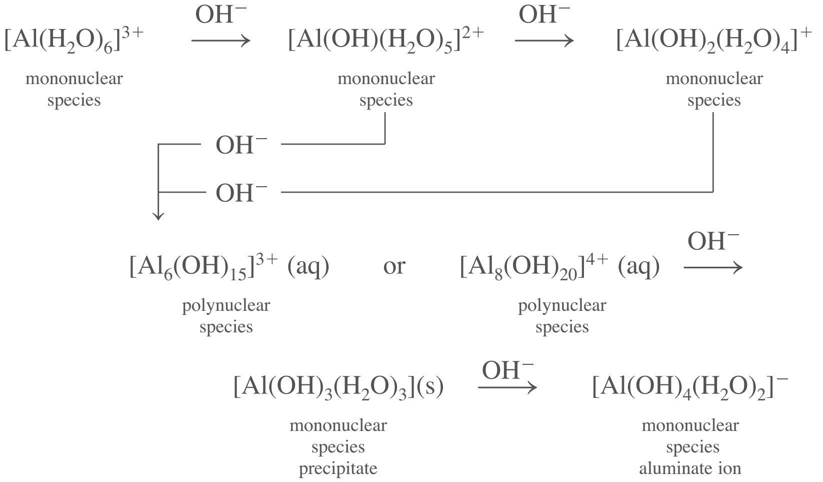
In addition, a number of the coordination compounds are also *amphoteric* in that they can exist both in strong acids and in strong bases (McMurry and Fay, 2011). For example, aluminum hydroxide behaves as follows in acidic and basic solutions:

$$\text{In acid:}\ \ Al(OH)_3(s) + 6H_3O^+(aq) \rightleftarrows Al^{3+}(aq) + 6H_2O \qquad (6\text{–}5)$$

$$\text{In base:}\ \ Al(OH)_3(s) + OH^-(aq) \rightleftarrows Al(OH)_4^-(aq) \qquad (6\text{–}6)$$

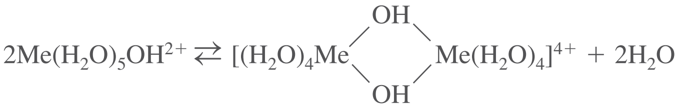
As shown in Eq. (6–5), $Al(OH)_3$ will dissolve in the presence of excess acid to form aqueous Al^{3+}. In the presence of excess hydroxide [see Eq. (6–6)], $Al(OH)_3$ will dissolve to form the aluminate ion, $Al(OH)_4^-$. The acid and base properties of the hydroxides and the nature of the covalent bonds will depend on the position of the element on the periodic table. Further, it should be noted some basic hydroxides will dissolve in strong acid, but not in a strong base (McMurry and Fay, 2011).

Over the past 50 years, it has been observed that the intermediate hydrolysis reactions of Al(III) are much more complex than would be predicted on the basis of a model in which a base is added to the solution. At the present time the complete chemistry for the formation of hydrolysis reactions and products is not well understood (Letterman et al., 1999). A hypothetical model [see Eq. (6–7)], proposed by Stumm (Fair et al., 1968) for Al(III), is useful for the purpose of illustrating the complex reactions involved. A number of alternative formation sequences have also been proposed (Letterman, 1991).



(6–7)

Before the reaction proceeds to the point where a negative aluminate ion is produced, polymerization as depicted in the following formula will usually take place (Thomas, 1934).



$$2Me(H_2O)_5OH^{2+} \rightleftarrows [(H_2O)_4Me(OH)_2Me(H_2O)_4]^{4+} + 2H_2O \tag{6–8}$$

As illustrated by Eqs. (6–7) and (6–8), the possible combinations of the various hydrolysis products are endless, and their enumeration is not the purpose here. What is important, however, is the realization that one or more of the hydrolysis products and or polymers may be responsible for the observed action of aluminum or iron.

Further, because the hydrolysis reactions follow a stepwise process, the effectiveness of aluminum and iron will vary with time. For example, an alum slurry that has been prepared and stored will behave differently from a freshly prepared solution when it is added to a wastewater. For a more detailed review of the chemistry involved, the excellent articles on this subject by Stumm and Morgan (1962) and Stumm and O'Melia (1968) are recommended. Additional details on the chemistry of aluminum and iron may be found in Benefield et al. (1982), Morel and Hering (1993), Pankow (2012), Snoeyink and Jenkins (1980), Sawyer et al. (2002), and Stumm and Morgan (1981).

Action of Hydrolyzed Metals Ions. The action of hydrolyzed metal ions in bringing about the destabilization and removal of colloidal particles may be divided into the following three categories:

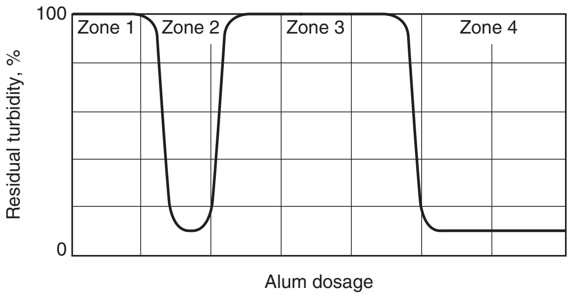
1. Adsorption and charge neutralization
2. Adsorption and interparticle bridging
3. Enmeshment in sweep floc

Adsorption and charge neutralization involves the adsorption of mononuclear and polynuclear metal hydrolysis species [see Eq. (6–7)] on the colloidal particles found in wastewater. It should be noted that it is also possible to get charge reversal with metal salts, as describe previously with the addition of counter-ions (see Fig. 6–5). Adsorption and interparticle bridging involves the adsorption of polynuclear metal hydrolysis species and polymer species [see Eqs. (6–7) and (6–8)] which, in turn, will ultimately form particle-polymer bridges, as described previously. As the coagulant requirement for adsorption and charge neutralization is satisfied, metal hydroxide precipitates and soluble metal hydrolysis products will form as defined by Eq. (6–5). If a sufficient concentration of metal salt is added large amounts of metal hydroxide floc will form. Following macroflocculation, large floc particles will be formed that will settle readily. In turn, as these floc particles settle, they sweep through the water containing colloidal particles. The colloidal particles that become enmeshed in the floc will thus be removed from the wastewater. In most wastewater applications, the sweep floc mode of operation is used most commonly where particles are to be removed by sedimentation.

The sequence of reactions and events that occur in the coagulation and removal of particles can be illustrated pictorially as shown on Fig. 6–7. In zone 1, sufficient coagulant has not been added to destabilize the colloidal particles, even though some reduction in surface charge may occur due to the presence of Fe^{3+} and some mononuclear hydrolysis species. In zone 2, the colloidal particles have been destabilized by the adsorption of mono- and polynuclear hydrolysis species, and, if allowed to flocculate and settle, the residual turbidity would be lowered as shown. In zone 3, as more coagulant is added, the surface charge of the particles has reversed due to the continued adsorption of mono- and polynuclear hydrolysis species (see Fig. 6–7). As the colloidal particles are now positively charged, they cannot be removed by perikinetic flocculation. As more coagulant is added, zone 4 is reached where large amounts of hydroxide floc will form. As the floc particles settle, the colloidal particles will be removed by the sweep action of the settling floc particles, and the residual turbidity will be lowered as shown. The coagulant dosage required to reach any of the zones will depend on the nature of the colloidal particles and the pH and temperature of the wastewater. Specific constituents (e.g., organic matter) will also have an effect on the coagulant dose.

Figure 6–7

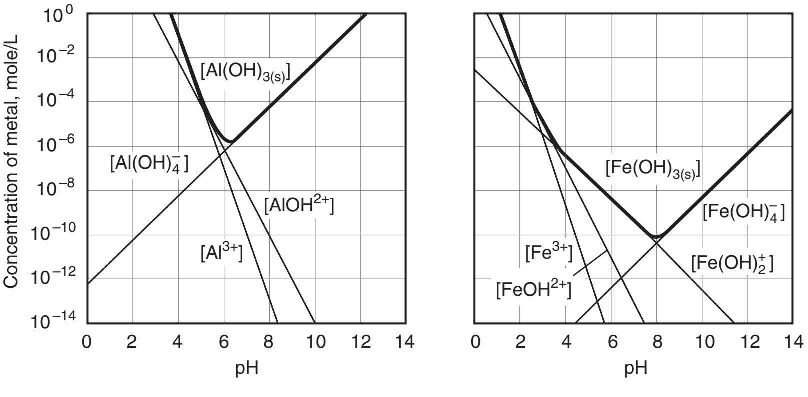
Definition sketch for the effects of the continued addition of a coagulant (e.g., alum) on the destabilization and flocculation of colloidal particles.



It is also important to note that the example reaction sequence given by Eq. (6–7), and the coagulation process illustrated on Fig. 6–7, is time dependent. For example, if it is desired to destabilize the colloidal particles in wastewater with mono- and polynuclear species, then *rapid* and *intense* initial mixing of the metal salt and the wastewater containing the particles to be destabilized is of critical importance. If the reaction is allowed to proceed to the formation of metal hydroxide floc, it will be difficult to contact the chemical and the particles. As discussed below, it has been estimated that the formation of the mono- and polynuclear and polymer hydroxide species occurs in a fraction of second.

Solubility of Metal Salts. To further appreciate the action of the hydrolyzed metal ions it will be useful to consider the solubility of the metal salts. The solubility of the various aluminum [Al(III)] and iron [Fe(III)] species are illustrated on Figs. 6–8(a) and 6–8(b), respectively in which the log molar concentrations have been plotted as a function of pH. In preparing these diagrams, only the mononuclear species for alum and iron have been plotted. The various mononuclear species for alum and iron are given in Table 6–2, along with the corresponding range of acid solubility products reported in the literature. The formation of some of the mononuclear species is also illustrated in Eq. (6–7). It should be noted that Hayden and Rubin (1974) compared experimental and predicted values and concluded that $Al(OH)_2^+$ is not an important mononuclear species. Accordingly, $Al(OH)_2^+$ has not been included in the development of Fig. 6–8(a). The solid lines trace the approximate total concentration of residual soluble alum [see Fig. 6–8(a)] and iron [see Fig. 6–8(b)] after precipitation.

Aluminum hydroxide and ferric hydroxide are precipitated within the areas above the bold line, and polynuclear and polymeric species are formed outside at higher and lower pH values. The region within the square boxes is where most precipitation operations are conducted when these coagulants are used in a sweep floc mode of operation. As shown the operating region for alum precipitation is from a pH range of 5 to about 7, with minimum solubility occurring at a pH of 6.0, and from about 7 to 9 for iron precipitation, with minimum solubility occurring at a pH of 8.0.



$\log[Al^{3+}] = 10.8 - 3pH$

$\log[AlOH^{2+}] = 5.8 - 2pH$

$\log[Al(OH)_4^-] = -12.2 + pH$

$C_T = [Al^{3+}] + [AlOH^{2+}] + [Al(OH)_4^-]$

(a)

$\log[Fe^{3+}] = 3.2 - 3pH$

$\log[FeOH^{2+}] = 1.0 - 2pH$

$\log[Fe(OH)_2^+] = -2.5 - pH$

$\log[Fe(OH)_4^-] = -18.4 + pH$

$C_T = [Fe^{3+}] + [FeOH^{2+}] + [Fe(OH)_2^+] + [Fe(OH)_4^-]$

(b)

Figure 6–8

Solubility diagram for alum [Al(III)] and iron [Fe(III)]. It should be noted that only the mononuclear species have been plotted. The polynuclear species are extremely dependent on the chemistry of the wastewater. The mononuclear species $Al(OH)_2^+$ has not been included in the development of Fig. 6–8(a). Further, because of the wide variation in the solubility and formation constants for the various metal hydroxides, the curves presented in this figure should only be used as a reference guide.

Table 6–2

Reactions and associated equilibrium constants for aluminum and iron species in equilibrium with amorphorous aluminum hydroxide and ferric hydroxide[a]

	Acid equilibrium constants		
Reaction	**Equilibrium constant**	**Range[a]**	**Used for Fig. 6–8**
Aluminum, Al(III)			
$Al(OH)_{3(s)} + 3H^+ \rightleftarrows Al^{3+} + 3H_2O$	$^*K_{s0}$	9.0–10.8	10.8
$Al(OH)_{3(s)} + 2H^+ \rightleftarrows AlOH^{2+} + 2H_2O$	$^*K_{s1}$	4.0–5.8	5.8
$Al(OH)_{3(s)} + H^+ \rightleftarrows Al(OH)_2^+ + H_2O$[b]	$^*K_{s2}$	1.5	1.5
$Al(OH)_{3(s)} \rightleftarrows Al(OH)_3$	$^*K_{s3}$	−4.2	−4.2
$Al(OH)_{3(s)} + H_2O \rightleftarrows AlOH_4^- + H^+$	$^*K_{s4}$	−7.7–(−12.5)	−12.2
Species not considered: $Al^2(OH)_2{}^{4+}$; $Al_8(OH)_{20}^{4+}$; $Al_{13}O_4(OH)_{24}^{7+}$; $Al_{14}(OH)_{32}^{10+}$			
Iron, Fe(III)			
$Fe(OH)_{3(s)} + 3H^+ \rightleftarrows Fe^{3+} + 3H_2O$	$^*K_{s0}$	3.2–4.891	3.2
$Fe(OH)_{3(s)} + 2H^+ \rightleftarrows FeOH^{2+} + 2H_2O$	$^*K_{s1}$	0.91–2.701	1.0
$Fe(OH)_{3(s)} + H^+ \rightleftarrows Fe(OH)_2^+ + H_2O$	$^*K_{s2}$	−0.779–(−2.5)	−2.5
$Fe(OH)_{3(s)} \rightleftarrows Fe(OH)_3$	$^*K_{s3}$	−8.709–(−12.0)	−12.0
$Fe(OH)_{3(s)} + H_2O \rightleftarrows FeOH_4^- + H^+$	$^*K_{s4}$	−16.709–(−19)	−18.4
Species not considered: $Fe_2(OH)_2^{4+}$; $Fe_3(OH)_4^{5+}$			

[a] Abstracted from Benefield et al.(1982), McMurray and Fay (2011), Morel and Hering (1993), Pankow (2012), Snoeyink and Jenkins, (1980), Sawyer et al. (2002), and Stumm and Morgan (1981).

[b] Hayden and Rubin (1974) compared experimental and predicted values and concluded that $Al(OH)_2^+$ is not an important mononuclear species.

Operating Regions for Action of Metal Salts. Because the chemistry of the various reactions is so complex, there is no complete theory to explain the action of hydrolyzed metal ions. To quantify qualitatively the application of alum as a function of pH, taking into account the action of alum as described above, Amirtharajah and Mills (1982) developed the diagram shown on Fig. 6–9. Although Fig. 6–9 was developed for water treatment applications, it has been found to apply reasonably well to most wastewater applications, with minor variations. The approximate regions in which the different phenomenon associated with particle removal in conventional sedimentation and filtration processes are operative are plotted on Fig. 6–9 as a function of the alum dose and the pH of the treated effluent after alum has been added. For example, optimum particle removal by sweep floc occurs in the pH range of 7 to 8 with an alum dose of 20 to 60 mg/L. Generally, for many wastewater effluents that have high pH values (e.g., 7.3 to 8.5), low alum dosages in the range of 5 to 10 mg/L will not be effective. With proper pH control it is possible to operate with low alum dosages. Because the characteristics of wastewater will vary from treatment plant to treatment plant, bench scale and/or pilot plant tests must be conducted to establish the appropriate chemical dosages.

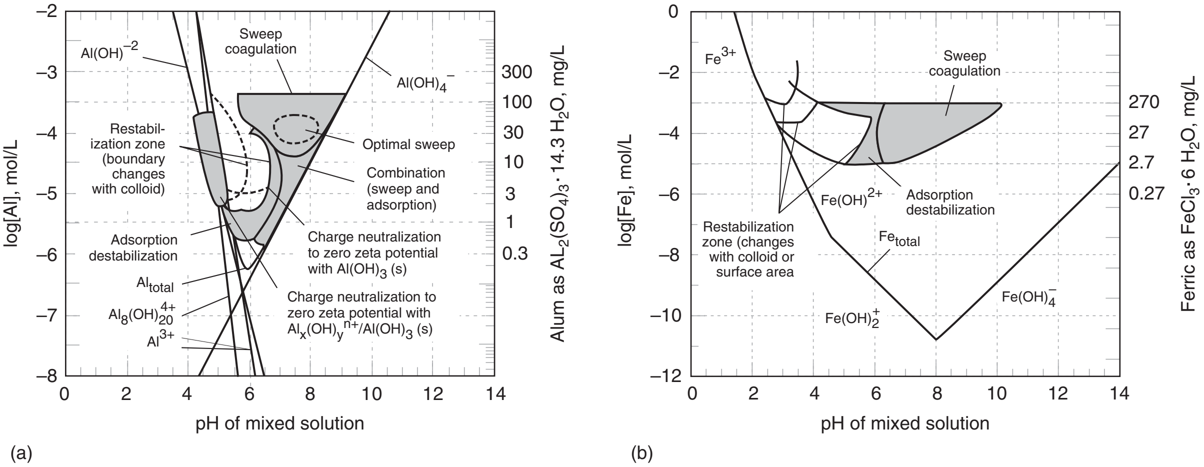


Figure 6–9

Typical operating ranges for coagulation with (a) alum and (b) ferric chloride. (Adapted from Crittenden et al., 2012; Amirtharajah and Mills, 1978).

Importance of Initial Chemical Mixing with Metal Salts. Perhaps the least appreciated fact about chemical addition of metal salts is the importance of the rapid initial mixing of the chemicals with the wastewater to be treated. In a 1967 article, Hudson and Wolfner (1967) noted that "coagulants hydrolyze and begin to polymerize in a fraction of a second after being added to water." Hahn and Stumm (1968) studied the coagulation of silica dispersions with Al(III). They reported that the time required for the formation of mono- and polynuclear hydroxide species appears to be on the order of 10^{-3} s. The time of formation for the polymer species was on the order of 10^{-2} s. Further, they found that the rate limiting step in the coagulation process was the time required for the colloidal transport step brought about by Brownian motion (i.e., perikinetic flocculation) which was estimated to be on the order of 1.5 to 3.3×10^{-3} s. The importance of initial and rapid mixing is also discussed by Amirtharajah and Mills (1982) and Vrale and Jorden (1971). Clearly, based on the literature and actual field evaluations, the instantaneous rapid and intense mixing of metal salts is of critical importance, especially where the metal salts are to be used as coagulants to lower the surface charge of the colloidal particles. It should be noted that although achieving suitable mixing times in large treatment plants is often difficult, adequate mixing times can be achieved by using multiple mixers. Typical mixing times for various chemicals are reported in Table 6–24 in Sec. 6–11.

6–3 CHEMICAL PRECIPITATION FOR IMPROVED PLANT PERFORMANCE

Chemical precipitation, as noted previously, involves the addition of chemicals to alter the physical state of dissolved and suspended solids and facilitate their removal by sedimentation. In the past, chemical precipitation was often used to enhance the degree of TSS and BOD removal (1) where there were seasonal variations in the concentration of the wastewater (such as in cannery wastewater), (2) where an intermediate degree of treatment was required, and (3) as an aid to the sedimentation process. Since about 1970, the need to provide more complete removal of the organic compounds and nutrients (nitrogen and phosphorus) contained in wastewater has brought about renewed interest in chemical precipitation. In current practice, chemical precipitation is used (1) as a means of improving the performance of primary settling facilities, (2) as a basic step in the independent physical-chemical treatment of wastewater, (3) for the removal of phosphorus, (4) for the removal of heavy metals, and (5) for improving the quality of water to be reused by softening.

Aside from the determination of the required chemical dosages and specification of the rapid mixing and flocculation facilities, the principal design considerations related to the use of chemical precipitation involve the analysis and design of the necessary sludge processing facilities, and the selection and design of the chemical storage, feeding, piping, and control systems (see Sec. 6–11).

Chemical Reactions in Wastewater Precipitation Applications

Over the years a number of different substances have been used as precipitants (Metcalf and Eddy, 1935). The degree of clarification obtained depends on the quantity of chemicals used and the care with which the process is controlled. It is possible by chemical precipitation to obtain a clear effluent, substantially free from matter in suspension or in the colloidal state. The chemicals added to wastewater interact with substances that are either normally present in the wastewater or added for this purpose. The most common chemicals are listed in Table 6–3. The reactions involved with (1) alum, (2) lime, (3) ferrous sulfate (copperas) and lime, (4) ferric chloride, (5) ferric chloride and lime, and (6) ferric sulfate and lime are considered in the following discussion.

Table 6–3

Inorganic chemicals used most commonly for coagulation and precipitation processes in wastewater treatment

Chemical	Formula	Molecular weight	Equiv. weight	Availability	
				Form	Percent
Alum	$Al_2(SO_4)_3 \cdot 18H_2O^a$	666.5		Liquid Lump	8.5 (Al_2O_3) 17 (Al_2O_3)
	$Al_2(SO_4)_3 \cdot 14H_2O^a$	594.4	114	Liquid Lump	8.5 (Al_2O_3) 17 (Al_2O_3)
Aluminum chloride	$AlCl_3$	133.3	44	Liquid	
Calcium hydroxide (lime)	$Ca(OH)_2$	56.1 as CaO	40	Lump Powder Slurry	63–73 (CaO) 85–99 (CaO) 15–20 [$Ca(OH)_2$]
Ferric chloride	$FeCl_3$	162.2	91	Liquid Lump	20 (Fe) 20 (Fe)
Ferric sulfate	$Fe_2(SO_4)_3$	400	51.5	Granular	18.5 (Fe)
Ferrous sulfate (copperas)	$FeSO_4 \cdot 7H_2O$	278.1	139	Granular	20 (Fe)
Sodium aluminate	$Na_2Al_2O_4$	163.9	100	Flake	46 (Al_2O_3)

[a] Number of bound water molecules will typically vary from 14 to 18.

Alum. When alum is added to wastewater containing calcium and magnesium bicarbonate alkalinity, a precipitate of aluminum hydroxide will form. The overall reaction that occurs when aluminum sulfate is added to water may be illustrated as follows:

$$\underset{\substack{\text{Calcium}\\ \text{bicarbonate}\\ \text{(Soluble)}}}{\overset{3\times 100\ (\text{as }\mathrm{CaCO_3})}{3\mathrm{Ca(HCO_3)_2}}} + \underset{\substack{\text{Aluminum}\\ \text{sulfate}\\ \text{(Soluble)}}}{\overset{666.5}{\mathrm{Al_2(SO_4)_3{\cdot}18H_2O}}} \rightleftarrows \underset{\substack{\text{Aluminum}\\ \text{hydroxide}\\ \text{(Insoluble)}}}{\overset{2\times 78}{2\mathrm{Al(OH)_3}}} + \underset{\substack{\text{Calcium}\\ \text{sulfate}\\ \text{(Soluble)}}}{\overset{3\times 136}{3\mathrm{CaSO_4}}} + \underset{\substack{\text{Carbon}\\ \text{dioxide}\\ \text{(Soluble)}}}{\overset{6\times 44}{6\mathrm{CO_2}}} + \overset{18\times 18}{18\mathrm{H_2O}} \tag{6–9}$$

The numbers above the chemical formulas are the combined molecular weights of the different substances and, therefore, denote the quantity of each one involved. The precipitation reaction given above also occurs with the addition of aluminum chloride ($AlCl_3$). The insoluble aluminum hydroxide is a gelatinous floc that settles slowly through the wastewater, sweeping out suspended material and producing other changes. The reaction is exactly analogous when magnesium bicarbonate is substituted for the calcium salt.

Because alkalinity in Eq. (6–9) is reported in terms of calcium carbonate ($CaCO_3$), the molecular weight of which is 100, the quantity of alkalinity required to react with 10 mg/L of alum is

$$(10.0\ \text{mg/L})\left[\frac{3(100\ \text{g/mole})}{(666.5\ \text{g/mole})}\right] = 4.5\ \text{mg/L}$$

If less than this amount of alkalinity is available, it must be added. Lime is commonly used for this purpose when necessary, but it is seldom required in the treatment of wastewater.

Lime. When lime alone is added as a precipitant, the principles of clarification are explained by the following reactions for carbonic acid [Eq. (6–10)] and alkalinity [Eq. (6–11)]:

$$\underset{\substack{\text{Carbonic}\\ \text{acid}\\ \text{(Soluble)}}}{\overset{44\text{ as }\mathrm{CO_2}}{\mathrm{H_2CO_3}}} + \underset{\substack{\text{Calcium}\\ \text{hydroxide}\\ \text{(Slightly}\\ \text{soluble)}}}{\overset{56\ (\text{as CaO})}{\mathrm{Ca(OH)_2}}} \rightleftarrows \underset{\substack{\text{Calcium}\\ \text{carbonate}\\ \text{(Somewhat}\\ \text{soluble)}}}{\overset{100}{\mathrm{CaCO_3}}} + \overset{2\times 18}{2\mathrm{H_2O}} \tag{6–10}$$

$$\underset{\substack{\text{Calcium}\\ \text{bicarbonate}\\ \text{(Soluble)}}}{\overset{100\ (\text{as }\mathrm{CaCO_3})}{\mathrm{Ca(HCO_3)_2}}} + \underset{\substack{\text{Calcium}\\ \text{hydroxide}\\ \text{(Slightly}\\ \text{soluble)}}}{\overset{56\text{ as CaO}}{\mathrm{Ca(OH)_2}}} \rightleftarrows \underset{\substack{\text{Calcium}\\ \text{carbonate}\\ \text{(Somewhat}\\ \text{soluble)}}}{\overset{2\times 100}{2\mathrm{CaCO_3}}} + \overset{2\times 18}{2\mathrm{H_2O}} \tag{6–11}$$

A sufficient quantity of lime must, therefore, be added to combine with all the free carbonic acid and with the carbonic acid of the bicarbonates (half-bound carbonic acid) to produce calcium carbonate. Much more lime is generally required when it is used alone than when sulfate of iron is also used (see the following discussion). Where industrial wastes introduce mineral acids or acid salts into the wastewater, these must be neutralized before precipitation can take place. Typical lime clarification facilities were shown on Fig. 6–1.

Ferrous Sulfate and Lime. In most cases, ferrous sulfate cannot be used alone as a precipitant because lime must be added at the same time to form a precipitate. When ferrous sulfate alone is added to wastewater the following reactions occur:

$$\overset{278}{\underset{\substack{\text{Ferrous}\\ \text{sulfate}\\ \text{(Soluble)}}}{\mathrm{FeSO_4{\cdot}7H_2O}}} + \overset{100(\text{as CaCO}_3)}{\underset{\substack{\text{Calcium}\\ \text{bicarbonate}\\ \text{(Soluble)}}}{\mathrm{Ca(HCO_3)_2}}} \rightleftarrows \overset{178}{\underset{\substack{\text{Ferrous}\\ \text{bicarbonate}\\ \text{(Soluble)}}}{\mathrm{Fe(HCO_3)_2}}} + \overset{136}{\underset{\substack{\text{Calcium}\\ \text{sulfate}\\ \text{(Soluble)}}}{\mathrm{CaSO_4}}} + \overset{7\times18}{\mathrm{7H_2O}} \tag{6–12}$$

$$\overset{178}{\underset{\substack{\text{Ferrous}\\ \text{bicarbonate}\\ \text{(Soluble)}}}{\mathrm{Fe(HCO_3)_2}}} \rightarrow \overset{4\times89.9}{\underset{\substack{\text{Ferrous}\\ \text{hydroxide}\\ \text{(Very slightly}\\ \text{soluble)}}}{\mathrm{Fe(OH)_2}}} + \underset{\substack{\text{Carbon}\\ \text{dioxide}\\ \text{(Soluble)}}}{\mathrm{CO_2}} \tag{6–13}$$

If sufficient alkalinity is not available, lime is often added in excess in conjunction with ferrous sulfate. The reaction of ferrous sulfate with lime is as follows

$$\overset{178}{\underset{\substack{\text{Ferrous}\\ \text{bicarbonate}\\ \text{(soluble)}}}{\mathrm{Fe(HCO_3)_2}}} + \overset{2\times56\text{ as CaO}}{\underset{\substack{\text{Calcium}\\ \text{hydroxide}\\ \text{(Slightly}\\ \text{soluble)}}}{\mathrm{2Ca(OH)_2}}} \rightleftarrows \overset{89.9}{\underset{\substack{\text{Ferrous}\\ \text{hydroxide}\\ \text{(Very slightly}\\ \text{soluble)}}}{\mathrm{Fe(OH)_2}}} + \overset{2\times100}{\underset{\substack{\text{Calcium}\\ \text{carbonate}\\ \text{(Somewhat}\\ \text{soluble)}}}{\mathrm{2CaCO_3}}} + \overset{2\times18}{\mathrm{2H_2O}} \tag{6–14}$$

The ferrous hydroxide can be oxidized to ferric hydroxide, the final form desired, by oxygen dissolved in the wastewater. The reaction is

$$\overset{89.9}{\underset{\substack{\text{Ferrous}\\ \text{hydroxide}\\ \text{(Very slightly}\\ \text{soluble)}}}{\mathrm{Fe(OH)_2}}} + \overset{1/4\times32}{\underset{\substack{\text{Oxygen}\\ \text{(Soluble)}}}{\mathrm{1/4O_2}}} + \overset{1/2\times18}{\mathrm{1/2\ H_2O}} \rightleftarrows \overset{106.9}{\underset{\substack{\text{Ferric}\\ \text{hydroxide}\\ \text{(Insoluble)}}}{\mathrm{Fe(OH)_3}}} \tag{6–15}$$

The insoluble ferric hydroxide is formed as a bulky, gelatinous floc similar to the alum floc. The alkalinity required for a 10 mg/L dosage of ferrous sulfate [see Eq. (6–12)] is

$$(10.0\text{ mg/L})\left[\frac{(100\text{ g/mole})}{(278\text{ g/mole})}\right] = 3.6\text{ mg/L}$$

The lime required (see Eq. 6–14) is

$$(10.0\text{ mg/L})\left[\frac{2(56\text{ g/mole})}{(278\text{ g/mole})}\right] = 4.0\text{ mg/L}$$

The oxygen required (see Eq. 6–15) is

$$(10.0\text{ mg/L})\left[\frac{(32\text{ g/mole})}{4\,(278\text{ g/mole})}\right] = 0.29\text{ mg/L}$$

Because the formation of ferric hydroxide is dependent on the presence of dissolved oxygen, the reaction given in Eq. (6–15) cannot be completed in most wastewaters, and, as a result, ferrous sulfate is not used commonly for wastewater.

Ferric Chloride. Because of the many problems associated with the use of ferrous sulfate, ferric chloride is the iron salt used most commonly in precipitation applications. When ferric chloride is added to wastewater the following reaction takes place:

$$\begin{array}{ccccccccc}
2\times 162.2 & & 3\times 100\text{ (as }CaCO_3) & & 2\times 106.9 & & & & \\
2FeCl_3 & + & 3Ca(HCO_3)_2 & \rightleftarrows & 2Fe(OH)_3 & + & 3CaCl_2 & + & 6CO_2 \\
\text{Ferric} & & \text{Calcium} & & \text{Ferric} & & \text{Calcium} & & \text{Carbon} \\
\text{chloride} & & \text{bicarbonate} & & \text{hydroxide} & & \text{chloride} & & \text{dioxide} \\
\text{(Soluble)} & & \text{(Soluble)} & & \text{(Insoluble)} & & \text{(Soluble)} & & \text{(Soluble)}
\end{array} \qquad (6\text{–}16)$$

Ferric Chloride and Lime. If lime is added to supplement the natural alkalinity of the wastewater, the following reaction can be assumed to occur:

$$\begin{array}{ccccccc}
2\times 162.2 & & 3\times 56\text{ (as CaO)} & & 2\times 106.9 & & 3\times 111 \\
2FeCl_3 & + & 3Ca(OH)_2 & \rightleftarrows & 2Fe(OH)_3 & + & 3CaCl_2 \\
\text{Ferric} & & \text{Calcium} & & \text{Ferric} & & \text{Calcium} \\
\text{chloride} & & \text{hydroxide} & & \text{hydroxide} & & \text{chloride} \\
\text{(Soluble)} & & \text{(Slightly} & & \text{(Insoluble)} & & \text{(Soluble)} \\
 & & \text{soluble)} & & & &
\end{array} \qquad (6\text{–}17)$$

Ferric Sulfate and Lime. The overall reaction that occurs when ferric sulfate and lime are added to wastewater may be represented as follows:

$$\begin{array}{ccccccc}
399.9 & & 3\times 56\text{ (as CaO)} & & 2\times 106.9 & & 3\times 136 \\
Fe_2(SO_4)_3 & + & 3Ca(OH)_2 & \rightleftarrows & 2Fe(OH)_3 & + & 3CaSO_4 \\
\text{Ferric} & & \text{Calcium} & & \text{Ferric} & & \text{Calcium} \\
\text{sulfate} & & \text{hydroxide} & & \text{hydroxide} & & \text{sulfate} \\
\text{(Soluble)} & & \text{(Slightly} & & \text{(Insoluble)} & & \text{(Soluble)} \\
 & & \text{soluble)} & & & &
\end{array} \qquad (6\text{–}18)$$

Chemically Enhanced Primary Treatment (CEPT)

The degree of clarification obtained when chemicals are added to untreated wastewater depends on the type and quantity of chemicals used, mixing times, and the care with which the process is monitored and controlled. With chemical precipitation, it is possible to remove 80 to 90 percent of the total suspended solids (TSS) including some colloidal particles and 50 to 80 percent of the BOD. Comparable removal values for well-designed and well-operated primary sedimentation tanks without the addition of chemicals are 50 to 70 percent of the TSS and 25 to 40 percent of the BOD. Enhanced removal of solids and BOD during primary treatment is a critical issue in energy management at wastewater treatment facilities. Solids from primary treatment have a high energy value, some of which can be recovered by anaerobic digestion or other thermal conversion processes (see Chap. 14). In addition, the removal of constituents in primary treatment that exert an oxygen demand reduces the amount of aeration energy required for secondary treatment. Thus, primary treatment has been

Table 6–4

Recommended surface loading rates for sedimentation tanks for various chemical suspensions

	Overflow rate			
	$m^3/m^2 \cdot d$		$gal/ft^2 \cdot d$	
Suspension	**Typical range**	**Peak hour**	**Typical range**	**Peak hour**
Alum floc[a]	30–70	80	700–1700	2000
Iron floc[a]	30–70	80	700–1700	2000
Lime floc[a]	35–80	90	900–2000	2200
Untreated wastewater	30–70	80	700–1700	2000

[a] Mixed with the settleable suspended solids in the untreated wastewater and colloidal or other suspended solids swept out by the floc.

Note: $m^3/m^2 \cdot d \times 24.5424 = gal/ft^2 \cdot d$.

identified as a key area of research in improving the sustainability of wastewater treatment processes.

Because of the variable characteristics of wastewater, the effectiveness of alternative coagulants and the required chemical dosages should be evaluated based on the results of bench- or pilot-scale tests. For example, dosages of $FeCl_3$ for coagulation of raw or screened wastewater range typically from about 15 to 40 mg/L, after a short reaction time anionic polymer may be added at a dosage of 0.1 to 1 mg/L to enhance floc development. Recommended surface loading rates for various chemical suspensions to be used in the design of the sedimentation facilities are given in Table 6–4.

Independent Physical-Chemical Treatment

In some localities, industrial wastewater has been found to be difficult to treat by biological means. In such situations, physical-chemical treatment in the absence of a biological treatment step may be an alternative approach. This method of treatment has met with limited success because of its lack of consistency in meeting discharge requirements, high costs for chemicals, handling and disposal of the great volumes of sludge resulting from the addition of chemicals, and numerous operating problems. Based on typical performance results of full scale plants using activated carbon, the activated carbon columns removed only 50 to 60 percent of the applied total BOD, and the plants did not meet consistently the effluent standards for secondary treatment. In some instances, substantial process modifications have been required to reduce the operating problems and meet performance requirements, or the process has been replaced by biological treatment. Because of these reasons, new applications of physical-chemical treatment for municipal wastewater are rare. Physical-chemical treatment is used more extensively for the treatment of industrial wastewater. Depending on the treatment objectives, the required chemical dosages and application rates should be determined from bench- or pilot-scale tests.

A flow diagram for the physical-chemical treatment of untreated wastewater is presented on Fig. 6–10. As shown, after first stage precipitation and pH adjustment by recarbonation (if required), the wastewater is passed through a granular medium filter to remove any residual floc and then through carbon columns to remove dissolved organic compounds. The filter is shown as optional, but its use is recommended to reduce the blinding and headloss buildup in the carbon columns. The treated effluent from the carbon column is usually chlorinated before discharge to the receiving waters.

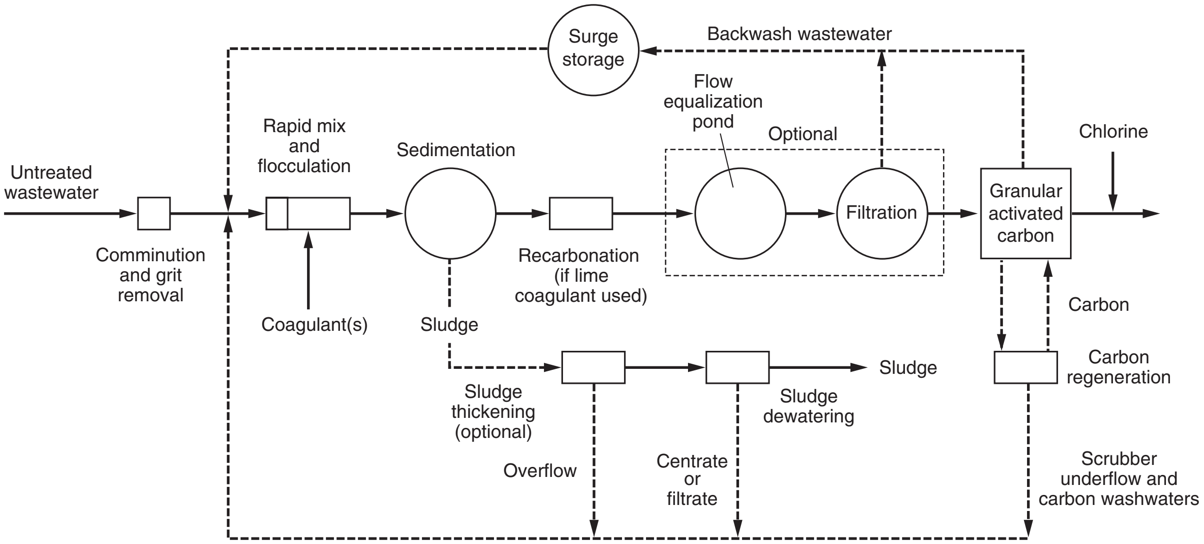

Figure 6–10

Typical flow diagram of an independent physical-chemical treatment plant.

Estimation of Sludge Quantities from Chemical Precipitation

The handling and disposal of the sludge resulting from chemical precipitation is one of the greatest difficulties associated with chemical treatment. Sludge is produced in great volume from most chemical precipitation operations, often reaching 0.5 percent of the volume of wastewater treated when lime is used. The computational procedures involved in estimating the quantity of sludge resulting from chemical precipitation with ferric chloride and lime are illustrated in Example 6–1.

EXAMPLE 6–1 **Estimation of Sludge Volume from Chemical Precipitation of Untreated Wastewater** Estimate the mass and volume of sludge produced from untreated wastewater without and with the use of ferric chloride for the enhanced removal of TSS. Also estimate the amount of lime required for the specified ferric chloride dose. Assume that 60 percent of the TSS is removed in the primary settling tank without the addition of chemicals, and that the addition of ferric chloride results in an increased removal of TSS to 85 percent. Assume that the following data apply to this situation:

1.	Wastewater flowrate, m^3/d	1000
2.	Wastewater TSS, mg/L	220
3.	Wastewater alkalinity as $CaCO_3$, mg/L	136
4.	Ferric chloride ($FeCl_3$) added, kg/1000 m^3	40
5.	Raw sludge properties	
	Specific gravity	1.03
	Moisture content, %	94

6. Chemical sludge properties (from Chap. 13)

Specific gravity	1.05
Moisture content, %	92.5

Solution

1. Compute the mass of TSS removed without and with chemicals.
   a. Determine the mass of TSS removed without chemicals.

$$M_{\text{TSS}} = \frac{0.6\,(220\ \text{g/m}^3)(1000\ \text{m}^3/\text{d})}{(10^3\ \text{g/1 kg})} = 132.0\ \text{kg/d}$$

   b. Determine the mass of TSS removed with chemicals.

$$M_{\text{TSS}} = \frac{0.85\,(220\ \text{g/m}^3)(1000\ \text{m}^3/\text{d})}{(10^3\ \text{g/1 kg})} = 187.0\ \text{kg/d}$$

2. Using Eq. (6–16), determine the mass of ferric hydroxide [$Fe(OH)_3$] produced from the addition of 40 kg/1000 m^3 of $FeCl_3$.

$$Fe(OH)_3\ \text{formed} = 40 \times \left(\frac{2 \times 106.9}{2 \times 162.2}\right) = 26.4\ \text{kg/1000 m}^3$$

3. Using Eq. (6–17), determine the mass of lime required to convert the ferric chloride to ferric hydroxide $Fe(OH)_3$.

$$\text{Lime required} = 40 \times \left(\frac{3 \times 56}{2 \times 162.2}\right) = 20.7\ \text{kg/1000 m}^3$$

$$\text{Lime required, expressed as alkalinity} = 20.7 \times \left(\frac{100}{56}\right) = 37\ \text{kg/1000 m}^3$$

$$\begin{aligned}\text{Alkalinity available per 1000 m}^3 &= (136\ \text{g/m}^3)(1000\ \text{m}^3)/(10^3\ \text{g/1 kg})\\ &= 136\ \text{kg/1000 m}^3\end{aligned}$$

   Because there is sufficient natural alkalinity no lime addition will be required.

4. Determine the total amount of sludge on a dry basis resulting from chemical precipitation.

   Total dry solids = 187 + 26.4 = 213.4 kg/1000 m^3

5. Determine the total volume of sludge resulting from chemical precipitation, assuming that the sludge has a specific gravity of 1.05 and a moisture content of 92.5 percent.

$$V_s = \frac{(213.4\ \text{kg/d})}{(1.05)(10^3\ \text{kg/m}^3)(1 - 0.925)} = 2.71\ \text{m}^3/\text{d}$$

6. Determine the total volume of sludge without chemical precipitation, assuming that the sludge has a specific gravity of 1.03 and a moisture content of 94 percent.

$$V_s = \frac{(132\ \text{kg/d})}{(1.03)(10^3\ \text{kg/m}^3)(1 - 0.94)} = 2.13\ \text{m}^3/\text{d}$$

7. Prepare a summary table of the sludge mass and volume produced without and with chemical precipitation.

	Sludge	
Treatment	Mass, kg/d	Volume, m^3/d
Without chemical precipitation	132.0	2.13
With chemical precipitation	213.4	2.71

Comment The magnitude of the sludge disposal problem when chemicals are used is evident from a review of the data presented in the summary table given in Step 7. Even larger volumes of sludge are produced when lime is used as the primary precipitant (see Example 6–2).

6–4 CHEMICAL PHOSPHORUS REMOVAL

Phosphorus in wastewater can be incorporated into either biological solids (e.g., microorganisms) or removed by the addition of chemicals. The fundamentals of biological phosphorus removal are considered in Chap. 8. The chemical removal of phosphorus is introduced in this section. The topics to be considered include (1) the chemicals used for phosphorus removal, (2) phosphorus removal from liquid stream with metal salts, (3) phosphorus removal from the liquid stream with calcium, and (4) strategies for chemical phosphorus removal. The removal of phosphorus from return flows and sidestreams is considered in Chap. 15. General consideration that may affect the implementation of chemical phosphorus removal systems are summarized in Table 6–5.

Chemicals Used for Phosphorus Removal

The principal chemicals used for the removal of phosphorus from the liquid stream include: aluminum [Al(lll)], ferric iron [Fe(lll)], ferrous iron [Fe(ll)], and calcium [Ca(ll)]. Polymers have been used effectively in conjunction with metal salts and lime as flocculant

Table 6–5

Factors affecting the implementation of chemical phosphorus removal[a]

- Influent phosphorus concentration and speciation
- Wastewater suspended solids
- Alkalinity
- Chemical cost (including transportation)
- Reliability of chemical supply
- Sludge handling facilities
- Ultimate disposal methods
- Compatibility with other treatment processes
- Required effluent phosphorus concentration
- Seasonal permit requirements
- Efficacy of other options (e.g., biological P removal)
- Management of sidestreams
- Phosphorus recovery objectives

[a] Adapted in part from Kugelman (1976).

aids. Because the chemistry of phosphate removal with aluminum and iron is quite different than with calcium, the two different types of chemical removal are considered separately in the following discussion.

Phosphate Removal with Aluminum and Iron. The removal of phosphate by the addition of metal salts is thought to occur in a number of different ways, including (WEF, 1998, 2011):

1. Formation of hydrous ferric or aluminum oxides which serve as a substrate for phosphate adsorption
2. Incorporation of phosphate into the hydrous oxide structure
3. Formation of mixed cation phosphates (e.g., Fe or Al phosphates)
4. Formation of ferric or aluminum phosphate

It should be noted that phosphate removal is only accomplished if, after the formation of the above compounds, they are removed by sedimentation (precipitation) or by filtration.

Historically, the following two reactions were used to describe the formation of ferric or aluminum phosphate.

Phosphate precipitation with aluminum:

$$\mathrm{Al}^{3+} + \mathrm{H}_n\mathrm{PO}_4^{3-n} \rightleftarrows \mathrm{AlPO}_4\downarrow + n\mathrm{H}^+ \tag{6–19}$$

Phosphate precipitation with iron:

$$\mathrm{Fe}^{3+} + \mathrm{H}_n\mathrm{PO}_4^{3-n} \rightleftarrows \mathrm{FePO}_4\downarrow + n\mathrm{H}^+ \tag{6–20}$$

Unfortunately, these reactions are deceptively simple and generally do not apply. It has been found that ferric phosphate occurs near a pH value of 3.5 and does not occur above pH 5 (Smith et al., 2008). Further, any precipitation reaction must be considered in light of the many competing reactions and their associated equilibrium constants, and the effects of alkalinity, pH, trace elements, and ligands found in wastewater. Based on more recent studies (Sedlak, 1991; WEF, 2011) it appears that the following overall reaction may provide a better description of what actually happens when metal salts are added for phosphorus removal.

$$r\mathrm{Me}^{3+} + \mathrm{HPO}_4^{-} + (3r - 1)\mathrm{OH}^- \rightarrow \mathrm{Me}_r\cdot\mathrm{H}_2\mathrm{PO}_4(\mathrm{OH})_{3r-1}(s) \tag{6–21}$$

where $r = 1.6$ for Fe(III) and 0.8 for Al(III).

However, because of the many competing reactions, Eq. (6–21) cannot be used to estimate the required chemical dosages directly. Therefore, dosages are generally established on the basis of bench-scale tests, occasionally by full-scale tests, especially if polymers are used, and from data from other operating treatment plants. For example, for equimolar initial concentrations of Al(III), Fe(III), and phosphate, the total concentration of soluble phosphate in equilibrium with both insoluble FePO_4 and AlPO_4 is shown on Fig. 6–11. The solid lines trace the concentration of residual soluble phosphate after precipitation. Metal phosphates are precipitated within the shaded area; mixed complex polynuclear species are formed outside of the shadowed area toward higher and lower pH values.

Phosphate Removal with Calcium. Calcium is usually added in the form of lime $\mathrm{Ca(OH)_2}$. From the equations presented previously, it will be noted that when lime is added to water it reacts with the natural bicarbonate alkalinity to precipitate $\mathrm{CaCO_3}$. As the pH value of the wastewater increases beyond about 10, excess calcium ions will then react

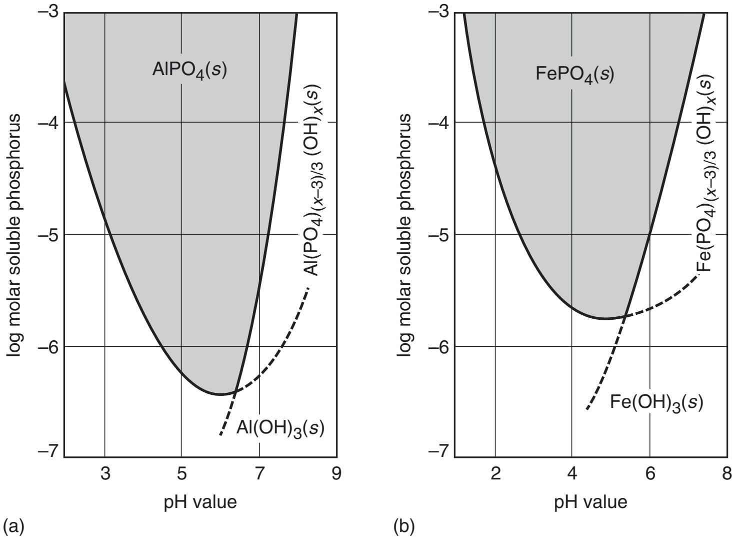

Figure 6–11

Concentration of aluminum and ferric phosphate in equilibrium with soluble phosphorus:
(a) Al(III)-phosphate;
(b) Fe(III)-phosphate.

with the phosphate, as shown in Eq. (6–22), to precipitate hydroxylapatite $Ca_{10}(PO_4)_6(OH)_2$. In practice, partial removal of phosphate has been accomplished by adding lime upstream of primary clarifiers to a target pH around 9.

$$10Ca^{2+} + 6PO_4^{3-} + 2OH^- \rightleftarrows \underset{\text{Hydroxylapatite}}{Ca_{10}(PO_4)_6(OH)_2} \tag{6–22}$$

Because of the reaction of lime with the alkalinity of the wastewater, the quantity of lime required will, in general, depend primarily on the alkalinity of the wastewater (see Fig. 6–12).

Estimate Chemical Requirements for Phosphate Removal. The chemical requirement for the removal of phosphate with metal salts and calcium are as follows.

For Aluminum and Iron.

$$Al_{dose} = (Al/P)(C_{P,in} - C_{P,res})[(26.98\ g/mole\ Al)/(30.97\ g/mole\ P)] \tag{6–23}$$

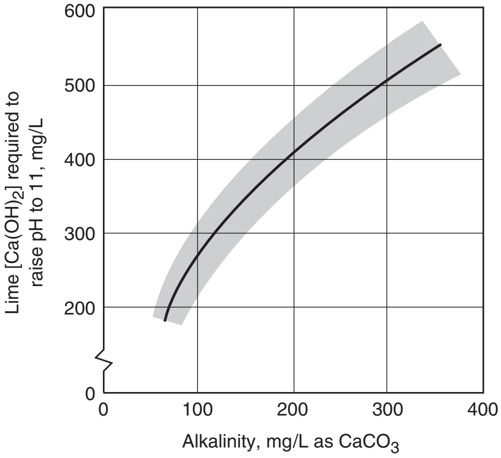

Figure 6–12

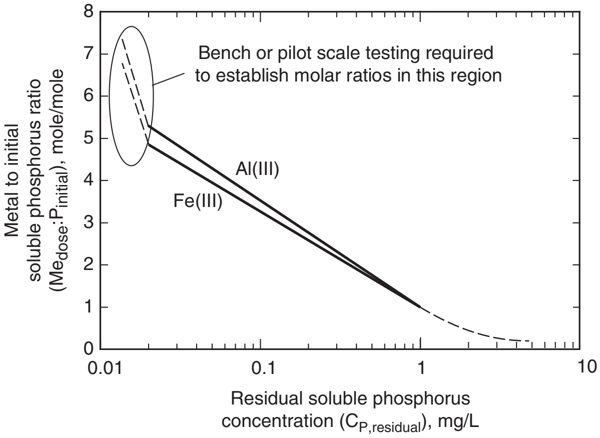
Lime dosage required to raise the pH to 11 as a function of untreated wastewater alkalinity.

Figure 6–13

Soluble phosphorus removal by aluminum and iron addition. (Adapted from Szabo et al., 2008.)



$$\text{Fe(III)}_{\text{dose}} = (\text{Fe/P})(C_{\text{P,in}} - C_{\text{P,res}})[(55.85\ \text{g/mole Fe})/(30.97\ \text{g/mole P})] \tag{6–24}$$

where $C_{p,in}$ = influent phosphate concentration, mg/L
$C_{p,res}$ = residual phosphate concentration, mg/L

The alum or ferric dose corresponds to the total amount that would be added for the removal of orthophosphate across the treatment plant. Molar ratios for aluminum and iron are given on Fig. 6–13 for various levels of residual orthophosphate. Typically, dosages of aluminum and iron salts on a molar ratio basis usually fall in the range of 1 to 3 if the residual phosphorus in the secondary effluent is on the order of 0.5 mg/L. The exact application rate is determined by on-site testing and varies with the characteristics of the wastewater and the desired variability in phosphorus removal rates.

For Calcium. The quantity of lime required to precipitate the phosphorus in wastewater is typically about 1.4 to 1.5 times the total alkalinity expressed as $CaCO_3$. When lime is added to raw wastewater or to secondary effluent, pH adjustment is usually required before subsequent treatment or disposal. Recarbonation with carbon dioxide (CO_2) is used to lower the pH value. Because of the additional expense associated with the use of lime, metal salts are now used most commonly for the chemical removal of phosphorus.

EXAMPLE 6–2 Determination of Ferric Chloride Dosage for Phosphorus Removal

Determine the amount of ferric chloride required to precipitate phosphorus from untreated wastewater with the characteristics given below. Also determine the required ferric chloride storage capacity if a 15 d supply is to be stored at the treatment facility and the added quantity of sludge generated from the ferric chloride addition.

1. Wastewater flowrate, m^3/d	3800
2. Wastewater TSS, mg/L	220
3. TSS removal without iron addition, %	60
4. TSS removal with iron addition, %	75
5. Influent total P, g/m^3	7

6.	Influent PO_4^{3-} as P, mg/L	5
7.	Effluent PO_4^{3-} as P, mg/L	0.1
8.	Wastewater alkalinity as $CaCO_3$, mg/L	240
9.	Ferric chloride solution, %	37
10.	Ferric chloride, unit weight	1.35 kg/L
11.	Raw sludge properties	
	Specific gravity	1.03
	Moisture content, %	94
12.	Chemical sludge properties (from Chap. 13)	
	Specific gravity	1.05
	Moisture content, %	92.5

Solution

1. Determine the weight of iron required to remove orthophosphate.
   a. From Fig. 6–13 for an effluent PO_4^{3-} concentration of 0.1 mg/L the required (Fe/P) mole ratio is approximately 3.3.
   b. Using Eq. 6–24, the required ferric chloride dose is

$$\text{Fe(III)}_{\text{dose}} = (\text{Fe/P})(C_{\text{P,in}} - C_{\text{P,res}})[(55.85\,\text{g/mole Fe})/(30.97\,\text{g/mole P})]$$

Substitute known values and solve for the dose

$$\begin{aligned}\text{Fe(III)}_{\text{dose}} &= (3.3)(5 - 0.1)[(55.85\text{ g/mole Fe})/(30.97\text{g/mole P})]\\ &= 29.2\text{ mg/L}\end{aligned}$$

2. Determine primary effluent P concentration.

$$\text{P, mg/L} = 7 - (5 - 0.1) = 2.1\text{ mg/L}$$

3. Determine the amount of ferric iron required per day.

$$\text{Fe Dose} = (3800\text{ m}^3\text{/d})(29.2\text{ mg/L})(1\text{ kg/}10^3\text{ g}) = 111.0\text{ kg/d}$$

4. Determine the amount of ferric chloride solution required per day and the 15 d storage requirement.
   a. Determine the percent ferric iron in $FeCl_3$.

$$\text{Percent Fe in FeCl}_3 = (55.85/162.3) \times 100 = 34.4\%$$

   b. Determine amount of a 34.4% solution of ferric chloride required per day.

$$\text{FeCl}_3\text{ solution} = [(111.0\text{ kg/d})/34.4](100) = 322.7\text{ kg/d}$$

   c. Determine volume of required $FeCl_3$ solution per day.

$$\text{FeCl}_3\text{ volume} = [(322.7\text{ kg/d})/0.0.37 \times 1.35\ ](1\text{ L/kg}) = 646.0\text{ L/d}$$

   d. Determine 15-d storage requirement based on average flowrate.

$$\text{15-d storage requirement} = (646.0\text{ L/d})(1\text{ m}^3/10^3\text{ L})(15) = 10.3\text{ m}^3$$

5. Determine the total mass of sludge on a dry basis resulting from chemical precipitation.
   a. Estimate the additional TSS removal resulting from the addition of $FeCl_3$ for P removal.

$$\begin{aligned}\text{Additional sludge} &= (0.15)(220\text{ g/m}^3)\ (3800\text{ m}^3\text{/d})(1\text{ kg/}10^3\text{ g})\\ &= 125.4\text{ kg/d}\end{aligned}$$

   b. Estimate the additional sludge resulting from the precipitate formed with P using Eq. (6–21).

$$1.6\text{Fe}^{3+} + \text{HPO}_4^{-} + 3.8\text{OH} \rightarrow \text{Fe}_{1.6}\cdot\text{H}_2\text{PO}_4(\text{OH})_{3.8}(\text{s})$$

Fe dose = (29.2 mg Fe/L)(1 g/10^3 mg)/(55.85 g/mole) = 0.52×10^{-3} mole/L

P removed = [(5 − 0.1) mg P/L)](1 g/10^3 mg)/(30.97 g/mole)
= 0.16×10^{-3} mole/L

$Fe_{1.6} \cdot H_2PO_4(OH)_{3.8}$ sludge = (0.16×10^{-3} mole/L)(251 g/mole)(10^3 mg/1 g)
= 40.2 mg/L

c. Estimate the additional sludge resulting from $Fe(OH)_3$.

Excess Fe added = 0.52×10^{-3} mole/L – 1.6 (0.16×10^{-3} mole/L)
= 0.264×10^{-3} mole/L

$Fe(OH)_3$ sludge = (0.264×10^{-3} mole/L)(106.8 g/mole)(10^3 mg/1 g)
= 28.2 mg/L

d. Estimate total chemical sludge resulting $FeCl_3$ addition.

Excess sludge = 40.2 mg/L + 28.2 mg/L = 68.4 mg/L

Excess sludge = (3800 m^3/d)(68.4 mg/L)(1 kg/10^3 g) = 259.9 kg/d

d. Estimate total excess sludge resulting $FeCl_3$ addition.

Total excess sludge = 125.4 kg/d + 259.9 kg/d = 385.3 kg/d

6. Compare total sludge production without and with chemical addition.
   a. Without chemical addition

   Sludge = (3800 m^3/d)(220.0 mg/L)(0.6)(1 kg/10^3 g) = 501.6 kg/d

   b. Total with chemical addition

   Total = 501.6 kg/d + 385.3 kg/d = 886.9 kg/d

7. Determine the total volume of sludge without chemical precipitation, assuming that the sludge has a specific gravity of 1.03 and a moisture content of 94 percent.

$$V_s = \frac{(501.6 \text{ kg/d})}{(1.03)(10^3 \text{ kg/m}^3)(0.06)} = 8.1 \text{ m}^3\text{/d}$$

8. Determine the total volume of sludge resulting from chemical precipitation, assuming that the sludge has a specific gravity of 1.05 and a moisture content of 92.5 percent.

$$V_s = \frac{(886.9 \text{ kg/d})}{(1.05)(10^3 \text{ kg/m}^3)(0.075)} = 11.3 \text{ m}^3\text{/d}$$

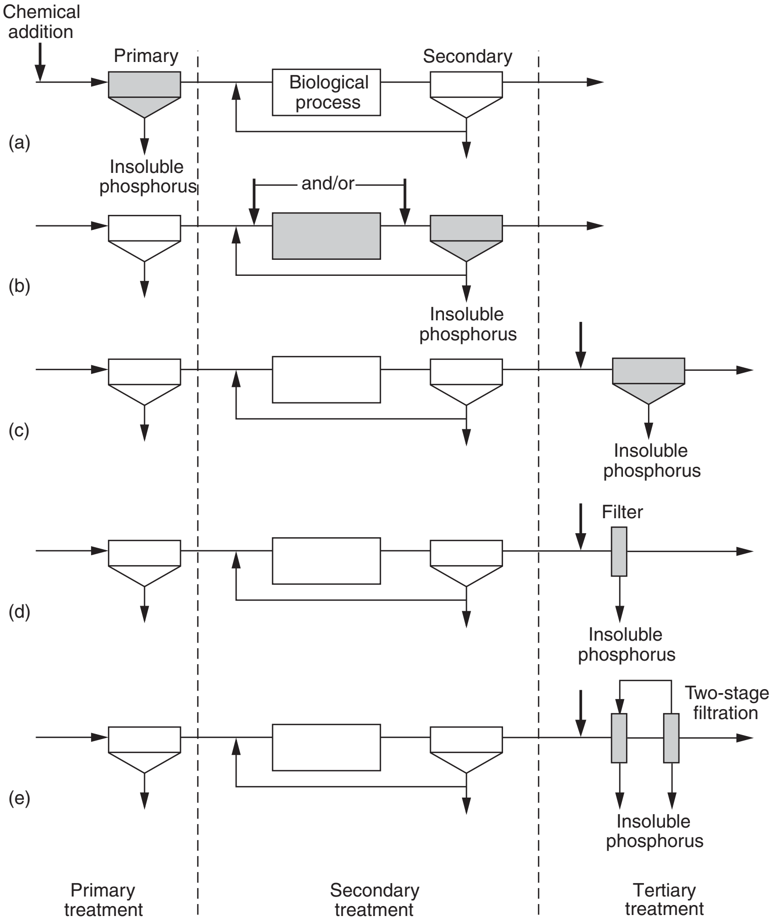
9. Prepare a summary table of sludge masses and volumes without and with chemical precipitation.

	Sludge	
Treatment	Mass, kg/d	Volume, m^3/d
Without chemical precipitation	501.6	8.1
With chemical precipitation	886.9	11.3

Comment The additional BOD and TSS removals afforded by chemical addition to primary treatment may also solve overloading problems on downstream biological systems, or may allow seasonal or year-round nitrification, depending on biological system designs. Alternatively, the total amount of ferric chloride could have been added at multiple locations.

Figure 6–14

Addition of chemicals at a single dosing point at various locations for phosphorus removal: (a) before primary sedimentation, (b) before and/or following biological treatment, (c) following secondary treatment, (d) chemical addition prior to single-stage filtration, and (e) chemical addition prior to dual-stage filtration.



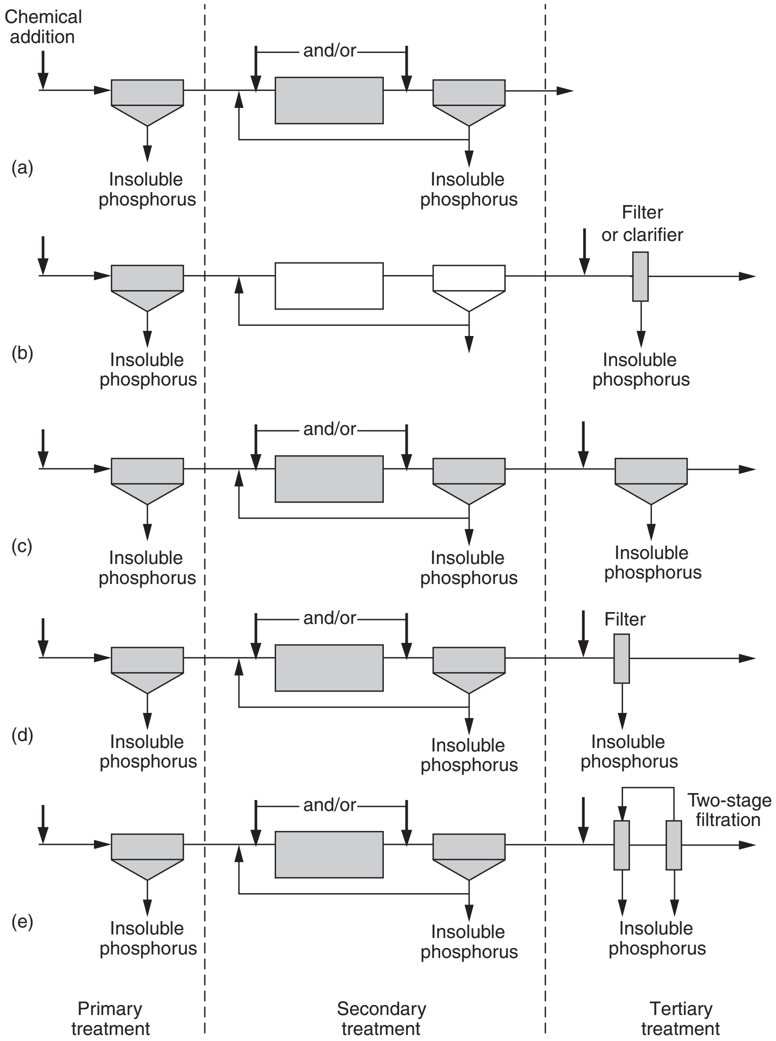
Phosphorus Removal from the Liquid Stream with Metal Salts

Phosphorus is removed from the liquid stream, as noted above, through a combination of precipitation, adsorption, exchange, and agglomeration followed by collection and removal with the process sludge. Metal salt, as illustrated on Figs. 6–14 and 6–15, can be added at a variety of different points in the treatment process, but because polyphosphates and organic phosphorus are less easily removed than orthophosphorus, adding aluminum or iron salts after secondary treatment (where organic phosphorus and polyphosphorus are transformed into orthophosphorus) may be necessary for the most complete removal of residual phosphorus. A number of the important features of adding metal salts and polymers at different points in the treatment process are discussed in this section.

Metal Salt Addition to Primary Sedimentation Tanks. When aluminum or iron salts are added to untreated wastewater, they react with the soluble orthophosphate to produce a precipitate. Organic phosphorus and polyphosphate are also removed partially by more complex reactions and by adsorption onto floc particles. The insolubilized

Figure 6–15

Addition of chemicals at multiple dosing points in a treatment process for phosphorus removal: (a) before primary and before and/or after biological treatment; (b) before primary and before tertiary treatment; (c), (d) and (e) at several locations in a treatment process (known as "split treatment").



phosphorus, as well as considerable quantities of BOD and TSS, are removed from the system as primary sludge. Adequate initial mixing and flocculation are necessary upstream of primary facilities, whether separate basins are provided or existing facilities are modified to provide these functions (Lijklema, 1980). Polymer addition may be required to aid in settling. In low alkalinity waters, the addition of a base is sometimes necessary to keep pH in the 5 to 7 range.

Metal Salt Addition to Secondary Treatment. Metal salts can be added in the influent to the activated sludge process, the activated sludge aeration tank, or the final clarifier influent channel. In trickling filter systems, the salts are added to the primary effluent or the trickling filter effluent which is to be recirculated. Multipoint additions have also been used. Theoretically, the minimum solubility of $AlPO_4$ occurs at about pH 6.3, and that of $FePO_4$ occurs at about pH 5.3; however, practical applications have yielded good phosphorus removal anywhere in the range of pH 6.5 to 7.0, which is compatible with most biological treatment processes. The use of ferrous salts is limited because they produce low phosphorus levels only at high pH values. In low alkalinity waters, either sodium aluminate and alum or ferric plus lime, or both, can be used to maintain the pH higher than 5.5. Improved settling and lower effluent BOD result from chemical addition, particularly if polymer is also added to the final clarifier.

Metal Salt Addition to Secondary Clarifiers. In certain cases, such as trickling filtration and extended aeration activated sludge processes, solids may not flocculate and settle well in the secondary clarifier. This settling problem may become acute in plants that are overloaded. The addition of aluminum or iron salts will cause the precipitation of metallic hydroxides or phosphates, or both. Aluminum and iron salts, along with certain organic polymers, can also be used to coagulate colloidal particles and to improve removals on filters. The resultant coagulated colloids and precipitates will settle readily in the secondary clarifier, reducing the TSS in the effluent and effecting phosphorus removal.

Metal Salt Addition to Effluent Filtration. Depending on the quality of the settled secondary effluent, chemical addition has been used to improve the performance of effluent filters. Chemical addition has also been used to achieve specific treatment objectives including the removal of specific contaminants such as phosphorus, metal ions, and humic substances. The removal of phosphorus by chemical addition to the contact filtration process is used in many parts of the country to remove phosphorus from wastewater treatment plant effluents which are discharged to sensitive water bodies. A two-stage filtration process (see Table 11–10 and discussion in Chap. 11) has also proven to be effective for the removal of phosphorus.

Phosphorus Removal from the Liquid Stream with Calcium

The use of calcium (lime) for phosphorus removal is declining because of (1) the substantial increase in the mass of sludge to be handled compared to metal salts and (2) the operation and maintenance problems associated with the handling, storage, and feeding of lime. When lime is used, the principal variables controlling the dosage are the degree of removal required and the alkalinity of the wastewater. The operating dosage is usually determined by on-site testing. Lime has been used customarily either as a precipitant in the primary sedimentation tanks or following secondary clarification.

Lime Addition to Primary Sedimentation Tanks. Both low and high lime treatment can be used to precipitate a portion of the phosphorus (usually about 65 to 80 percent). When lime is used, both the calcium and the hydroxide react with the orthophosphorus to form an insoluble hydroxyapatite [$Ca_5(OH)(PO_4)_3$]. A residual phosphorus level of 1.0 mg/L can be achieved with the addition of effluent filtration facilities to which chemicals can be added. In the high lime system, sufficient lime is added to raise the pH to about 11. After precipitation, the effluent must be recarbonated before biological treatment. In activated sludge systems, the pH of the primary effluent should not exceed 9.5 or 10; higher pH values can result in biological process upsets. In the trickling filter process, the carbon dioxide generated during treatment is usually sufficient to lower the

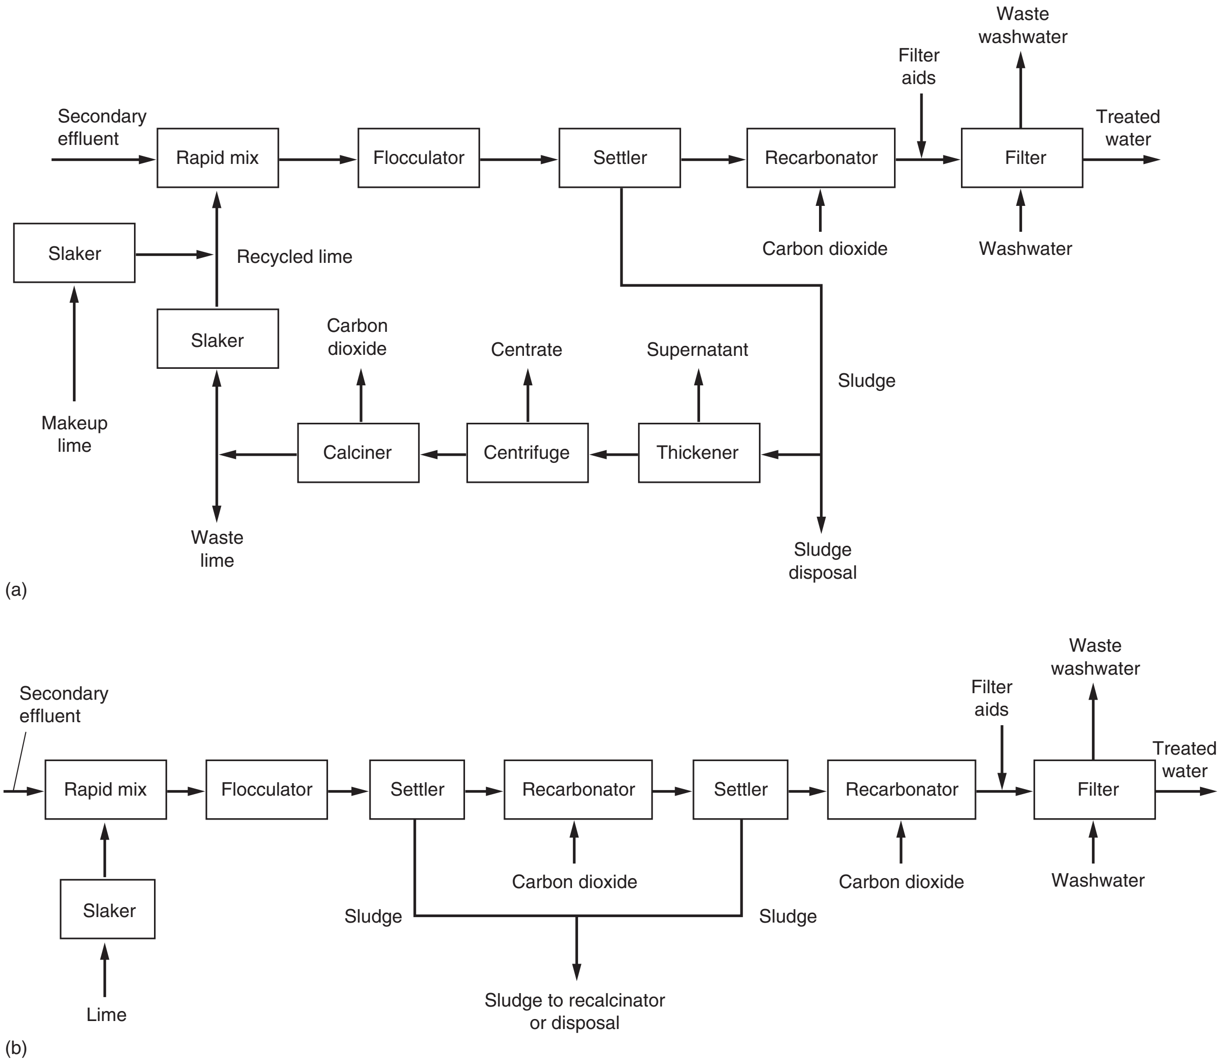


Figure 6–16

Typical lime treatment process flow diagrams for phosphorus removal: (a) single-stage system and (b) two-stage system.

pH without recarbonation. The dosage for low lime treatment is usually in the range of 75 to 250 mg/L as $Ca(OH)_2$ at pH values of 8.5 to 9.5. In low lime systems, however, the conditions required for precipitation are more specialized; the Ca^{2+}/Mg^{2+} mole ratio is $\leq 5/1$ (Sedlak, 1991).

Lime Addition Following Secondary Treatment. Lime can be added to the waste stream after biological treatment to reduce the level of phosphorus and TSS. Single-stage process and two-stage process flow diagrams for lime addition are shown on Fig. 6–16. On Fig. 6–16(a), a single-stage lime precipitation process is used for the treatment of secondary effluent. In the first stage clarifier of the

Figure 6–17

Large reactor clarifier used for the lime precipitation of secondary effluent. The settled effluent is treated further by microfiltration before reuse in industrial applications.

two-stage process shown on Fig. 6–16(b), sufficient lime is added to raise the pH above 11 to precipitate the soluble phosphorus as basic calcium phosphate (apatite). The calcium carbonate precipitate formed in the process acts as a coagulant for TSS removal. An example of a large lime precipitation unit is shown on Fig. 6–17. The excess soluble calcium is removed in the second stage clarifier as a calcium carbonate precipitate by adding carbon dioxide gas to reduce the pH to about 10. Generally, there is a second injection of carbon dioxide to the second stage effluent to reduce the formation of scale. To remove the residual levels of TSS and phosphorus, the secondary clarifier effluent is passed through a multimedia filter or a membrane filter. Care should be taken to limit excess calcium in the filter feed to ensure cementing of the filter media will not occur.

Lime Recalcination. Although lime recalcination lowers chemical costs, it is a feasible alternative only for large plants. Where a lime recovery system is required for a cost-effective operation, it includes a thermal regeneration facility, which converts the calcium carbonate in the sludge to lime by heating to 980°C (1800°F). The carbon dioxide from this process or other on-site stack gas (containing 10 to 15 percent carbon dioxide) is generally used as the source of recarbonation for pH adjustment of the wastewater.

Strategies for Chemical Phosphorus Removal

Depending on the characteristics of the wastewater and treatment facilities a number different operating strategies can be employed for the chemical removal of phosphorus. In general, the strategies can be divided into categories: single point addition or multiple points of addition. The advantages and disadvantages of each of these approaches for the removal of phosphorus are summarized in Table 6–6. It is recommended that each alternative point of application be evaluated carefully.

Table 6–6

Single and multiple chemical dosing strategies for the removal of phosphorus from the liquid stream with metal salts[a]

Point of application	Advantages	Disadvantages
Single point of application (see Fig. 6–14)		
Primary	Applicable to most plants; increased BOD and suspended solids removal; can achieve good removal of influent phosphate at Me:P ratios of 0.5 to 1.	Polymer may be required for flocculation; sludge more difficult to dewater than primary sludge; must leave residual P for biological process.
Secondary bioreactor	Improved stability of activated sludge; polymer not required.	Overdose of metal may cause low pH toxicity; with low alkalinity wastewaters, a pH control system may be necessary; cannot use lime because of excessive pH; inert solids added to activated sludge mixed liquor, reducing the percentage of volatile solids.
Secondary clarifier	Improved settling in secondary clarifier.	Metal carry over may impact disinfection with UV.
Tertiary clarifier	Low effluent phosphorus achievable at high Me:P ratios.	High capital cost.
Tertiary filter	Low cost; can be combined with the removal of residual suspended solids.	Length of filter run may be reduced with single-stage filtration. Additional expense with two-stage filtration process.
Multiple points of addition (see Fig. 6–15)		
Two locations (e.g., raw wastewater and secondary sedimentation or settled secondary effluent before filtration	Enhanced control over phosphorus concentration in effluent. Multiple dosing method is most suitable for locations with restrictive effluent discharge limits.	High capital cost, as two separate chemical dosing stations are required. Metal carry over may impact disinfection with UV.
Three or more locations.	As above.	As above.

6–5 CHEMICAL FORMATION OF STRUVITE FOR AMMONIUM AND PHOSPHORUS REMOVAL

The removal of phosphorus from wastewater by precipitation was considered in the previous section. The combined removal of ammonium and phosphorus is considered in this section. In wastewater treatment, one of the more serious problems in the processing of primary sludge and waste activated sludge in anaerobic digesters is the formation of magnesium ammonium phosphate hexahydrate, $MgNH_4PO_4 \cdot 6H_2O$, commonly known as struvite. Other precipitates that occur in anaerobic digesters include calcium phosphate [$Ca(PO_4)_2 \cdot nH_2O$], vivianite [$Fe_3(PO_4)_2 \cdot 8H_2O$], and variscite ($AlPO_4 \cdot 2H_2O$).

Figure 6–18

Image of struvite precipitation in wastewater piping.

The formation and accumulation of struvite crystals and vivianite can cause problems in process pipelines, pumps, and dewatering facilities (see Fig. 6–18). The formation of struvite, the means to control the formation of struvite, and the recovery of nitrogen and phosphorus using the basic principles of struvite formation are considered in this section. The practical application of struvite formation for nutrient recovery is considered in Chap. 15.

Chemistry of Struvite Formation

During anaerobic digestion, magnesium, ammonium, and phosphate are released from the digestion of primary and waste activated sludge. If the concentrations of soluble magnesium, ammonium, and orthophosphate exceed the solubility limit for the formation of struvite at a given pH, crystals of struvite will form. The formation of struvite can be described by the following general reaction.

$$Mg^{2+} + NH_4^+ + PO_4^{3-} + 6H_2O \rightleftarrows MgNH_4PO_4 \cdot 6H_2O \tag{6–25}$$

Although the struvite reaction is deceptively simple, the process is complex depending on the ionic strength, pH, alkalinity, and temperature of the waste stream. Once initiated, the growth of struvite crystals will continue to form as long as favorable conditions exist including the presence of the three constituents in a molar ratio of 1 : 1 : 1 of Mg^{2+} : NH_4^+ : PO_4^{3-}. The corresponding solubility product constant for struvite is given by the following equation,

$$\{Mg^{2+}\}\{NH_4^+\}\{PO_4^{3-}\} = K_{so} \quad \text{(struvite)} \tag{6–26}$$

where the term within the ellipses corresponds to the ion activity concentration of the constituent.

The principal side reactions involved in the precipitation of struvite are summarized in Table 6–7. The conditional solubility product, P_s, used to account for side reactions involving the constituents, ion activity, and ionic strength is given by the following expression.

Table 6–7

Chemical reactions involved in struvite chemistry and expressions for the total concentration of magnesium, ammonium, and phosphate in solution.

Reaction	p*K* Range	p*K* Typical
$NH_4^+ \rightleftarrows NH_{3(aq)} + H^+$	9.25–9.3	9.25
$H_3PO_4 \rightleftarrows H_2PO_4^- + H^+$	2.1	2.1
$H_2PO_4^- \rightleftarrows H_2PO_4^{2-} + H^+$	7.2	7.2
$HPO_4^{2-} \rightleftarrows PO_4^{3-} + H^+$	12.3	12.3
$MgOH^+ \rightleftarrows Mg^{2+} + OH^-$	2.56	2.56
$MgH_2PO_4^+ \rightleftarrows H_2PO_4^- + Mg^{2+} + OH^-$	0.45	0.45
$MgHPO_4 \rightleftarrows H_2PO_4^{2-} + Mg^{2+}$	2.91	2.91
$MgPO_4^- \rightleftarrows PO_4^{3-} + Mg^{2+}$	4.8	4.8
$MgNH_4PO_4{\cdot}6H_2O \rightleftarrows Mg^{2+} + NH_4^+ + PO_4^{2+} + Mg^{2+} + H_2O$	12.6–13.26	13.0
$AlPO_{4(s)} \rightleftarrows Al^{3+} + PO_4^{3-}$	21	21
$FePO_{4(s)} \rightleftarrows Fe^{3+} + PO_4^{3-}$	21.9–23	22.0

$C_{T,Mg} = [Mg^{2+}] + [MgOH^+] + [MgH_2PO_4^+] + [MgHPO_4] + [MgPO_4^-]$

$C_{T,NH_3} = [NH_4^+] + [NH_3]$

$C_{T,P} = [PO_4^{3-}] + [H_3PO_4] + [H_2PO_4^-] + [HPO_4^{2-}] + [MgH_2PO_4^+] + [MgHPO_4] + [MgPO_4^-]$

$$P_s = C_{T,\,Mg}C_{T,\,NH_3}C_{T,\,PO_4} = \frac{K_{so}}{\alpha_{Mg^{2+}}\alpha_{NH_4^+}\alpha_{PO_4^{3-}}\gamma_{Mg^{2+}}\gamma_{NH_4^+}\gamma_{PO_4^{3-}}} \tag{6–27}$$

where C_{Mg}, C_{NH_3}, C_{PO_4} = total analytical concentration of individual constituents

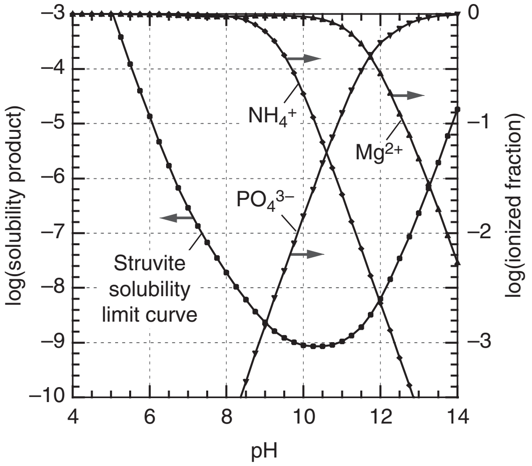
$\alpha_{Mg^{2+}}$, $\alpha_{NH_4^+}$, $\alpha_{PO_4^{3-}}$ = ionization fraction of the individual constituents

$\gamma_{Mg^{2+}}$ $\gamma_{NH_4^+}$ $\gamma_{PO_4^{3-}}$ = ionic strength of the individual constituents

The ionization fraction is defined as the ratio of the free constituent concentration of magnesium, ammonium, and phosphate over the total concentration in solution (e.g., $\alpha = [Mg^{2+}]/C_{T,\,Mg}$). Expressions for the total concentration for magnesium, ammonium, and phosphate in solution are also given in Table 6–7. Using Eq. (6–27), the equations and corresponding pK values given in Table 6–7 for the various equilibrium relationships, the minimum solubility for struvite, as illustrated in Fig. 6–19, occurs at a pH of about 10.3 (Ohlinger et al., 1998).

Figure 6–19

Plot of struvite solubility limit curve and ionization fraction developed using MINTEQA2 with an ionic strength value set constant at μ = 0.1 (Ohlinger et al., 1998).



The struvite solubility limit curve shown on Fig. 6–19 can be used to determine if struvite formation is likely to occur. The P_s value is calculated from the analytical concentrations of magnesium, ammonium, and phosphate using the left side of Eq. 6–27, and then plotted along with the solubility limit curve corresponding to the relevant ionic strength. If the P_s values fall outside of the area bounded within the curve, then struvite precipitation is not expected to occur.

The chemical system composed of the species and equilibrium constants presented in Table 6–7 can be modeled using chemical speciation software such as MINEQL+ or MINTEQA2. The model output, consisting of constituent concentration data, can then be used to compute P_s with the right side of Eq. 6–27. The MINTEQA2 software package, used for the generation of Fig. 6–19, was developed by U.S. EPA and is available for download at http://www.epa.gov/ceampubl/mmedia/minteq/. Details on the development and use of the solubility product equation can be found in Snoeyink and Jenkins (1980) and Ohlinger et al. (1998). Application of the curve given in Fig. 6–19 is illustrated in Example 6–3.

EXAMPLE 6–3 **Assessment of Potential for Struvite Precipitation** The following analytical test results were reported by Snoeyink and Jenkins (1980) for sludge obtained from the Hyperion wastewater treatment plant in Los Angeles, CA. Using the plot of struvite solubility given on Fig. 6–18, determine if struvite precipitation is likely to occur.

		Constituent concentration, mole/L[a]		
Sample	pH	$C_{T,Mg}$	$C_{T,NH3}$	$C_{T,PO4}$
Raw sludge	5.5	0.005	0.005	0.04
Digested sludge	7.5	0.005	0.1	0.07
Diluted digested sludge	7.5	0.001	0.025	0.02

[a] Data adapted from Snoeyink and Jenkins (1980).

Solution

1. Compute the conditional solubility product as the product of the analytical concentrations for each of the sludge samples using the left side of Eq. 6–27:

$$P_s = (C_{T,\,Mg})(C_{T,\,NH_3})(C_{T,\,PO_4})$$

a. Raw sludge

$$P_s = (0.005)(0.005)(0.04) = 0.000001$$

$$\log(P_s) = \log(0.000001) = -6$$

b. Digested sludge

$$P_s = (0.005)(0.1)(0.07) = 0.000035$$

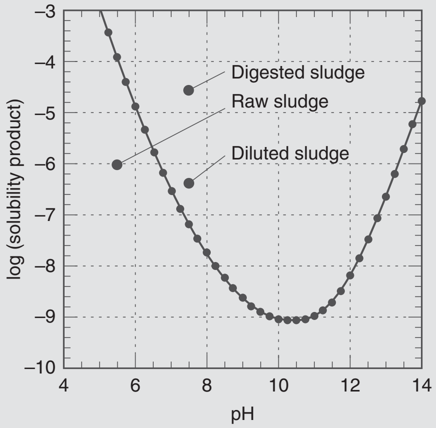
$$\log(P_s) = \log(0.000035) = -4.5$$

c. Diluted digested sludge

$$P_s = (0.001)(0.025)(0.02) = 0.0000005$$

$$\log(P_s) = \log(0.000001) = -6.3$$

2. Plot the conditional solubility product, log(P_s), values as a function of pH on the solubility limit curve to determine if struvite precipitation is expected to occur. The struvite solubility limit curve from Step 1 is shown below with the data computed in Step 2.



Comment As shown in the plot presented in Step 2, the raw sludge sample is not within the region where struvite precipitation would be expected. However, both the as-received and diluted digested sludge are both subject to potential struvite precipitation. Further dilution of the digested sludge or reduction in the sludge pH may be recommended to inhibit struvite formation.

Control and/or Mitigation Measures for the Formation of Struvite

The control of struvite is not only important from the standpoint of its accumulation in process equipment, it is also important because of the beneficial effects on wastewater treatment that accrue as a result of the elimination of phosphorus and ammonium in the return flows to the treatment process. The formation of struvite can be controlled by chemical addition and/or harvesting and removal. The chemical methods that have been used over the years are considered below. Struvite harvesting is considered following the discussion of chemical methods. The principal methods of struvite control are summarized in Table 6–8. As reported in Table 6–8, the principal chemical methods involve the use of alum and iron salts, lime, and proprietary chemicals. In the precipitation methods, the fundamental concept is to reduce one or more of the constituents involved in the formation of struvite below the conditional solubility product and, thus, limit the formation of struvite. Other chemical means include the use of proprietary chemicals to suppress the formation of struvite and the addition of chemicals to lower the pH and, thus, limit the formation of struvite. Additional details of the formation and control of struvite are discussed in Chap. 15.

Enhanced Struvite Formation for Nutrient Removal

From a review of Eq. (6–27) and the equilibrium expressions given in Table 6–7, if the conditions controlling the formation of struvite were optimized, it should be possible to

Table 6–8

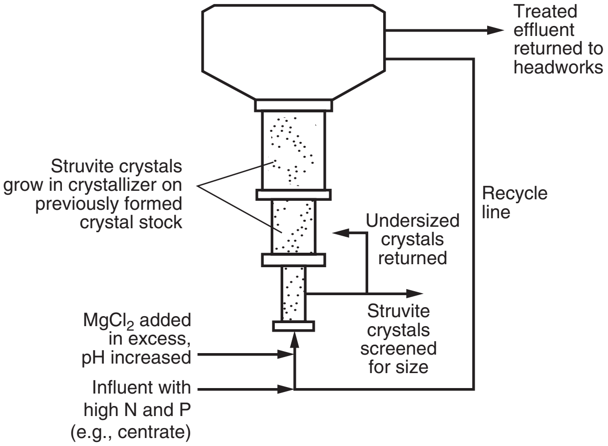
Methods used to control and/or limit the formation of struvite.

Method	Description
Alum [$Al_2(SO_4)_3 \cdot 14H_2O$] addition	Used to precipitate phosphorus. Because alum addition depletes alkalinity, lime is used to add the necessary alkalinity. Can be added upstream of anaerobic digestion, to anaerobic digester, and downstream of anaerobic digestion.
Ferric chloride ($FeCl_3$) addition	Used to precipitate phosphorus. Because ferric addition depletes alkalinity, lime is used to add the necessary alkalinity. Can be added upstream of anaerobic digestion, to anaerobic digester, and downstream of anaerobic digestion.
Ferrous chloride ($FeCl_2$) addition	Used to precipitate phosphorus. Can be added upstream of anaerobic digestion, to anaerobic digester, and downstream of anaerobic digestion.
Ferric sulfate[$Fe_2(SO_4)_3$] addition	Used to precipitate phosphorus. Generally not recommended because of the potential to form hydrogen sulfide during the digestion process.
Lime [$Ca(OH)_2$] addition	Used to precipitate phosphorus and to adjust the alkalinity.
Addition of proprietary chemicals	Propriety chemicals are also available that suppress the formation of struvite. The fate of the phosphorus is unknown.
Addition of anti-scalent chemicals	Propriety anti-scalent chemicals are available that suppress the formation of struvite.
pH reduction	Acid or carbon dioxide (CO_2) can be added to reduce the pH of the waste stream. Carbon dioxide is favored over acid addition for safety reasons and because it is difficult to overdose.
Minimization of carbon dioxide release	Carbon dioxide can be released at points of turbulence in the process piping. When carbon dioxide is released, the pH goes up and struvite precipitation can occur.
Routine maintenance	Depending on where struvite forms, routine flushing of process lines with high-pressure water jets has proven effective in controlling the formation of struvite.

enhance the removal of ammonium and phosphate. Worldwide there are more than 10 technologies in various states of development for the removal of nutrients in the form of struvite. The method used most commonly for the removal of ammonium and phosphate involves the formation of recoverable struvite crystals in an upflow fluidized bed reactor (see Fig. 6–20). As shown on Fig. 6–20, the formation of struvite crystals is accelerated by the addition of an excess amount of Mg^{2+} which is added to the waste stream at an elevated pH and temperature. Other technologies employ complete-mix reactors in a variety of configurations. Based on numerous literature citations, optimum conditions for the removal of phosphorus (and ammonium) occur when the molar ratio Mg^{2+}: PO_4^{3-} is between 1.1 and 1.6, the pH is between 9 and 10.5, and the temperature is about 25°C. The specific values will depend on the chemical composition and ionic strength of the wastewater streams and local conditions. The removal of nutrients is considered further in Chap. 15.

Figure 6–20

Reactor used for struvite precipitation.



6–6 CHEMICAL PRECIPITATION FOR REMOVAL OF HEAVY METALS AND DISSOLVED SUBSTANCES

The technologies available for the removal of heavy metals from wastewater include chemical precipitation, carbon adsorption, ion exchange, and reverse osmosis. Of these technologies, chemical precipitation is most commonly employed for most of the metals. Common precipitants include hydroxide (OH) and sulfide (S^{2-}). Carbonate (CO_3^{2-}) has also been used in some special cases. Metals may be removed separately or co-precipitated with phosphorus. Adsorption, ion exchange, and RO are discussed in Chap. 11

Precipitation Reactions

Metals of interest include arsenic (As), barium (Ba), cadium (Cd), copper (Cu), mercury (Hg), nickel (Ni), selenium (Se), and zinc (Zn). Most of these metals can be precipitated as hydroxides or sulfides. Solubility products for free metal concentrations in equilibrium with hydroxide and sulfide precipitates are reported in Table 6–9.

In wastewater treatment facilities, metals are precipitated most commonly as metal hydroxides through the addition of lime or caustic to a pH of minimum solubility. However, several of these compounds are, as discussed previously, amphoteric (i.e., capable of either accepting or donating a proton) and exhibit a point of minimum solubility. The pH value at minimum solubility varies with the metal in question as illustrated on Fig. 6–21 for hydroxide precipitation. The solid line shown on Fig. 6–21 represents the total metal in solution in equilibrium with the precipitate. The curves were developed based on the mononuclear hydroxide species using the same procedures as illustrated on Fig. 6–8 for Al^{3+} and Fe^{3+}. It is important to remember that the location of the minimum solubility will vary depending on the constituents in the wastewater. The curves given on Fig. 6–21 are useful in establishing the pH ranges for testing.

Metals can also be precipitated as sulfides as illustrated on Fig. 6–22. The minimum effluent concentration levels that can be achieved in the chemical precipitation of heavy metals are reported in Table 6–10. In practice, the minimum achievable residual metal concentrations will also depend on the nature and concentration of the organic matter in the wastewater as well as the temperature. It should also be noted that some metals, such

Table 6–9

Solubility products for free metal ion concentrations in equilibrium with hydroxides and sulfides [a,b]

Metal species	Half reaction	pK_{sp}
Cadmium hydroxide	$Cd(OH)_2 \rightleftarrows Cd^{2+} + 2OH^-$	13.93

Because of the wide variation in the solubility and formation constants for the various metal sulfides, the curves presented in this figure should only be used as a reference guide (see also Table 6–9).

as Hg and As, have multiple oxidation states that can impact the efficiency of precipitation. Because of the many uncertainties associated with the precipitation of metals, laboratory bench scale or pilot plant testing should be conducted.

Co-precipitation with Phosphorus

As discussed previously, precipitation of phosphorus in wastewater is usually accomplished by the addition of coagulants, such as alum, iron, or calcium. Coincidentally with

Table 6–10

Practical effluent concentration levels achievable in heavy metals removal by precipitation[a]

Metal	Achievable effluent concentration, mg/L	Type of precipitation and technology
Arsenic	0.05	Sulfide precipitation with filtration
	0.005	Ferric hydroxide co-precipitation
Barium	0.5	Sulfide precipitation
Cadmium	0.05	Hydroxide precipitation at pH 10–11
	0.05	Co-precipitation with ferric hydroxide
	0.008	Sulfide precipitation
Copper	0.02–0.07	Hydroxide precipitation
	0.01–0.02	Sulfide precipitation
Mercury	0.01–0.02	Sulfide precipitation
	0.001–0.01	Alum co-precipitation
	0.0005–0.005	Ferric hydroxide co-precipitation
	0.001–0.005	Ion exchange
Nickel	0.12	Hydroxide precipitation at pH 10
Selenium	0.05	Sulfide precipitation
Zinc	0.1	Hydroxide precipitation at pH 11

[a] From Eckenfelder et al. (2009).

the addition of these chemicals for the removal of phosphorus, removal of various inorganic ions, principally some of the heavy metals, occurs as co-precipitation. Dissolved metals may be adsorbed onto the hydroxide complex, while particulate and colloidal forms may be incorporated into flocculated material. Where both industrial and domestic wastes are treated together, it may be necessary to add chemicals to the primary settling facilities, especially if on-site pretreatment measures prove to be ineffective. When chemical precipitation is used, anaerobic digestion for sludge stabilization may not be possible because of the toxicity of the precipitated heavy metals. As noted previously, one of the disadvantages of chemical precipitation is that it usually results in a net increase in the total dissolved solids of the wastewater that is being treated.

6–7 CONVENTIONAL CHEMICAL OXIDATION

Conventional chemical oxidation in wastewater treatment typically involves the use of oxidizing agents such as ozone (O_3), hydrogen peroxide (H_2O_2), permanganate (MnO_4), chlorine dioxide (ClO_2), chlorine (Cl_2 or HOCl), and oxygen (O_2), to bring about change in the chemical composition of a compound or a group of compounds. Advanced oxidation processes (AOPs) in which the free hydroxyl radical (HO•) is used as a strong oxidant to destroy specific organic constituents and compounds that cannot be oxidized easily by conventional oxidants are discussed in Sec. 6–8.

Applications for Conventional Chemical Oxidation

The principal applications of conventional chemical oxidation in wastewater treatment are for (1) odor control, (2) hydrogen sulfide control, (3) color removal, (4) iron and manganese removal, (5) disinfection, (6) control of biofilm growth and biofouling in treatment processes and distribution system components, and (7) oxidation of selected trace organic constituents. Some of the more important applications of chemical oxidation in wastewater management are summarized in Table 6–11. Chemical oxidation is especially effective for the elimination of odorous compounds (e.g., oxidation of sulfides and mercaptans) and is covered further in Chap. 16. Because of its importance, chemical disinfection is considered separately in Chap. 12.

In addition to the applications reported in Table 6–11, chemical oxidation is now commonly used to (1) improve the treatability of nonbiodegradable (refractory) organic compounds, (2) eliminate the inhibitory effects of certain organic and inorganic compounds to microbial growth, and (3) reduce or eliminate the toxicity of certain organic and inorganic compounds to microbial growth and aquatic flora. Additional details on the applications of conventional oxidation may be found in Rakness (2005), Crittenden et al. (2012), U.S. EPA (1999), and Black and Veatch Corporation (2010).

Oxidants Used in Chemical Oxidation Processes

Oxidants that are used frequently in wastewater treatment include (1) chlorine, (2) ozone, (3) chlorine dioxide, (4) permanganate, and (5) hydrogen peroxide. The oxidation kinetics of oxygen are usually too slow to be of practical use beyond secondary biological treatment. Chemical oxidants are usually added at specific points during treatment (e.g., to control odors or membrane fouling) or at the final stage of treatment before discharge or reuse (e.g., disinfection). The rate of oxidation typically follows the trend given below; however, there will be exceptions depending on the characteristics of the solution (e.g., pH) and type of compound that is to be oxidized.

$$HO\cdot > O_3 > H_2O_2 > HOCl > ClO_2 > MnO_4^- > O_2 > OCl^- \tag{6–28}$$

Table 6–11

Typical applications of chemical oxidation in wastewater collection, treatment, and dispersal

Application	Chemicals used[a]	Remarks
Collection		
Slime-growth control	Cl_2, H_2O_2	Control of fungi and slime-producing bacteria
Corrosion control (H_2S)	Cl_2, H_2O_2, O_3	Control brought about by oxidation of H_2S
Odor control	Cl_2, H_2O_2, O_3	Especially in pumping stations and long, flat sewers
Treatment		
Grease removal	Cl_2	Added before preaeration
BOD reduction	Cl_2, O_3	Oxidation of organic substances
Ferrous sulfate oxidation	Cl_2	Production of ferric sulfate and ferric chloride
Filter-ponding control	Cl_2	Maintaining residual at filter nozzles
Filter-fly control	Cl_2	Maintaining residual at filter nozzles during fly season
Sludge-bulking control	Cl_2, H_2O_2, O_3	Temporary control measure
Control of filamentous microorganisms	Cl_2	Dilute chlorine solution sprayed on foam caused by filamentous organisms
Digester supernatant oxidation	Cl_2	
Digester foaming control	Cl_2	
Ammonium oxidation	Cl_2	Conversion of ammonia to nitrogen gas
Odor control	Cl_2, H_2O_2, MnO_4, O_3	
Oxidation of refractory organic compounds	O_3	
Reuse/dispersal		
Bacterial reduction	Cl_2, ClO_2, H_2O_2, O_3	Plant effluent, overflows, and stormwater
Odor control	Cl_2, H_2O_2, MnO_4, O_3	
Color removal	Cl_2, H_2O_2, MnO_4, O_3	

[a] Cl_2 = chlorine, ClO_2 = chlorine dioxide, H_2O_2 = hydrogen peroxide, MnO_4 = permanganate, O_3 = ozone.

The behavior of the hydroxyl radical, HO•, discussed in detail in Sec. 6–8, is introduced briefly here as related to its formation from ozonation. Of the conventional chemical oxidants, ozonation is effective for the destruction of organic compounds either by direct reactions with O_3, or indirect reactions with HO•, as shown in Eq. (6–29).

$$O_3 \rightarrow \left[\begin{array}{l} \xrightarrow[O_3]{\text{Direct Pathway}} O_3 + R \rightarrow \text{Product 1} \\ \xrightarrow[\text{NOM}]{\text{Indirect Pathway}} HO\cdot + R \rightarrow \text{Product 2} \end{array} \right. \qquad (6\text{–}29)$$

The reaction of ozone with natural organic matter (NOM) to produce HO•, is among the most important mechanisms used to destroy target compounds (Elovitz and von Gunten,

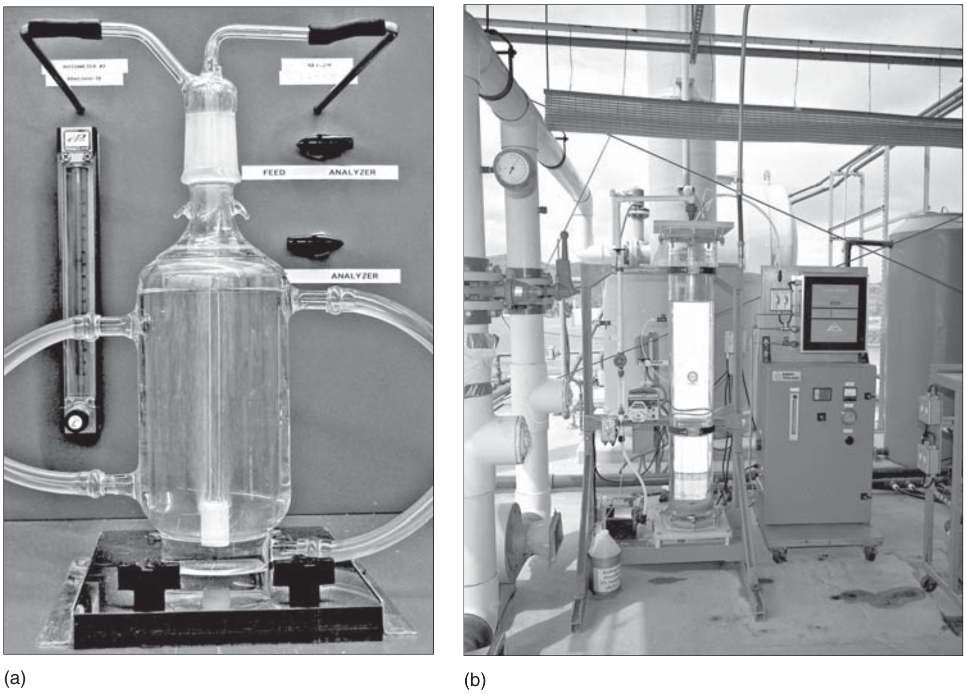

Figure 6–23

Contactors used for evaluation of chemical oxidation using ozone (a) bench scale and (b) pilot scale.

1999; Westerhoff et al., 1999). However, substantial removals of residual pharmaceuticals in low-DOC reclaimed water are possible by direct ozonation, even at low ozone dosages (Huber et al., 2005). Views of ozone contactors used for bench and pilot scale evaluation are shown on Fig. 6–23. Transformation of some pharmaceuticals is also possible during chlorine disinfection, however, the effectiveness will depend on the structure of the chemical compound, the form of chlorine, the contact time, and application of dechlorination (Pinkston and Sedlak, 2004).

Fundamentals of Chemical Oxidation

The purpose of the following discussion is to introduce the basic concepts involved in chemical oxidation reactions. The topics to be discussed include (1) oxidation-reduction reactions, (2) half reaction potentials, (3) reaction potentials, (4) equilibrium constants for redox equations, and (5) rate of oxidation-reduction reactions.

Oxidation-Reduction Reactions. Oxidation-reduction reactions (known as redox reactions) take place between an *oxidizing agent* and a *reducing agent*. In redox reactions electrons are exchanged and there is a change in the oxidation states of the constituents involved in the reaction. While an oxidizing agent causes the oxidation to occur, it is reduced in the process. Similarly, a reducing agent which causes a reduction to occur is oxidized in the process. For example, consider the following reaction.

$$Cu^{2+} + Zn \rightleftarrows Cu + Zn^{2+} \tag{6–30}$$

In the above reaction copper (Cu) changes from a +2 to zero oxidation state and the zinc (Zn) changes from a zero to a +2 state. Because of the electron gain or loss, oxidation-reduction reactions can be separated into two half reactions. The oxidation half reaction

Table 6–12

Chemicals that have been used for the disinfection of wastewater, along with their their oxidation half reaction and standard electrode potential[a]

Disinfectant	Half reaction	Oxidation potential[b], V
Ozone	$O_3 + 2H^+ + 2e^- \rightleftarrows O_2 + H_2O$	+2.07
Hydrogen peroxide	$H_2O_2 + 2H^+ + 2e^- \rightleftarrows 2H_2O$	+1.78
Permanganate	$MnO_4^- + 4H^+ + 3e^- \rightleftarrows MnO_2 + 2H_2O$	+1.67
Chlorine dioxide	$ClO_2 + e^- \rightleftarrows ClO_2^-$	+1.50
Hypochlorous acid	$HOCl + H^+ + 2e^- \rightleftarrows Cl^- + H_2O$	+1.49
Hypoiodous acid	$HIO + H^+ + e^- \rightleftarrows 1/2I_2 + H_2O$	+1.45
Chlorine gas	$Cl_2 + 2e^- \rightleftarrows 2Cl^-$	+1.36
Oxygen	$O_2 + 4H^+ + 4e^- \rightleftarrows 2H_2O$	+1.23
Bromine	$Br_2 + 2e^- \rightleftarrows 2Br^-$	+1.09
Hypochlorite	$ClO^- + H_2O + 2e^- \rightleftarrows Cl^- + 2OH^-$	+0.90
Chlorite	$ClO_2^- + 2H_2O + 4e^- \rightleftarrows Cl^- + 4OH^-$	+0.76
Iodine	$I_2 + 2e^- \rightleftarrows 2I^-$	+0.54

[a] Derived in part from Bard (1966) and Black and Veatch Corporation (2010).

[b] Reported values will vary depending on source. The electrical potential or voltage (V) is used commonly to characterize various oxidation reduction reactions.

involves the loss of electrons while the reduction half reaction involves the gain of electrons. The two half reactions that comprise Eq. (6–30) are as follows:

$$Zn - 2e^- \rightleftarrows Zn^{2+} \qquad \text{(oxidation)} \tag{6–31}$$

$$Cu^{2+} + 2e^- \rightleftarrows Cu \qquad \text{(reduction)} \tag{6–32}$$

Referring to the above equations there is a two electron change.

Half Reaction Potentials. Because of the almost infinite number of possible reactions, there are no summary tables of equilibrium constants for oxidation-reduction reactions. What is done instead is the chemical and thermodynamic characteristics of the half reactions, such as those given by Eqs. (6–31) and (6–32), are determined and tabulated so that any combination of reactions can be studied. Half reactions for disinfection processes are given in Table 6–12 and other representative half reactions are given in Table 6–13. Of the many properties that can be used to characterize oxidation-reduction reactions, the electrical potential (i.e., voltage) of the half reaction is used most commonly. Thus, every half reaction involving an oxidation or reduction has a *standard potential* $E°$ associated with it. The potentials for the half reactions given by Eqs. (6–33) and (6–34) are as follows:

$$Zn + 2e^- \rightleftarrows Zn^{2+} \qquad E° = -0.763 \text{ V} \tag{6–33}$$

$$Cu^{2+} + 2e^- \rightleftarrows Cu \qquad E° = 0.340 \text{ V} \tag{6–34}$$

The potentials for a number of half reactions are given in Table 6–13. The half reaction potential is a measure of the tendency of a reaction to proceed to the right. Half reactions with large positive potential, $E°$, tend to proceed to the right. Conversely, half reactions with large negative potential, $E°$, tend to proceed to the left.

Table 6–13

Selected standard electrode potentials for oxidation-reduction half reactions[a]

Half reaction	Oxidation potential[b], V
$Li^+ + e^- \rightarrow Li$	−3.03
$K^+ + e^- \rightarrow K$	−2.92
$Ba^{2+} + 2e^- \rightarrow Ba$	−2.90
$Ca^{2+} + 2e^- \rightarrow Ca$	−2.87
$Na^+ + e^- \rightarrow Na$	−2.71
$Mg(OH)_2 + 2e^- \rightarrow Mg + 2OH^-$	−2.69
$Mg^{2+} + 2e^- \rightarrow Mg$	−2.37
$Al^{3+} + 3e^- \rightarrow Al$	−1.66
$MnO_4^- + 8H^+ + 5e^- \rightarrow Mn^{2+} + 4H_2O$	−1.51
$Mn^{2+} + 2e^- \rightarrow Mn$	−1.18
$2H_2O + 2e^- \rightarrow H_2 + 2OH^-$	−0.828
$Zn^{2+} + 2e^- \rightarrow Zn$	−0.763
$Fe^{2+} + 2e^- \rightarrow Fe$	−0.440
$Cd^{2+} + 2e^- \rightarrow Cd$	−0.40
$Ni^{2+} + 2e^- \rightarrow Ni$	−0.250
$S + 2H^+ + 2e^- \rightarrow H_2S$	−0.14
$Pb^{2+} + 2e^- \rightarrow Pb$	−0.126
$2H^+ + 2e^- \rightarrow H_2$	0.000
$Cu^{2+} + e^- \rightarrow Cu^+$	+0.15
$N_2 + 4H^+ + 3e^- \rightarrow NH_4{}^+$	+0.27
$Cu^{2+} + 2e^- \rightarrow Cu$	+0.34
$I_2 + 2e^- \rightarrow 2I^-$	+0.54
$O_2 + 2H^+ + 2e^- \rightarrow H_2O_2$	+0.68
$Fe^{3+} + e^- \rightarrow Fe^{2+}$	+0.771
$Ag^+ + e^- \rightarrow Ag$	+0.799
$ClO^- + H_2O + 2e^- \rightarrow Cl^- + 2OH^-$	+0.90
$Br_2(aq) + 2e^- \rightarrow 2Br^-$	+1.09
$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$	+1.229
$Cl_2(g) + 2e^- \rightarrow 2Cl^-$	+1.360
$H_2O_2 + 2H^+ + 2e^- \rightarrow 2H_2O$	+1.776
$O_3 + 2H^+ + 2e^- \leftrightarrow O_2 + H_2O$	+2.07
$F_2 + 2H^+ + 2e^- \rightarrow 2HF$	+2.87

[a] Adapted in part from Bard (1966) and Benefield et al. (1982).

[b] Reported values will vary depending on source. The electrical potential or voltage (V) is used commonly to characterize various oxidation reduction reactions.

Reaction Potentials. The half-reaction potentials, discussed above, can be used to predict whether a reaction comprised of two half-reactions will proceed as written. The tendency of a reaction to proceed is obtained by determining the $E^\circ_{\text{reaction}}$ for the entire reaction as given by the following expression.

$$E^\circ_{\text{reaction}} = E^\circ_{\text{reduction}} - E^\circ_{\text{oxidation}} \tag{6–35}$$

Where $E^\circ_{\text{reaction}}$ = the potential of the overall reaction, V
$E^\circ_{\text{reduction}}$ = the potential of the reduction half reaction, V
$E^\circ_{\text{oxidation}}$ = the potential of the oxidation half reaction, V

For example, for the reaction between copper and zinc (see Eq. 6–30) the $E^\circ_{\text{reaction}}$ is determined as follows:

$$E^\circ_{\text{reaction}} = E^\circ_{\text{Cu}^{2+},\text{Cu}} - E^\circ_{\text{Zn}^{2+},\text{Zn}} \tag{6–36}$$

$$E^\circ_{\text{reaction}} = 0.340 - (-0.763) = +1.103 \text{ V} \tag{6–37}$$

The positive value for the $E^\circ_{\text{reaction}}$ is taken as an indication that the reaction will proceed as written. The magnitude of the value, as will be illustrated subsequently, can be taken as measure of the extent to which the reaction as written will proceed. For example, if Eq. (6–30) had been written as follows:

$$\text{Cu} + \text{Zn}^{2+} \rightleftarrows \text{Cu}^{2+} + \text{Zn} \tag{6–38}$$

The corresponding $E^\circ_{\text{reaction}}$ for this reaction is:

$$E^\circ_{\text{reaction}} = E^\circ_{\text{Zn}^{2+},\text{Zn}} - E^\circ_{\text{Cu}^{2+},\text{Cu}} \tag{6–39}$$

$$E^\circ_{\text{reaction}} = (-0.763) - 0.340 = -1.103 \text{ V} \tag{6–40}$$

Because the $E^\circ_{\text{reaction}}$ for the reaction is negative, the reaction will proceed in the opposite direction from what is written.

EXAMPLE 6–4 **Determination of Reaction Potential** Determine whether hydrogen sulfide (H_2S) can be oxidized with hydrogen peroxide (H_2O_2). The pertinent half reactions from Table 6–13 are as follows:

$$H_2S \rightleftarrows S + 2H^+ + 2e^- \qquad E^\circ = -0.14 \text{ V}$$

$$H_2O_2 + 2H^+ + 2e^- \rightleftarrows 2H_2O \qquad E^\circ = +1.78 \text{ V}$$

Solution

1. Determine the overall reaction by adding the two half reactions.

$$\begin{array}{l} H_2S \rightleftarrows S + 2H^+ + 2e^- \\ \underline{H_2O_2 + 2H^+ + 2e^- \rightleftarrows 2H_2O} \\ H_2S + H_2O_2 \rightleftarrows S + 2H_2O \end{array}$$

2. Determine the $E^\circ_{\text{reaction}}$ for overall reaction.

$$E^\circ_{\text{reaction}} = E^\circ_{H_2O_2,\, H_2O} - E^\circ_{H_2S,\, S}$$

$$E^\circ_{\text{reaction}} = (1.78) - (-0.14) = +1.92 \text{ V}$$

Because the $E^\circ_{\text{reaction}}$ for the reaction is positive, the reaction is expected to proceed as written.

Equilibrium Constants for Redox Equations. The equilibrium constant for oxidation reduction reactions is calculated using the Nernst equation as defined below.

$$\ln K = \frac{nFE^\circ_{\text{reaction}}}{\text{RT}} \tag{6–41}$$

$$\log K = \frac{nFE^\circ_{\text{reaction}}}{2.303\,RT} \tag{6–42}$$

Where K = equilibrium constant
n = number of electrons exchanged in the overall reaction
F = Faraday's constant
= 96,485 C/g-eq (Note: C = coulomb)
$E^\circ_{\text{reaction}}$ = reaction potential
R = universal gas constant
= 8.3144 J (abs)/g-mole
T = temperature, K (273.15 + °C)

For example, at 25°C

$$\log K = \frac{n\,(96{,}485\text{ C/g eq})\,E^\circ_{\text{reaction}}}{(2.303)(8.3144\text{ J/mole}\cdot\text{K})[(273.15 + 25)K]} = \frac{nE^\circ_{\text{reaction}}}{0.0592}$$

The application of the Nernst equation is illustrated in Example 6–5.

EXAMPLE 6–5 **Determination of Equilibrium Constant for Oxidation-Reduction Reaction** Determine the equilibrium constant for the following oxidation-reduction reactions:

$$Cu^{2+} + Zn \rightleftarrows Cu + Zn^{2+}$$

$$H_2S + H_2O_2 \rightleftarrows S + 2H_2O$$

Solution

1. Determine the equilibrium constant for the following equation using Eq. (6–42).

$$Cu^{2+} + Zn \rightleftarrows Cu + Zn^{2+}$$

As computed above, the $E^\circ_{\text{reaction}}$ for the reaction is +1.1 volts, and the number of electrons exchanged is 2. Using this information, the K value is determined as follows:

$$\log K = \frac{nE^\circ_{\text{reaction}}}{0.0592} = \frac{2(1.10)}{0.0592} = 37.2$$

$$K = 1.58 \times 10^{37} = \frac{[Zn^{2+}]}{[Cu^{2+}]}$$

2. Determine the equilibrium constant for the following equation using Eq. (6–42).

$$H_2S + H_2O_2 \rightleftarrows S + 2H_2O$$

From Example 6–4, the $E^\circ_{\text{reaction}}$ for the above reaction is $+1.92$ volts. The value of the equilibrium constant is

$$\log K = \frac{nE^\circ_{\text{reaction}}}{0.0592} = \frac{2(1.92)}{0.0592} = 64.9$$

$$K = 7.94 \times 10^{64} = \frac{[\text{S}]}{[\text{H}_2\text{S}][\text{H}_2\text{O}_2]}$$

Rate of Oxidation-Reduction Reactions. As noted previously, the half-reaction potentials can be used to predict whether a reaction will proceed as written. Unfortunately, the reaction potential provides no information about the rate at which the reaction will proceed. Chemical oxidation reactions often require the presence of one or more catalysts for the reaction to proceed or to increase the rate of reaction. Transition metal cations, enzymes, pH adjustment, and a variety of proprietary substances have been used as catalysts.

Chemical Oxidation of Organic Constituents

The overall reaction for the oxidation of organic molecules comprising residual COD, for example, with ozone, can be represented as follows:

$$\begin{matrix}\text{Organic} & & \text{Intermediate} & & \text{Simple} \\ \text{molecule} & \xrightarrow{O_3} & \text{oxygenated} & \xrightarrow{O_3} & \text{end products} \\ \text{(e.g., COD)} & & \text{molecules} & & \text{(e.g., CO}_2\text{, H}_2\text{O, etc.)}\end{matrix} \qquad (6\text{–}43)$$

Multiple arrows in the direction of the reaction are used to signify that a number of steps are involved in the overall reaction sequence. The use of oxidizing agents such as oxygen, chlorine, ozone, and hydrogen peroxide is termed "simple oxidation." In general the overall reaction rates are usually too slow to be applicable generally for the removal of recalcitrant COD during wastewater treatment (SES, 1994). Advanced oxidation processes (AOPs), which typically involve the use of the hydroxyl radical for the oxidation of complex organic molecules, are considered in Sec. 6–8.

Typical chemical dosages for both chlorine and ozone for the oxidation of the organics in wastewater are reported in Table 6–14. The dosages increase with the degree of treatment, which is reasonable when it is considered that the organic compounds that remain after biological treatment are typically composed of low molecular weight polar organic compounds and complex organic compounds built around the benzene ring structure.

It is recommended that bench and/or pilot plant studies be conducted when chlorine, chlorine dioxide, or ozone is to be used for the oxidation of organics. Because ozone can be generated conveniently at treatment plants that use the high purity oxygen activated sludge process, it is anticipated that its use may become more common at these locations in the future.

Chemical Oxidation of Ammonium

The chemical process in which chlorine is used to oxidize the ammonium nitrogen in solution to nitrogen gas and other stable compounds is known as breakpoint chlorination. Perhaps the most important advantage of this process is that, with proper control, all the

Table 6–14

Typical chemical dosages for the oxidation of organics in wastewater[a]

Chemical	Use	Dosage, kg/kg destroyed Range	Typical
Chlorine	BOD reduction		
	Settled wastewater	0.5–2.5	1.75
	Secondary effluent	1.0–3.0	2.0
Ozone	COD reduction		
	Settled wastewater	2.0–4.0	3.0
	Secondary effluent	3.0–8.0	6.0

[a] Derived in part from Black and Veatch Corporation (2010).

ammonium nitrogen in the wastewater can be oxidized. However, because the process has a number of disadvantages including cost, the buildup of acid (HCl) which will react with the alkalinity, the buildup of total dissolved solids, and the formation of unwanted chloro-organic compounds, ammonium oxidation is seldom used for effluents that have not undergone nitrification. Where nitrification is practiced, however, breakpoint chlorination can be an effective tool to achieve high levels of disinfection and eliminate residual ammonium.

Although the theory and practice of breakpoint chlorination is described in greater detail in Chap 12, it is, nevertheless, instructive to assess whether the reaction is feasible using the oxidation-reduction concepts presented above. The pertinent half reactions are as follows:

$$\mathrm{HOCl} + \mathrm{H}^+ + 2\mathrm{e}^- \rightleftarrows \mathrm{Cl}^- + \mathrm{H_2O} \qquad E^\circ = +1.49\ \mathrm{V} \tag{6–44}$$

$$\mathrm{N_2} + 8\mathrm{H}^+ + 6\mathrm{e}^- \rightleftarrows 2\mathrm{NH_4^+} \qquad E^\circ = +0.27\ \mathrm{V} \tag{6–45}$$

Rewrite Eq. (6–45) as a reduction

$$2\mathrm{NH_4^+} \rightleftarrows \mathrm{N_2} + 8\mathrm{H}^+ + 6\mathrm{e}^- \qquad E^\circ = -0.27\ \mathrm{V} \tag{6–46}$$

Combining Eqs. (6–44) and (6–46) yields

$$\begin{array}{l} 2\mathrm{NH_4^+} \rightleftarrows \mathrm{N_2} + 8\mathrm{H}^+ + 6\mathrm{e}^- \\ \underline{(3)\mathrm{HOCl} + (3)\mathrm{H}^+ + (3)2\mathrm{e}^- \rightleftarrows (3)\mathrm{Cl}^- + (3)\mathrm{H_2O}} \\ 3\mathrm{HOCl} + 2\mathrm{NH_4^+} \rightleftarrows \mathrm{N_2} + 3\mathrm{HCl} + 2\mathrm{H}^+ + 3\mathrm{H_2O} \end{array} \tag{6–47}$$

Determine the $E^\circ_{\mathrm{reaction}}$ for overall reaction

$$E^\circ_{\mathrm{reaction}} = E^\circ_{\mathrm{HOC1,Cl^-}} - E^\circ_{\mathrm{NH_4^+,N_2}}$$

$$E^\circ_{\mathrm{reaction}} = (1.49) - (-0.27) = +1.96\ \mathrm{V}$$

Because the $E^\circ_{\mathrm{reaction}}$ for the reaction is positive, the reaction will proceed as written. The stoichiometric mass ratio of chlorine as $\mathrm{Cl_2}$ to ammonium as N, as computed using Eq. (6–47) is 7.6:1. In practice, the ratio has been found to vary from 8:1 to 10:1.

Chemical Oxidation Process Limitations

Aside from the expense of chemical addition, the primary concern with any chemical oxidation process is the potential for the formation of toxic byproducts due to incomplete oxidation. While the hydroxyl radical oxidation processes discussed in Sec. 6–8 are able to achieve complete mineralization of many constituents under optimal conditions, conventional chemical oxidation is typically not powerful enough to reach this endpoint. Therefore, subsequent treatment processes, such as adsorption, will be needed to remove the oxidation byproducts. Further, chemical oxidation will increase the biodegradability of some constituents, potentially requiring the use of a biological process to remove residual biodegradable organic material. Byproduct formation may be controlled by removal of the byproduct precursors before application of the oxidant and careful control of the oxidant dose.

The properties of chemical oxidants that justify their use in wastewater treatment also contribute to their potential to be corrosive under certain conditions. Thus, careful control of oxidant dosage and the use of compatible materials are important factors to prevent corrosion of facilities and equipment. A number of methods are available to evaluate the potential, type, and rate of corrosion by chemical oxidants with a given material under certain conditions, including thermodynamics, electrokinetics (mixed-potential models), and experimental testing.

6–8 ADVANCED OXIDATION

Advanced oxidation processes (AOPs) can be used to destroy trace constituents that cannot be oxidized completely by conventional oxidants, including constituents that are known to affect the endocrine system (Rosenfeldt and Linden, 2004). Treated effluent water following tertiary treatment typically contains a variety of natural and synthetic organic chemicals at low concentrations that may need to be removed or destroyed to protect public health and the environment, especially in potable reuse applications. The conventional oxidants described in Sec. 6–7 are able to remove some of the constituents of interest; however, there is uncertainty regarding the formation of toxic byproducts following conventional chemical oxidation. Moreover, some trace constituents may be found in the permeate from reverse osmosis treatment.

The advantage of advanced oxidation is the ability to generate elevated concentrations of hydroxyl radical ($HO\cdot$), a strong oxidant capable of the complete oxidation of most organic compounds into carbon dioxide, water, and mineral acids (e.g., HCl). The dot is added after the radical species to denote that an unpaired electron is present in the outer orbital of the molecule. Because of the unpaired electron, hydroxyl radicals are reactive electrophiles (electron-loving) that react rapidly with nearly all electron-rich organic compounds. The reactions with hydroxyl radical are second order because the reactions depend on the concentration of the constituent that is oxidized and the concentration of the hydroxyl radical species. The second order hydroxyl radical rate constants for many dissolved organic compounds are on the order of 10^8 to 10^9 L/mole·s (Buxton and Greenstock, 1988), three to four orders of magnitude greater than second order rate constants for other oxidants.

Applications for Advanced Oxidation

The relative oxidizing power of the hydroxyl radical expressed as electrochemical oxidation potential, along with other common oxidants, is summarized in Table 6–15. As shown, with the exception of fluorine, the hydroxyl radical is one of the most active oxidants known.

Table 6–15
Oxidants, forms, and applications methods

Oxidant	Forms	Applications[a]	Application methods	Electrical potential, V
Fluorine	Not used	—	Not used	2.87
Hydroxyl radical	Generated in specially designed reactors at the moment of use due to short life	A, B, C, D	See Sec. 6–8	2.80
Ozone	Ozone is a gas that is generated on site by passing dry compressed air or pure oxygen across a high voltage electrode	A, B, C, D	Ozone is applied to water as a gas. Mass transfer is an important issue and ozone contactors usually use fine bubble diffusers and water depth to ensure high transfer efficiency	2.08
Peracetic acid	Stabilized liquid solution	A, D	Concentrated solution mixed with water to be treated	—
Hydrogen peroxide	Liquid solution	A	Concentrated solution mixed with water to be treated	1.78
Permanganate	Available in bulk as granules	A, B	Added as a dry chemical using a feeder or as a concentrated solution (no more than 5 percent by weight due to its limited solubility)	1.67
Chlorine, free	Chlorine gas, NaOCl solution	A, D	Gas eductors and spray jets	1.36
Chlorine, combined (chloramines)	Addition of ammonia: anhydrous ammonia gas, ammonium sulfate, aqua ammonia (20 to 30 percent ammonia solution)	A, D	Gas eductors, dry chemical feeders, spray jets	—
Chlorine dioxide	Chlorine dioxide gas is produced on-site using a 25 percent sodium chlorite solution. The sodium chlorite solution is reacted with the following constituents to form $ClO_{2\,(g)}$: (1) gaseous chlorine (Cl_2), (2) aqueous chlorine (HOCl), or acid (usually hydrochloric acid, HCl)	A	Gas eductors	1.27
Oxygen	Gas and Liquid	—	Pure oxygen or the oxygen in air is applied as a gas	1.23

[a] A = Oxidation of reduced inorganic species such as soluble metals, complexed metal species, and destruction of odor causing compounds.
B = Oxidation of organics such as toxic organic compounds, colors, reduce TOC and NOM.
C = Improve coagulation.
D = Used as a biocide to control algae in reservoirs and basins, for disinfection, to control growth in distributions system.

Advanced oxidation processes differ from the other advanced treatment processes discussed (such as adsorption, ion exchange, or stripping) because organic compounds in water are degraded rather than concentrated or transferred into a different phase. Further, compounds that are not adsorbable or only partially adsorbable may be destroyed by reaction with hydroxyl radical. Because a secondary waste stream is not generated, there is no additional cost to dispose of or regenerate materials. Hydroxyl radicals are capable of oxidizing almost all reduced materials present without restriction to specific classes or groups of compounds, as compared to other oxidants. In addition to being non-selective, many AOPs operate at normal temperature and pressures. Other processes that can generate hydroxyl radicals, but require elevated temperature and/or pressure, include catalytic oxidation, gas-phase combustion, supercritical oxidation, and wet oxidation processes. Additional details on AOPs may be found in Singer and Reckhow (1999) and Crittenden et al. (2012).

Degree of Degradation. Depending on the application, it may not be necessary to oxidize completely a given compound or group of compounds, as partial oxidation may be sufficient to render specific compounds more amenable to subsequent biological treatment or to reduce their toxicity. The oxidation of specific compounds may be characterized by the extent of degradation of the final oxidation products as follows (Rice, 1996).

1. *Primary degradation.* A structural change in the parent compound.
2. *Acceptable degradation (defusing).* A structural change in the parent compound to the extent that toxicity is reduced.
3. *Ultimate degradation (mineralization).* Conversion of organic carbon to inorganic CO_2.
4. *Unacceptable degradation (fusing).* A structural change in the parent compound resulting in increased toxicity.

Oxidation of Refractory Organic Compounds. Hydroxyl radicals are used most commonly for the oxidation of trace amounts of refractory organic compounds found in highly treated effluents (e.g., following reverse osmosis). The hydroxyl radicals, once generated can attack organic molecules by (1) radical addition, (2) hydrogen abstraction, (3) electron transfer, and (4) radical combination (SES, 1994) as described below.

1. By radical addition:
   The addition of the hydroxyl radical to an unsaturated aliphatic or aromatic organic compound (e.g., C_6H_6) results in the production of a radical organic compound that can be oxidized further by compounds such as oxygen or ferrous iron to produce stable oxidized end products. Radical addition is much more rapid than hydrogen abstraction. In the following reactions the abbreviation R is used to denote the reacting organic compound.

   $$R + HO\cdot \rightarrow ROH\cdot \tag{6–48}$$

2. By hydrogen abstraction:
   The hydroxyl radical can be used to remove a hydrogen atom from organic compounds. The removal of a hydrogen atom results in the formation of a radical organic compound, initiating a chain reaction where the radical organic compound reacts with oxygen, producing a peroxyl radical, which can react with another organic compound, and so on.

   $$R + HO\cdot \rightarrow R\cdot + H_2O \tag{6–49}$$

3. By electron transfer:
   Electron transfer results in the formation of ions of a higher valance. Oxidation of a monovalent negative ion will result in the formation of an atom or a free radical. In the following reaction, n is used to denote the charge on the reacting organic compound R.

   $$R^n + HO\cdot \rightarrow R^{n-1} + OH^- \tag{6–50}$$

4. By radical combination:
Two radicals can combine to form a stable product.

$$HO\cdot + HO\cdot \rightarrow H_2O_2 \qquad (6\text{–}51)$$

The reaction of HO· with organic compounds by radical addition reactions with double bonds and hydrogen abstraction are among the most common processes. In general, the reaction of hydroxyl radicals with organic compounds, at completion, will produce water, carbon dioxide, and mineral salts; this process is also known as *mineralization*.

Disinfection. Because it was recognized that free radicals generated from ozone were more powerful oxidants than ozone alone, it was reasoned that the hydroxyl free radicals could be used effectively to oxidize microorganisms in wastewater. Unfortunately, because the half-life of the hydroxyl free radicals is short, on the order of microseconds, it is not possible to develop hydroxyl radicals in high concentrations. With extremely low concentrations, the required detention times for microorganism disinfection, based on the C_Rt concept (see Chap. 12), are prohibitive. However, AOPs that incorporate high dosages of UV energy (1000 to 2000 mJ/cm^2) to initiate photolysis reactions may be of sufficient intensity to accomplish significant levels of disinfection. Challenge testing using pilot or full scale installations may be used to determine the actual level of disinfection accomplished.

Processes for Advanced Oxidation

Based on numerous studies, it has been found that AOPs are more effective than any of the individual oxidizing agents (e.g., ozone, UV, hydrogen peroxide). Several technologies are available to produce HO· in the aqueous phase (U.S. EPA, 1998). Selected technologies are summarized in Table 6–16. In water reclamation, AOPs are usually applied to low COD wastewaters (typically following treatment by reverse osmosis) because of the cost of ozone and/or H_2O_2 required to generate the hydroxyl radicals. Of the technologies reported in Table 6–16, the commercially available AOPs for water reclamation are ozone/UV, ozone/hydrogen peroxide, and hydrogen peroxide/UV.

The major advantages and disadvantages of various AOPs are also provided in Table 6–16. It should be noted that following oxidation, constituents that were previously resistant to degradation may be transformed into biodegradable compounds that will require further biological treatment.

Ozone/UV. Production of the free radical HO· with UV light can be illustrated by the following reactions for the photolysis of ozone (Glaze et al., 1987; Glaze and Kang, 1990). The first step of ozone/ultraviolet light (O_3/UV) process is the formation of H_2O_2 by photolysis of ozone.

$$O_3 + H_2O + UV(\lambda < 310\text{ nm}) \rightarrow O_2 + HO\cdot + HO\cdot \rightarrow O_2 + H_2O_2 \qquad (6\text{–}52)$$

As shown in Eq. (6–52), the photolysis of ozone in wet air results in the formation of hydroxyl radicals. In water, the photolysis of ozone leads to the formation of hydrogen peroxide, which is subsequently photolyzed or reacted with O_3 to form hydroxyl radicals. The ozone/UV process can degrade compounds through direct ozonation, photolysis, or reaction with the hydroxyl radical, resulting in a process that is more effective when the compounds of interest can be degraded through the absorption of the UV irradiation as well as through the reaction with the hydroxyl radicals. Basic components of the ozone/UV process include ozone gas generation, ozone injection facilities, and UV photolysis reactors. A schematic flow diagram and view of a typical ozone/UV oxidation process is illustrated on Fig. 6–24.

Table 6–16

Advantages and disadvantages of various oxidation processes that produce hydroxyl radicals[a]

Advanced oxidation process	Advantages	Disadvantages
Commercially available AOPs for water reclamation		
Hydrogen peroxide/ultraviolet light	H_2O_2 is fairly stable and can be stored on site temporarily prior to use	H_2O_2 has poor UV absorption characteristics and if the water matrix absorbs UV light energy then most of the light input to the reactor will be wasted Special reactors which are designed for UV illumination are required Residual H_2O_2 must be removed Potential for UV lamp fouling
Hydrogen peroxide/ozone	Waters with poor UV-light transmission may be treated Special reactors designed for UV illumination are not required Volatile organics will be stripped from the ozone contactor (VOCs may require treatment)	Production of O_3 can be an expensive and inefficient process Gaseous ozone which is present in the off gas of the ozone contactor must be removed Maintaining and determining the proper O_3/H_2O_2 dosages may be difficult Low pH is detrimental to the process
Ozone/UV	No need to maintain precise dosages of O_3/H_2O_2 Residual oxidant will degrade rapidly (typical half life of O_3 is 7 minutes) Ozone absorbs more UV light than an equivalent dosage of hydrogen peroxide. (~200 times more at 254 nm) Volatile compounds will be stripped from the process (VOCs may require treatment)	Must use O_3 and UV light to produce H_2O_2, which is the primary means of producing HO· and using O_3 to produce H_2O_2 is very inefficient as compared to just adding H_2O_2 Special reactors which are designed for UV illumination are required Ozone in the off-gas must be removed Potential for UV lamp fouling
Other selected AOPs		
Ozone/UV/H_2O_2	Commercial processes that utilize the technology are available H_2O_2 promotes ozone mass transfer Volatile compounds will be stripped from the process. (VOCs may require treatment)	Special reactors that are designed for UV illumination are required Ozone in the off-gas must be removed Potential for UV lamp fouling
Fenton's reactions (Fe/hydrogen peroxide, photo-Fenton's or Fe/ozone)	Some effluents may contain sufficient Fe to drive the Fenton's reaction Commercial processes are available that utilize the technology	Process requires low pH
Titanium dioxide/UV	Activated with near UV light; consequently greater light transmission is achievable	Fouling of the catalyst may occur When used as a slurry, the TiO_2 must be recovered Potential for UV lamp fouling
Ozone at elevated pH (8 to >10)	Does not require the addition of UV light or hydrogen peroxide	Ozone is the off-gas must be removed pH adjustment is not practical in most wastewater applications There are no commercial applications Process does not yield an appreciable destruction for contaminants for reason provided in Sec. 6–7

(b)

Figure 6–24

Advanced oxidation process involving the use of ozone and UV radiation (a) schematic representation (ozone contactor shown without chimneys, see also Chap. 12) and (b) view of full scale installation.

While it is possible for UV light to split H_2O_2 into HO•, the extinction coefficient for O_3 is greater than that for H_2O_2 at λ_{254} nm. Thus, using ozone to produce H_2O_2, which in turn reacts with O_3 to produce HO•, may not be the most efficient way to produce HO• radicals because of the large amount of energy required to form ozone onsite. Processes involving ozone and UV dosages in the range of 16 to 24 mg/L and 810 to 1610 mJ/cm^2, respectively, have been found to mineralize a portion of the TOC and to reduce disinfection byproduct formation potential as compared to the use of either UV or ozone alone (Chin and Berube, 2005). As with all UV processes, fouling of the UV lamp sleeve, lamp replacement costs, and energy consumption are important considerations.

Ozone/Hydrogen Peroxide. For compounds that do not adsorb UV or where the transmittance of the water to be treated inhibits photolysis, AOPs involving ozone/H_2O_2 may be more effective than ozone/UV. Processes using O_3/H_2O_2 have been used to reduce the concentration of assorted VOCs, petroleum compounds, industrial solvents, and pesticides in water (Karimi et al., 1997; Mahar et al., 2004; Chen et al., 2006). The overall reaction for the production of hydroxyl radicals using hydrogen peroxide and ozone is as follows.

$$H_2O_2 + 2O_3 \rightarrow HO\cdot + HO\cdot + 3O_2 \qquad (6\text{–}53)$$

According to Eq. (6–53), 0.5 moles of H_2O_2 are needed for every mole of O_3 or a mass ratio of 0.354 kg of H_2O_2 is needed for every kg of O_3. However, there are several issues that impact the proper dosages of H_2O_2 and O_3. First, O_3 tends to be more reactive with background organic matter and inorganic species than with H_2O_2. As a result, the required O_3 dosage will be higher than estimated from stoichiometry. Typical ozone and hydrogen peroxide concentrations range from 5 to 30 mg/L and 5 to 15 mg/L, respectively. Pilot studies are usually conducted to determine the chemical dosage required for a given level of trace constituent removal. However, an excess O_3 dosage has the potential of wasting O_3, forming oxidation byproducts (e.g., bromate), and quenching HO• radicals via the following reaction:

$$O_3 + HO\cdot \rightarrow HO_2\cdot + O_2 \qquad (6\text{–}54)$$

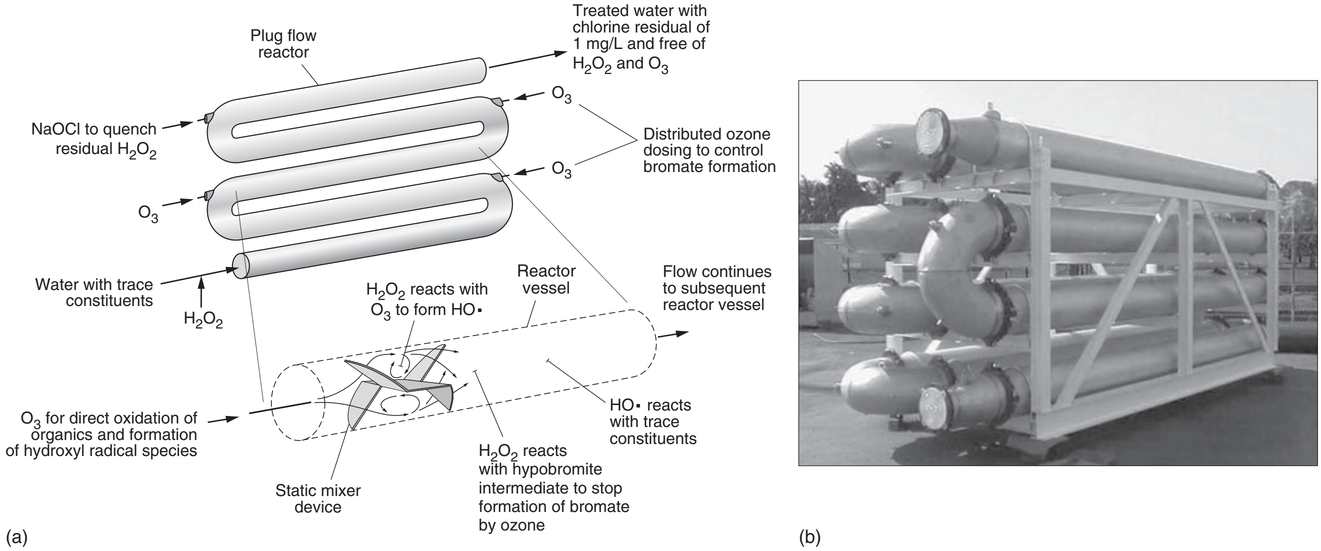

Figure 6–25

Advanced oxidation process involving the use of ozone and hydrogen peroxide (a) schematic of HiPOx® reactor and (b) view of reactor described in (a) (courtesy of Applied Process Technology, Inc., Pleasant Hill, CA.).

The $HO_2\cdot$ radical, formed by Eq. (6–54), may react to produce additional $HO\cdot$. To overcome the problem of byproduct formation and quenching of $HO\cdot$, new reactor designs have incorporated the addition of H_2O_2 or O_3 at multiple points in a single reactor and by using multiple reactors in series. A schematic flow diagram and view of a reactor used for reacting hydrogen peroxide and ozone is shown on Fig. 6–25. Excess H_2O_2 is also detrimental to the H_2O_2/O_3 AOP because it may scavenge $HO\cdot$. Further, the H_2O_2 residual can be more problematic than ozone because hydrogen peroxide is more stable than ozone and, in some applications, it may be necessary to remove residual hydrogen peroxide before reuse. Hydrogen peroxide reacts quickly with hypochlorite to form water, oxygen, and chloride ion.

Hydrogen Peroxide/UV. Hydroxyl radicals are also formed when water containing H_2O_2 is exposed to UV light (200 to 280 nm). The following reaction can be used to describe the photolysis of H_2O_2.

$$H_2O_2 + \text{UV (or } h\nu,\ \lambda \approx 200 \text{ to } 280 \text{ nm)} \rightarrow HO\cdot + HO\cdot \tag{6–55}$$

In some cases the use of the hydrogen peroxide/UV process has not been feasible because H_2O_2 has a small molar extinction coefficient, requiring high concentrations of H_2O_2 and high UV dosages. A schematic flow diagram and a typical installation of the hydrogen peroxide/UV process is shown on Fig. 6–26.

The basic elements of the hydrogen peroxide/ultraviolet light (H_2O_2/UV) process includes hydrogen peroxide injection and mixing followed by a reactor that is equipped with UV lights (see Fig. 6–26) Typical H_2O_2/UV reactors configurations include inline stainless steel reactors with low pressure (low and high intensity) or medium pressure UV lamps arranged parallel to the flow, perpendicular to the flow, or in upflow columns with crisscrossing lamps oriented perpendicular to the direction of flow.

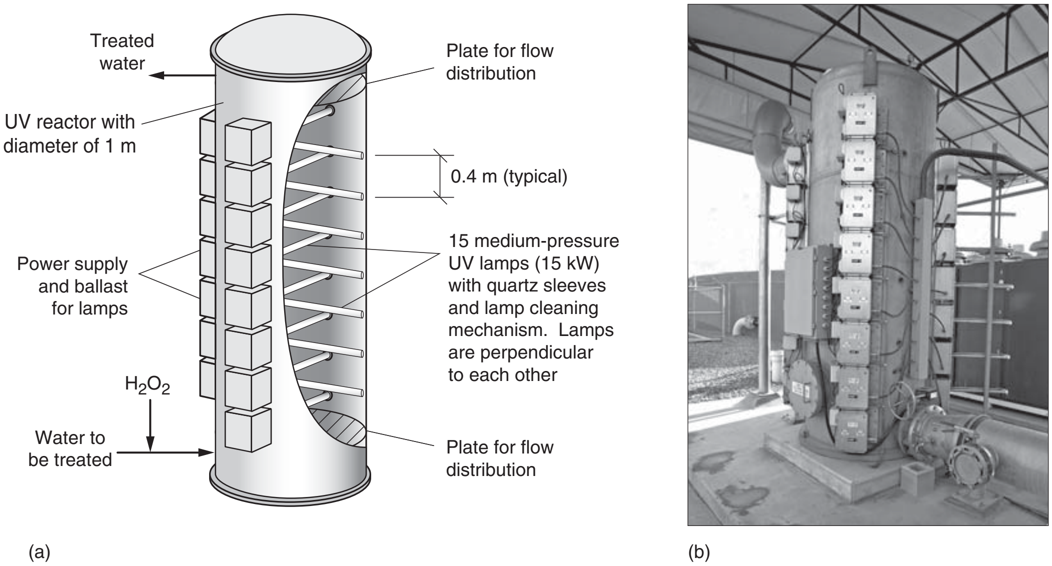

Figure 6–26

Hydrogen peroxide and UV radiation advanced oxidation process (a) schematic diagram (from Crittenden et al., 2012) and (b) photograph of typical vertical flow UV reactor.

The H_2O_2/UV process has not been used commonly for potable water treatment because it normally results in high effluent H_2O_2 concentrations. However, the residual hydrogen peroxide is not a concern in water reclamation. High effluent H_2O_2 concentrations occur because high initial dosages of H_2O_2 are required to efficiently utilize the UV light and produce hydroxyl radical. The residual H_2O_2 will consume chlorine and interfere with disinfection. In some instances, where high UV doses are required, as in the photolyisis of NDMA (see Chap. 2), H_2O_2 may be added to achieve advanced oxidation of other constituents that are resistant to photolysis alone (Linden et al., 2004). This method of operation is now being used in a number of water reclamation applications. The details required for modeling the H_2O_2/UV process can be found in Crittenden et al. (1999). As discussed in Chap. 12, UV processes are subject to fouling of the UV lamp sleeve, lamp replacement costs, and high energy consumption.

Other Processes. Other reactions which yield HO· include the reactions of H_2O_2 and UV with Fenton's reagent and the adsorption of UV by semiconductor metal oxides such as TiO_2 suspended in water which acts as a catalyst. Still others are currently under development.

Basic Considerations for Advanced Oxidation Processes

The engineering of an advanced oxidation process consists of the selection of a process to generate hydroxyl radicals, estimation of the reaction kinetics with the compounds of interest, and design of a reactor in which the reaction will take place. In addition, the presence of background organic and inorganic matter that reacts with the HO· will reduce the process efficiency for the target compound. Therefore, bench and/or pilot studies are always necessary to determine process efficiency for a given water matrix.

Commercially available advanced oxidation processes are rated for a given hydroxyl radical output. Reported field HO· concentrations range from 10^{-11} to 10^{-9} moles/L (Glaze et al., 1987; Glaze and Kang, 1990). The second order hydroxyl radical rate constants for

Table 6–17

Hydroxyl rate constants for selected constituents[a]

Compound name	**HO· rate constant, L/mole·s**	**Compound name**	**HO· rate constant, L/mole·s**
Ammonia	9.00×10^7	Hypobromous acid	2.0×10^9
Arsenic trioxide	1.0×10^9	Hypoiodous acid	5.6×10^4
Bromide ion	1.10×10^{10}	Iodide ion	1.10×10^{10}
Carbon tetrachloride	2.0×10^6	Iodine	1.10×10^{10}
Chlorate ion	1.00×10^6	Iron	3.2×10^8
Chloride ion	4.30×10^9	Methyl tertiary butyl ether (MTBE)	1.6×10^9
Chloroform	5×10^6	Nitrite ion	1.10×10^{10}
CN^-	7.6×10^9	N-Dimethylnitrosamine (NDMA)	4×10^8
CO_3^{2-}	3.9×10^8	Ozone	1.1×10^8
Dibromochloropropane	1.5×10^8	p-Dioxane	2.8×10^9
1,1-Dichloroethane	1.8×10^8	Tetrachloroethylene	2.6×10^9
1,2-Dichloroethane	2.0×10^8	Tetrachloroethylene	1.0×10^7
H_2O_2	2.7×10^7	Tribromomethane	1.8×10^8
HCN	6.0×10^7	Trichloroethylene	4.2×10^9
HCO_3^-	8.5×10^6	Trichloromethane	5.0×10^6
Hydrogen sulfide	1.5×10^{10}	Vinyl chloride	1.2×10^{10}

[a] Adapted from Crittenden et al. (2012).

several compounds of interest are presented in Table 6–17. As mentioned previously, the reactions are second order because they depend on the concentration of the hydroxyl radical and the compound undergoing oxidation. The reaction between HO· and an organic compound of interest, R, is represented as follows:

$$HO\cdot + R \rightarrow \text{byproducts} \tag{6–56}$$

The second order rate law, r_R, corresponding to the reaction shown in Eq. 6–56, is given by the following expression.

$$r_R = -K_R C_{HO}\cdot C_R \tag{6–57}$$

where r_R = second order rate law, mole/L·s
K_R = second order rate constant for the destruction of R with HO· radicals, L/mole·s
$C_{HO\cdot}$ = concentration of hydroxyl radical, mole/L
C_R = concentration of the target organic R, mole/L

The half-life of the target organic compounds may be calculated assuming that the HO· is constant and equal to a typical field value or manufacturer specification. The expression for the half-life of an organic compound is obtained by substituting the rate law into a mass balance on a batch reactor whose contents are mixed completely and solving and rearranging the result, as follows:

$$\frac{dC_R}{dt} = -k_R C_{HO\cdot} C_R \qquad (6–58)$$

$$t_{1/2} = \frac{\ln(2)}{k_R C_{HO\cdot}} \qquad (6–59)$$

where $t_{1/2}$ = the half life of the organic compound R, s.

The use of Eqs. (6–58) and (6–59) is shown in the following example.

EXAMPLE 6–6 **Advanced Oxidation Process for Removal of NDMA** NDMA ($C_2H_6N_2O$) is a compound of concern present in many secondary and tertiary treated wastewater effluents. From Table 6–17, the second order rate constant of HO· for NDMA is 4×10^8 L/mole·s. Compute the time required to lower the concentration of NDMA from 200 μg/L to 20 μg/L for a HO· concentration of 10^{-9} mole/L using an ideal plug flow reactor.

Solution

1. Develop an expression of the concentration of NDMA as a function of time in a completely mixed batch reactor (CMBR). Note that the residence time for an ideal plug flow reactor is equivalent to the residence time in a completely mixed batch reactor.
   a. Using Eq. (6–58), the rate expression for a CMBR, where C_R represents the concentration of NDMA is given by

$$r_R = \frac{dC_R}{dt} = -k_R C_{HO\cdot} C_R = -k' C_R$$

   where $k' = k_R C_{HO\cdot}$

   b. The integrated form of the rate expression for a CMBR is:

$$\int_{C_{RO}}^{C_R} \frac{dC_R}{C_R} = -\int_o^t k't$$

$$C_R = C_{RO} e^{-k't}$$

2. Calculate the time it would take to achieve a concentration of 20 μg/L using the equation developed in step 1.
   a. Rearrange the above equation to solve for t.

$$t = \frac{1}{k'} \ln\left(\frac{C_{RO}}{C_R}\right)$$

   b. Solve for t.

   The value of k' from step 1 is

$$k' = k_R C_{HO\cdot} = (4 \times 10^8 \text{ L/mole·s})(10^{-9} \text{ mole/L}) = 0.4 \text{ 1/s}$$

$$t = \frac{1}{0.4} \ln\left(\frac{200}{20}\right) = 5.8 \text{ s}$$

Comment Advanced oxidation of NDMA appears to be feasible given the short contact time required for the reaction. Because some organic compounds of interest react more slowly with HO•, these compounds will require longer reaction times and/or high concentrations of HO•. The presence of background organic matter, carbonate, bicarbonate, and pH will also reduce the efficiency of the AOP and must be considered during process design. As discussed in Chap. 4, bench and/or pilot testing will be required to determine site specific process design and operational parameters.

Advanced Oxidation Process Limitations

The feasibility and efficiency of AOPs are determined by a number of factors, including interferences and the production of byproducts, as described below. Means of overcoming most process limitations in water reuse applications are also considered.

Byproducts of Advanced Oxidation Processes. Advanced oxidation processes (and processes that use ozone), have been found to produce brominated byproducts and bromate (BrO_3^-) in waters containing bromide ion. The concentration of bromide ion, total organic carbon (TOC) concentration, and pH determine the quantity of brominated byproducts formed. Some AOPs have been designed to minimize bromate formation by pH control or ammonia addition (Crittenden et al., 2012).

Both hydrogen abstraction and radical addition produce reactive organic radicals. The organic radicals undergo subsequent oxidation and may combine with dissolved oxygen to form peroxy organic radicals (ROO•), which subsequently undergo radical chain reactions that produce a variety of oxygenated byproducts. A general pattern of oxidation is presented in Eq. (6–60) (Bolton and Cater, 1994).

$$\begin{matrix}\text{Organic}\\\text{compound}\end{matrix} \rightarrow \text{Aldehydes} \rightarrow \begin{matrix}\text{Carboxylic}\\\text{acids}\end{matrix} \rightarrow \begin{matrix}\text{Carbon dioxide}\\\text{and mineral acids}\end{matrix} \qquad (6\text{–}60)$$

Carboxylic acids are of particular concern as the second order rate constants for these compounds are much lower than for most other organics, which may inhibit degradation of these constituents. Other byproducts that may be of concern are the halogenated acetic acids, formed from the oxidation of halogenated alkenes such as trichloroethene (Crittenden et al., 2012).

Impact of Bicarbonate and Carbonate. High concentrations of carbonate and bicarbonate in some wastewater can react with HO• and reduce the efficiency of advanced oxidation treatment processes. Bicarbonate and carbonate ions are known scavengers of HO• radicals and reduce the rate of organics destruction significantly. Unfortunately, the concentrations of HCO_3^- and CO_3^{2-} are often three orders of magnitude higher than the organic pollutants targeted for destruction. Even low alkalinities (50 mg/L) reduce the rate of TCE destruction by a factor of 10 at a pH of 7 (Crittenden et al., 2012). However, at high pH a given alkalinity is more detrimental because the second order rate constant with CO_3^{2-} is much larger than HCO_3^-. Wastewater with high pH and alkalinity are more difficult to treat using AOPs. To overcome these difficulties and improve the effectiveness of AOPs, pretreatment processes such as softening or reverse osmosis are used to remove the alkalinity.

Impact of pH. The pH affects AOP performance because it determines the distribution of the carbonate species, HCO_3^- and CO_3^{2-}, as discussed above. The pH will also control the concentration of HO_2^- (H_2O_2 has a pK_a of 11.6), which is important in the H_2O_2 type advanced oxidation processes. For example, in the H_2O_2/UV process, HO_2^- has about 10 times the UV absorbance at 254 nm (228 L/mole·cm) than does H_2O_2; consequently, H_2O_2/UV may be more effective at higher pH. Raising the pH to improve the process performance would only be practical if the pH was raised for other purposes such as softening. Finally, pH affects the charge on the organic compounds if they are weak acids or bases. The reactivity and light absorption properties of the compound can be affected by its charge, an observation to be considered in the design of AOPs (Crittenden et al., 2012).

Impact of Metal Ions. Metal ions in reduced oxidation states, such as Fe(II) and Mn(II), can consume a significant quantity of chemical oxidants as well as scavenge HO· radicals. Consequently, the concentration of reduced metal ions should be measured as part of any treatability study, and the dosage of oxidants needed should include the COD of the reduced metal species.

Impact of Other Factors. Other factors that also affect the treatment process include suspended material (which affects light transmission) and the type and nature of the residual TOC and COD. For example, NOM, which reacts with hydroxyl radicals, can have a great influence on the reaction rate. Because the chemistry of the water matrix is different for each reclaimed water, bench and/or pilot testing is almost always required to test the technical feasibility, to obtain usable design data and information, and to obtain operating experience with a specific AOP.

Means of Overcoming Process Limitations. To overcome the problems noted above, advanced oxidation processes are typically applied following treatment by reverse osmosis. Further, if adequate reaction time is provided, $>$99 percent of the organic constituents (as measured by a TOC mass balance) are mineralized (Stefan and Bolton, 1998; Stefan et al., 2000).

6–9 PHOTOLYSIS

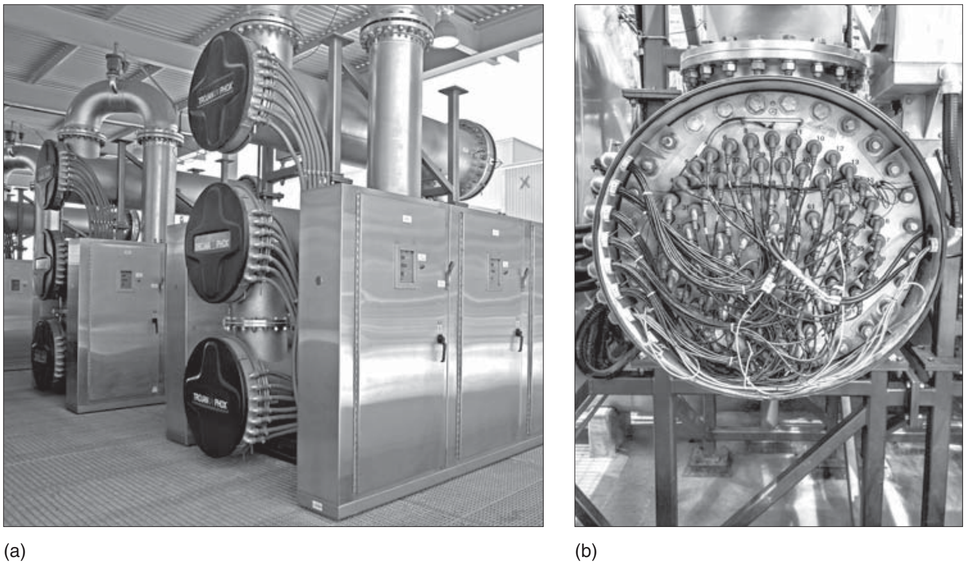
Photolysis is a process by which constituents are broken down by exposure and absorption of photons from a light source. As with AOPs, the primary use of photolysis is for the removal of trace organic compounds in water reuse applications. In natural systems, sunlight is the light source for photolysis reactions, however, in engineered systems, ultraviolet (UV) lamps are used to produce the photonic energy. The photons that are absorbed cause the electrons in the outer orbital of some compounds to become unstable and split or become reactive. The effectiveness of the photolysis process depends, in part, on the characteristics of the reclaimed water, structure of the compounds, design of the photolysis reactor, and dose and wavelength of the applied light. The photolysis rate can be estimated from the rate at which the compound absorbs light and the photonic efficiency of the reaction (quantum yield).

Applications for Photolysis

Photolysis may be used for the removal of various compounds, such as NDMA (see Chap. 3) and other trace organic constituents. It should be noted that many compounds are not removed using photolysis alone, and that the addition of hydrogen peroxide can

Figure 6–27

View of photolysis reactors for advance oxidation for the removal of constituents such as NDMA from reclaimed water: (a) three reactors in series each containing 72 UV lamps and (b) end cover removed from a reactor showing wiring to the 72 UV lamps.



(a)
(b)

enhance the degradation of these constituents. However, the addition of hydrogen peroxide may actually reduce the photolysis of some compounds, such as NDMA (Linden et al., 2004). As described in Sec. 6–8, the photolysis of hydrogen peroxide, resulting in the formation of hydroxyl radicals, is an advanced oxidation process known for its effective destruction of most organic compounds.

Photolysis Processes

Engineered photolysis reactions are conducted in specially designed reactors optimized with respect to UV dose. Photolysis reactors are typically comprised of a stainless steel column or pipe containing UV lamps arranged parallel to the flow, perpendicular to the flow, or in a crisscrossing pattern perpendicular to the direction of flow. An example of a reactor used for photolysis is shown on Fig. 6–27. Fouling that may occur on the outside of the UV lamp protective quartz sleeve may be managed using an automatic cleaning system consisting of a collar that periodically moves along the lamp to remove precipitates and intercepted matter. When used in conjunction with reverse osmosis pretreatment, the chemicals added to reduce the pH for scale control in the membranes will also reduce the potential for precipitation on the UV lamps.

Photolysis reactions are caused by light emission in the ultraviolet range (200 to 400 nm, see also Fig. 12–33 in Chap. 12). There are three types of UV lamps used for photolysis processes: (1) low-pressure low-intensity, (2) low-pressure high-intensity, and (3) medium-pressure high-intensity lamps. Low-pressure lamps emit much of their energy at a wavelength of 254 nm while medium pressure lamps emit energy at multiple wavelengths (see Fig. 12–33 in Chap. 12). The type of lamp used and reactor configuration will depend on the constituent to be removed as well as the water matrix and site-specific conditions.

Basic Considerations for Photolysis Processes

Photolysis occurs when an electron in the outer orbital of a constituent absorbs a photon and forms an unstable compound that splits apart or becomes reactive. Many non-target constituents may be present in reclaimed water, depending on the prior treatment applied, that absorb light during the photolysis process. As an introduction to the photolysis process, the concepts involved in photolysis are presented in the following discussion for the case of a single absorbing solute. The fundamentals of photolysis consist of (1) absorption of UV light by a compound in water, (2) rate of photolysis, (3) electrical efficiency, and (4) photolysis process limitations.

Absorption of UV Light. The absorption of light by a compound in water or other aqueous solution can be described using the Beer-Lambert Law. The absorbance of a solution is a measure of the amount of light absorbed by constituents in the solution using a spectrophotometer at a specified wavelength and over a fixed path length.

$$A(\lambda) = -\log\left(\frac{l}{I_o}\right) = \varepsilon(\lambda)Cx = k(\lambda)x \tag{6–61}$$

where $A(\lambda)$ = absorbance, dimensionless
l = light intensity after passing through solution containing constituents of interest at wavelength, λ, einsteins/cm^2·s (note: an einstein is equal to one mole of photons)
I_o = light intensity after passing through a blank solution (i.e., distilled water) of known depth (typically 1.0 cm) at wavelength, λ, einstein/cm^2·s
$\varepsilon(\lambda)$ = base 10 extinction coefficient or molar absorptivity of light absorbing solute at wavelength λ, L/mole·cm
λ = wavelength, nm
C = concentration of light absorbing solute, mole/L
x = length of light path, cm
$k(\lambda)$ = absorptivity (base 10), 1/cm

The extinction coefficient is a function of wavelength because as the wavelength decreases more energetic photons are absorbed and the absorptivity of a light absorbing compound increases. Values of the extinction coefficients for several compounds at various wavelengths are given in Table 6–18. The use of Eq. (6–61) is presented in Example 6–7.

Table 6–18

Selected quantum yields and extinction coefficients for compounds commonly found in water.

Compound	Primary quantum yield in aqueous phase, mole/einstein	Extinction coefficient at 253.7 nm, L/mole·cm
NO_3^-	—	3.8
HOCl (at 330 nm)	0.23	15
OCl^-	0.23	190
HOCl	—	53.4
OCl^-	0.52	155
O_3	0.5	3300
ClO_2	0.44	108
Sodium chlorite	0.72	—
TCE	0.54	9
PCE	0.29	205
NDMA	0.3	1974
Water	—	0.0000061

[a] Adapted from Crittenden et al. (2012).

EXAMPLE 6–7 **UV Absorbance by NDMA** The chemical compound NDMA (see Chap. 2) is commonly found at low concentrations in reclaimed water, even after treatment by reverse osmosis. Estimate the absorptivity of NDMA ($C_2H_6N_2O$) at a wavelength of 254 nm, assuming NDMA is present at a concentration of 30 ng/L.

Solution

1. Convert the mass concentration of NDMA in solution to mole/L.
   Using the periodic table from the back inside cover of this textbook, the molecular weight of NDMA is 74.09 g/mole. The concentration is determined as follows:

$$C = \frac{(30 \text{ ng/L})}{(74.09 \text{ g/mole})}(1 \text{ g}/10^9 \text{ ng}) = 4.05 \times 10^{-10} \text{ mole/L}$$

2. Compute the absorptivity of NDMA using Eq. (6–61).
   a. Determine the extinction coefficient, $\varepsilon(\lambda)$, of NDMA from Table 6–18. The extinction coefficient of NDMA at a wavelength of 254 nm is 1974 L/mole•cm.
   b. The absorptivity, $k(\lambda)$, of NDMA is:

$$\begin{aligned} k(\lambda) &= \varepsilon(\lambda_{254})C = (1974 \text{ L/mole}\cdot\text{cm})(4.05 \times 10^{-10} \text{ mole/L}) \\ &= 8.0 \times 10^{-7} \text{ cm}^{-1} \end{aligned}$$

Comment Because of the low concentration of NDMA in the water, the absorptivity is also low. If photolysis was to be used for removal of NDMA, other constituents in the water matrix that will absorb photons would need to be considered as well as the background absorbance of the water matrix.

Light absorption by a single compound in water was described in the previous analysis. In practice, however, a number of absorbing compounds will be present in solution. The absorption of light as it passes through a solution containing several different compounds may be determined by summing the absorption that would result from each individual compound as shown in the following expression:

$$\ln\left(\frac{I}{I_o}\right) = -\left[\sum \varepsilon'(\lambda)_i C_i\right] x \tag{6–62}$$

where $\varepsilon'(\lambda)_i$ = extinction coefficient of compound i at wavelength λ (base e), L/(mole•cm); Note: $\varepsilon'(\lambda)_i = 2.303\varepsilon(\lambda)_i$.
C_i = concentration of compound i, mole/L

Other terms as defined previously.

The relationship shown in Eq. (6–62) is based on a single incident wavelength, such as with low-pressure UV lamps. Multiple wavelength situations, such as with the use of medium-pressure UV lamps, can be determined using a similar approach, that is, summing adsorption of each compound for each wavelength.

Energy Input for Photolysis. The lamp output and reactor size can be used to estimate the energy input for the photolysis reaction. The theoretical maximum photonic energy input per unit volume of the reactor can be determined using the following expression:

$$P_R = \frac{P\eta}{N_P\, V\, hv} \tag{6–63}$$

where P_R = photonic energy input per unit volume of the reactor, einstein/L•s
P = lamp power, J/s (W)
h = Planck's constant, 6.62×10^{-34} J•s
η = output efficiency at the wavelength of interest (as a fraction)
N_P = number photons per mole (as einstein), 6.023×10^{23} 1/einstien
V = reactor volume, L
$v = \dfrac{c}{\lambda}$ = frequency of light, 1/s
c = the speed of light, 3.00×10^{8} m/s
λ = wavelength of the light, m

While the above analysis is satisfactory for a theoretical assessment, the actual performance of a photoreactor is expected to be lower than computed using Eq. (6–63) due to light being absorbed by the reactor walls or blocked by the precipitate that forms on the lamp sleeve. While a safety factor specific to a particular system could be applied to compensate for these inefficiencies, pilot studies are used to obtain more reliable design criteria.

Rate of Photolysis. The rate at which a compound is photolyzed depends on the rate and frequency of photon absorption. The volumetric photon absorption rate, derived from Eq. (6–62), is:

$$I_v = -\frac{dl}{dx} = \varepsilon'(\lambda)\cdot C\cdot I_o\cdot e^{-\varepsilon'(\lambda)Cx} \tag{6–64}$$

where I_v = rate that photons are absorbed per volume of solution at a particular point, einstein/cm^3•s
$\varepsilon'(\lambda)$ = base *e* extinction coefficient or molar absorptivity of light absorbing solute at wavelength $\lambda = 2.303\varepsilon(\lambda)$, L/mole•cm

Other terms as defined previously.

The quantum yield is a quantity used to describe the frequency at which photon absorption results in a photolysis reaction and is specific to the type of compound and the wavelength. The quantum yield, $\phi(\lambda)$, is defined as being equal to the number of photolysis reactions divided by the number of photons absorbed by the molecule as follows:

$$\phi(\lambda) = \frac{-r_R}{I_V} = \frac{\text{Reaction rate}}{\text{Rate of photon absorption}} \tag{6–65}$$

where $\phi(\lambda)$ = quantum yield at wavelength λ, mole/einstein
r_R = photolysis rate, mole/(cm^3•s)

As a general rule, the quantum yield increases as wavelength decreases (increasing photonic energy). Selected quantum yields at a wavelength 254 nm are summarized in Table 6–18.

Typically, the light absorption by the component that is targeted for removal is minor as compared to the light absorption by the background water matrix (Crittenden et al., 2012). The pseudo first order rate law for the photolysis reaction is

$$r_{\text{avg}} = \left[\phi(\lambda) P_R \frac{\varepsilon'(\lambda)}{k'(\lambda)}\right] C = kC \tag{6–66}$$

where r_{avg} = overall average photolysis rate of the constituent in the reactor, mole/L·s
$\phi(\lambda)$ = quantum yield of the constituent at wavelength λ, mole/einstein
$\varepsilon'(\lambda)$ = the extinction coefficient of the constituent (base e), L/mole·cm
C_i = the concentration of the constituent, mole/L
$k'(\lambda)$ = measured absorptivity of the water matrix at wavelength (base e) λ, 1/cm
k = pseudo-first order rate coefficient, 1/s

After obtaining the rate law, r_{avg}, an appropriate reactor model may be used for determination of the expected performance.

Electrical Efficiency. The electrical energy requirement for photolytic reactions is significant due to the process inefficiencies. Consequently, it is important to compare process efficiency on the basis of electrical usage per amount of compound destruction. One such measure is the electrical efficiency per log order (EE/O) of compound destruction (Bolton and Cater, 1994). The definition of EE/O is the electrical energy (in kWh) required to reduce the concentration of a constituent by one order of magnitude for 3785 L (1000 U.S. gallons) of water.

$$\text{EE/O} = \frac{Pt}{V \log\left(\dfrac{C_i}{C_f}\right)} \text{ (for batch systems)} \tag{6–67}$$

$$\text{EE/O} = \frac{P}{Q \log\left(\dfrac{C_i}{C_f}\right)} \text{ (for continuous flow systems)} \tag{6–68}$$

where EE/O = electrical efficiency per log order reduction, kWh/m^3
P = lamp power output, kW
t = irradiation time, h
V = reactor volume, m^3
C_i = initial concentration, mg/L
C_f = final concentration, mg/L
Q = water flowrate, m^3/h

For a flow through system, the power input can be divided by the EE/O to obtain an estimate of the flowrate that can be treated in a given reaction and achieve one order of magnitude reduction in concentration. Consequently, EE/O is a convenient measure because it can be used to estimate the energy that is required to reduce the contaminant concentration by one order of magnitude.

Because of the variability in wastewater characteristics, the required EE/O value for a one log order of reduction (i.e., 100 to 10) of NDMA can range from 21 to 265 kWh/10^3 m^3·log order (0.08 to 1.0 kWh/10^3 gal·log order) with a 5 to 6 mg/L dose of H_2O_2, although testing should be conducted to determine if peroxide is necessary (Soroushian et al., 2001).

EXAMPLE 6–8 **Design of Direct Photolysis Process for NDMA** A water reclamation plant produces 1.9×10^4 m^3/d (5 Mgal/d) of reverse osmosis (RO) effluent containing 50 ng/L of NDMA. Determine the number of photolysis reactors needed to reduce the NDMA concentration of the RO effluent to 1 ng/L prior to groundwater injection. The photolysis reactors under evaluation are 0.5 m in diameter and 1.5 m long with an effective water volume of 242 L. Each reactor has 72 lamps rated at 200 W per lamp and an output efficiency of 30 percent at 254 nm. Assume that the hydraulic detention time, τ, of the reactor can be described using the tanks in series model, $\tau = n[(C_e/C_o)^{1/n} - 1]/k$, where k is the reaction rate constant and n is the number of tanks in series. Use three tanks in series and neglect all other losses. The RO water has an absorptivity measured at a wavelength of 254 nm of $k'(\lambda) = 0.02\ \text{cm}^{-1}$. Calculate the EE/O and daily energy usage for the photolysis process.

Solution

1. Calculate the photonic energy input per unit volume of the reactor.
   a. Calculate the total lamp power.

$$P = (72 \text{ lamps} \times 200 \text{ W/lamp}) = 14{,}400 \text{ W} = 14{,}400 \text{ J/s}$$

   b. Calculate the photonic energy input for the reactor using Eq. (6–63).

$$P_R = \frac{(14{,}400 \text{ J/s})(0.3)(254 \times 10^{-9} \text{ m})}{(6.023 \times 10^{23} \text{ 1/einstein})(6.62 \times 10^{-34} \text{J·s})(3.0 \times 10^{8} \text{ m/s})(242 \text{ L})}$$

$$= 3.80 \times 10^{-5} \text{ einstein/L·s}$$

2. Calculate the rate constant for NDMA.
   a. The extinction coefficient of NDMA at 254 nm can be obtained from Table 6–18.

$$\varepsilon(\lambda_{254}) = 1974 \text{ L/mole·cm}$$

$$\varepsilon'(\lambda_{254}) = 2.303[\varepsilon(\lambda_{254})] = 2.303 \times 1974 = 4546 \text{ L/mole·cm}$$

   b. The quantum yield for NDMA can be obtained from Table 6–18.

$$\phi(\lambda_{\text{NDMA}}) = 0.3 \text{ mole/einstein}$$

   c. Compute k_{NDMA} using Eq. (6–66).

$$k_{\text{NDMA}} = \phi(\lambda_{\text{NDMA}})P_R \frac{\varepsilon'(\lambda_{\text{NDMA}})}{k'(\lambda)}$$

$$= (0.3 \text{ mole/einstein})(3.80 \times 10^{-5} \text{ einstein/L·s})\left[\frac{(4546 \text{ L/mole·cm})}{(0.01/\text{cm})}\right]$$

$$= 2.59 \text{ 1/s}$$

3. Calculate the flowrate, that can be treated per reactor.
   a. Calculate hydraulic detention time for the reactor.

$$\tau = \frac{n[(C_{\text{NDMA,o}}/C_{\text{NDMA,e}})^{1/n} - 1]}{k_{\text{NDMA}}} = \frac{3[(50/1)^{1/3} - 1]}{(2.59 \text{ 1/s})} = 3.11 \text{ s}$$

   b. Calculate the flowrate, that can be processed by one reactor.

$$Q = \frac{V}{\tau} = \frac{242 \text{ L}}{3.11 \text{ s}} = 77.7 \text{ L/s}$$

4. Determine the number of reactors needed to treat the full flow.
   a. The total flow to be treated is $1.9 \times 10^4\ \mathrm{m^3/d} = 219\ \mathrm{L/s}$.
   b. The number of reactors needed is (219 L/s) / (77.7 L/s) = 2.8 (use 3).
   c. The actual number of reactors needed will be greater than the computed value to compensate for lamp failure, fouling, and so that one or more reactors can be taken off line for lamp maintenance without interrupting the flow. It should be noted that the extra reactors will not be in continuous operation, but will only be used when needed or in a service rotation to reduce costs.
5. Calculate the EE/O for the photolysis process.

$$\mathrm{EE/O} = \frac{P}{Q \log\left(\dfrac{C_i}{C_f}\right)}$$

$$= \frac{(14.4\ \mathrm{kW})(10^3\ \mathrm{L/1\ m^3})}{(77.7\ \mathrm{L/s})\left\{\log\left[\dfrac{(50\ \mathrm{ng/L})}{(1\ \mathrm{ng/L})}\right]\right\}(3600\ \mathrm{s/h})} = 0.0303\ \mathrm{kWh/m^3}$$

The computed EE/O value is low compared to the typical range for ground and surface waters because of the high quality effluent from the RO process. Reverse osmosis removes or reduces many of the constituents that would interfere with photolysis of specific constituents and can produce effluent with low absorbance, improving the efficiency of the photolysis process.

6. Estimate the overall daily energy usage for the process.
   For the two operational reactors, the estimated energy usage is

$$3\ \text{reactors} \times 14.4\ \mathrm{kW} \times 24\ \mathrm{h/d} = 1037\ \mathrm{kWh/d}$$

Comment The photolysis reactors sized in the design example represent a minimum size and do not include correction factors for nonideal flow, variability in lamp output, and other inefficiencies. Bench and/or pilot studies are always required to determine actual design parameters.

Photolysis Process Limitations

The efficiency of the photolysis process depends, in part, on the characteristics of the water matrix and compounds targeted for degradation. For example, the extinction coefficient for residual organic matter varies over a wide range and may interfere with the photolysis of other compounds. In addition, the light energy input may be absorbed by the other constituents, there may be photon losses upon reflection off the reactor wall, and the precipitate that builds up on the exterior surface of sleeves that cover the lamps due to the elevated temperature will block light transmission. For some constituents, the performance of direct photolysis processes have been improved by the addition of hydrogen peroxide (Linden et al., 2004), as described in Sec. 6–8. To overcome the limitations associated with photolysis processes related to absorbance of UV energy by non-target constituents in water reuse, pretreatment using reverse osmosis should be used to remove most of the interfering compounds and improve the overall process performance. Pilot studies should be conducted to characterize the expected efficiency of photolysis and the rate and characteristics of fouling of the lamp sleeve.

6–10 CHEMICAL NEUTRALIZATION, SCALE CONTROL, AND STABILIZATION

The removal of excess acidity or alkalinity by treatment with a chemical of the opposite composition is termed *neutralization*. In general, all treated wastewaters with excessively low or high pH will require neutralization before they can be dispersed to the environment. Scaling control is required for nanofiltration and reverse osmosis treatment to control the formation of scale, which can severely impact performance. Chemical stabilization is often required for highly treated wastewaters to control their aggressiveness with respect to corrosion. These subjects are considered briefly below.

pH Adjustment

In a variety of wastewater treatment operations and processes, there is often a need for pH adjustment. Because a number of chemicals are available that can be used, the choice will depend on the suitability of a given chemical for a particular application and prevailing economics. General information on the chemicals used most commonly for pH adjustment is given in Table 6–19. Wastewater that is acidic can be neutralized with any number of

Table 6–19

Chemicals used most commonly for the control of pH (neutralization)

				Availability	
Chemical	**Formula**	**Molecular weight**	**Equiv weight**	**Form**	**Percent**
Chemicals used to raise pH					
Calcium carbonate	$CaCO_3$	100.0	50.0	Powder crushed	96 to 99
Calcium hydroxide (lime)	$Ca(OH)_2$	74.1	37.1	Powder granules	82 to 95
Calcium oxide	CaO	56.1	28.0	Lump, pebble, ground	90 to 98
Dolomitic hydrated lime	$[Ca(OH)_2]_{0.6}$ $[Mg(OH)_2]_{0.4}$	67.8	33.8	Powder	58 to 65
Dolomitic quicklime	$(CaO)_{0.6}(MgO)_{0.4}$	49.8	24.8	Lump, pebble, ground	55–58 CaO
Magnesium hydroxide	$Mg(OH)_2$	58.3	29.2	Powder	
Magnesium oxide	MgO	40.3	20.2	Powder, granules	99
Sodium bicarbonate	$NaHCO_3$	84.0	84.0	Powder, granules	99
Sodium carbonate (soda ash)	Na_2CO_3	106.0	53.0	Powder	99.2
Sodium hydroxide (caustic soda)	$NaOH$	40.0	40.0	Solid flake, ground flake, liquid	98
Chemicals used to lower pH					
Carbonic acid	H_2CO_3	62.0	31.0	Gas (CO_2)	
Hydrochloric acid	HCl	36.5	36.5	Liquid	27.9, 31.45, 35.2
Sulfuric acid	H_2SO_4	98.1	49.0	Liquid	77.7 (60° Be) 93.2 (66° Be)

[a] Adapted in part from Eckenfelder et al. (2009).

basic chemicals, as reported in Table 6–19. Sodium hydroxide (NaOH, also known as caustic soda) and sodium carbonate, although somewhat expensive, are convenient and are used widely by small plants or for treatment where small quantities are adequate. Lime, which is cheaper, but somewhat less convenient, is the most widely used chemical. Lime can be purchased as quicklime or slaked hydrated lime, high-calcium or dolomitic lime, and in several physical forms. Limestone and dolomitic limestone are cheaper, but less convenient to use and slower in reaction rate. Because they can become coated in certain waste treatment applications, their use is limited. Calcium and magnesium chemicals often form sludges that require disposal.

Alkaline wastes are less of a problem than acid wastes, but nevertheless often require treatment. If acidic waste streams are not available or are not adequate to neutralize alkaline wastes, sulfuric acid is commonly employed. In some treatment plants, carbon dioxide (CO_2) in the form of flue gas has been used to neutralize alkaline wastewaters as illustrated by the following reactions.

$$2OH^- + CO_2 \rightarrow CO_3^{2-} + H_2O \tag{6–69}$$

$$CO_3^{2-} + CO_2 + H_2O \rightarrow 2HCO_3^- \tag{6–70}$$

Based on the chlorine dose used for disinfection, the pH of the disinfected effluent will be lower than that allowed for reuse applications and for dispersal to the environment. In such cases, neutralization is controlled by automatic instruments using a feedback loop, and the final effluent pH is recorded. Depending on the sensitivity of the environment, two-stage neutralization may be required. The reagent chemicals can be fed automatically, in the form of solutions, slurries, or dry materials. If the reaction rate is slow, instrumentation and control design must take this factor into account.

Analysis of Scaling Potential

With the increasing use that is being made of nanofiltration, reverse osmosis, and electrodialysis in wastewater reuse applications, adjustment of the scaling characteristics of the effluent to be treated is important to avoid calcium carbonate and sulfate scale formation. Depending on the recovery rate, the concentration of salts can increase by a factor of up to ten within the treatment module. When such a salt concentration increase occurs, it is often possible to exceed the solubility product of calcium carbonate and other scale-forming compounds. The formation of scale within the treatment module will cause deterioration in the performance, ultimately leading to the failure of the membrane module.

Over the past 75 years, a number of theories of scale formation (principally calcium carbonate scale) has been advanced and applied. Generally, these theories have resulted in the formation of relative indexes that are used to assess whether a water is undersaturated, balanced, or supersaturated with respect to calcium carbonate. An undersaturated water will tend to dissolve an existing calcium carbonate film; a balanced water will neither dissolve or form a film; a supersatured water will tend to form a film. Representative indexes that are used to assess the potential for scale formation are presented in Table 6–20. It is interesting to note that most of the available indexes were developed for the water supply and petroleum industry. The Langelier saturation index and the Ryzner stability index, used commonly in the wastewater field, are discussed in greater detail below. It should be noted that a variety of computer programs are available that can be used to solve the index equations, many of which are quite complex, such as the

Table 6–20

Representative indexes used to assess the stability of water

Index	General form of relationship	Undersaturated systems	Saturated systems	Oversaturated systems
Aggressiveness Index (AI)[a,b]	AI $= \mathrm{pH} + \log_{10}[(\mathrm{Ca})(\mathrm{Alk})]$ Ca and Alk expressed as mg $CaCO_3$/L	AI < 10 highly aggressive	$10 <$ AI < 12 moderately aggressive	AI > 12 nonaggressive (i.e. . protective)
Calcium saturation index (CSI)[b]	CSI $= \mathrm{pH} + \mathrm{Tf} + \mathrm{Af} + \mathrm{Cf} - 12.1$ Where Tf = temperature, Af = alkalinity, and Cf = calcium factors taken from tables	CSI < -0.3 scale may form	CSI ~ 0 water is balanced	CSI > 0 water will not form scale
Calcium carbonate precipitation potential (CCPP)[c,b]	Complex computer based model the solution			
Driving force index (DFI)[d,b]	DFI $= (Ca^{2+})(CO_3^{2-})/K's \cdot 10^{10}$ Ca^{2+} and CO_3^{2-} expressed as mg $CaCO_3$/L	DFI < 1	DF $= 1$	DFI < 1
Langelier saturation index (LSI)[e,b]	LSI $= \mathrm{pH} - \mathrm{pH}_s$	LSI < 0	LSI $= 0$	LSI > 0 LI
Larson-Skold index[f]	$L - SI = (Cl^- + SO_4^{2-})/(HCO_3^- + CO_3^{2-})$ all expressed as equivalents per million (epm)	$>>0.6$ high corrosion rates expected	$>> 0.2$ but $<<0.6$ chlorides and sulfate may interfere with film formation	$<<0.2$ chlorides and sulfate will not interfere with film formation
Saturation level (SL)	$\mathrm{SL} = \dfrac{\gamma_{Ca}[Ca]\gamma_{CO_3}[CO_3]}{K_{sp}}$	<1	1	>1
Puckorius scaling index (PSI)[g,b]	PSI $= 2(\mathrm{pH}_s) - \mathrm{pH}_{eq}$	$<<6$ scale forming tendence	6 water is stable	$>>6 - 7$ scale should not form
Ryznar stability index (RSI)[h,b]	RSI $= 2\mathrm{pH}_s - \mathrm{pH}$	RSI > 6.8	$6.2 <$ RSI < 6.8	RI < 6.2
Momentary excess (ME)[i,b]	$[Ca - X][CO_3 - X]\ K_{spc}$ where X is the precipitation required to restore equilibrium	ME < 0	ME ~ 0	ME > 0

[a] Millette et al. (1980), [b]Temkar et al. (1990), [c]Standard Methods (2012), [d]McCauley (1960),
[e] Langelier (1936), [f]Larson and Skold (1958), [g]Puckorius and Brooke (1991), [h]Ryzner (1944), [i]Dye (1952).

calcium carbonate precipitation potential (Truesdell and Jones, 1973; Merrill and Sanks, 1977a, b and 1978; Ball and Nordstrom, 1991; WaterCycle®, 2012). Computer programs are also available that can be used to compare the results obtained with the various models (WaterCycle®, 2012).

Another approach to assess water chemistry involves the use of chemical equilibrium models, such as MINTEQA2 and MINEQL+. With these models, the chemical components and concentrations are selected and used as inputs to the model. Thermodynamic relationships are used to solve a system of equations that determine which species may form, what the resulting species concentration is expected to be, and what precipitates may form. Additional information of chemical equilibrium models is presented in Standard Methods (2012).

Langelier Saturation Index. The tendency to develop calcium carbonate ($CaCO_3$) scale during the advanced treatment of treated effluent can be approximated by calculating the Langelier Saturation Index (LSI) of the concentrate stream (Langelier, 1946).

$$\text{LSI} = \text{pH} - \text{pH}_s \tag{6–71}$$

where pH = measured pH in concentrate stream water sample
pH_s = saturation pH for calcium carbonate

The scaling criteria for the Langelier Saturation Index are

$\text{LSI} > 0$	Water is supersaturated with respect to calcium carbonate ($CaCO_3$) and scaling may occur.
$\text{LSI} < 0$	Water is undersaturated with respect to calcium carbonate. Undersaturated water has a tendency to remove existing calcium carbonate protective coatings in pipelines and equipment.
$\text{LSI} = 0$	Water is considered to be neutral (i.e., neither scale forming or scale removing).

It should be noted that undersatured water is also sometimes referred to as *corrosive*, but use of the term corrosive is incorrect, as the LSI index only applies to the presence or absence of a calcium carbonate scale. The diagram presented in Fig. 6–28 can also be used to estimate LSI.

Ryzner Stability Index. An alternative index known as the *stability index* was proposed by Ryzner (1944) and is used in a number of industrial applications. The Ryzner Stability Index (RSI) is given by the following expression:

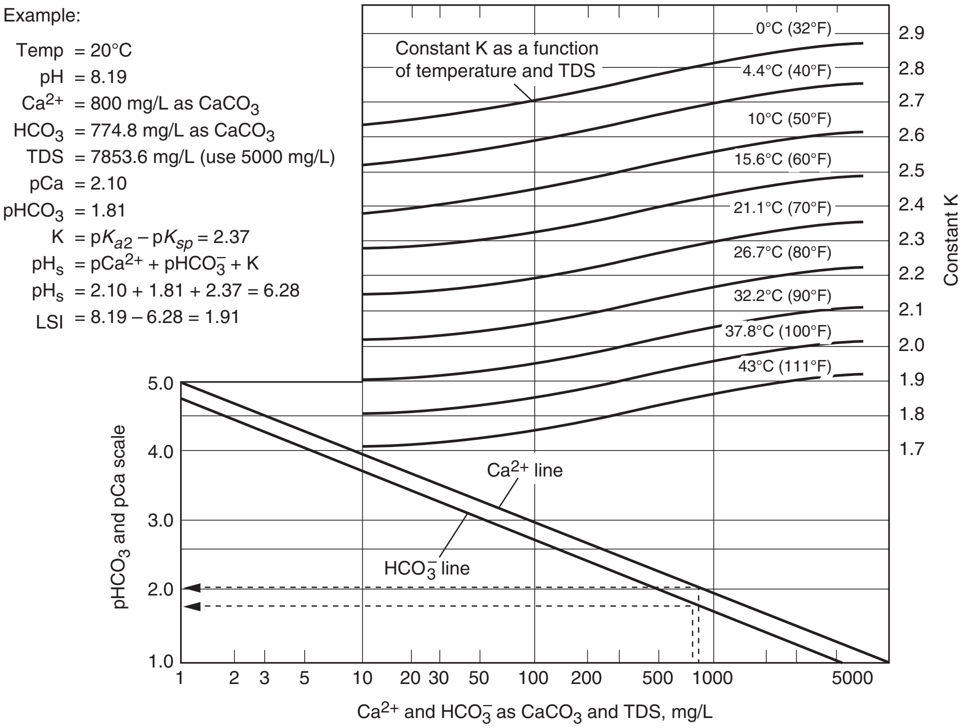
$$\text{RSI} = 2\text{pH}_s - \text{pH} \tag{6–72}$$

The scaling criteria for the Ryzner Index are as follows:

$\text{RSI} < 5.5$	Heavy scale will form
$5.5 < \text{RSI} < 6.2$	Scale will form
$6.2 < \text{RSI} < 6.8$	No difficulties
$6.8 < \text{RSI} < 8.5$	Water is aggressive
$\text{RSI} > 8.5$	Water is very aggressive

Figure 6–28

Chart for determining the value of the Langelier saturation index. (Adapted from DuPont Company, 1992.)



Application of Indexes. The saturation pH_s used in the above equations can be computed using the following expression:

$$pH_s = -\log\left(\frac{K_{a2}\gamma_{Ca^{2+}}[Ca^{2+}]\gamma_{HCO_3^-}[HCO_3^-]}{K_{sp}}\right) \tag{6–73}$$

where K_{a2} = equilibrium constant for the dissociation of bicarbonate
$\gamma_{Ca^{2+}}$ = activity coefficient for calcium
$[Ca^{2+}]$ = concentration of calcium, mole
$\gamma_{HCO_3^-}$ = activity coefficient for bicarbonate
$[HCO_3^-]$ = concentration of bicarbonate, mole
K_{sp} = solubility product constant for the dissociation of calcium carbonate

The activity coefficient can be estimated using Eq (2–10) given in Chap. 2.

$$\log \gamma = -0.5\,(Z_i)^2\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I\right) \tag{2–10}$$

where Z_i = charge on ionic species
I = ionic strength

The ionic strength can be estimated using Eq (2–12) given in Chap. 2.

$$I = 2.5 \times 10^{5-} \times \text{TDS} \tag{2–12}$$

Table 6–21
Carbonate equilibrium constants as function of temperature[a]

Temperature, °C	Equilibrium constant[b]		
	$K_{a1} \times 10^7$	$K_{a2} \times 10^{11}$	$K_{sp} \times 10^9$
5	3.020	2.754	8.128
10	3.467	3.236	7.080
15	3.802	3.715	6.02
20	4.169	4.169	5.248
25	4.467	4.477	4.571
40	5.012	6.026	3.090

[a] Adapted from Snoeyink and Jenkins (1980) and Pankow (2012).
[b] The reported values have been multiplied by the indicated exponents. Thus, the value K_2 at 20°C is equal to 4.169×10^{-11}.

The saturation pH_s for calcium carbonate ($CaCo_3$) solubility in the pH range from 6.5 to 9.0 is given by

$$pH_s = pK_{a2} - pK_{sp} + p[Ca^{2+}] + p[HCO_3^-] - \log \gamma_{Ca^{2+}} - \log \gamma_{HCO_3} \tag{6–74}$$

where pK_{a2} = negative logarithm of the equilibrium constant for the dissociation of bicarbonate
pK_{sp} = negative logarithm of equilibrium constant for the dissociation of calcium carbonate
$p[Ca^{2+}]$ = negative logarithm of calcium concentration
$p[HCO_3^-]$ = negative logarithm of bicarbonate concentration

Values of K_1, K_2, and K_{sp} for the carbonate system are given in Table 6–21 as a function of temperature. The application of these equations is illustrated in Example 6–9.

EXAMPLE 6–9 **Analysis of Scaling Potential** Estimate the scaling potential using both the Langelier and Ryzner indexes for a treated wastewater with the following chemical characteristics:

	Concentration	
Constituent	g/m³	mole/L
Ca^{2+}	5	0.125×10^{-3}
HCO_3^-	10	0.164×10^{-3}
TDS	20	
pH	7.7	

Solution

1. Estimate the ionic strength of the treated water using Eq. (2–11).

$$I = 2.5 \times 10^{-5} \times \text{TDS}$$
$$I = 2.5 \times 10^{-5} \times 20 = 50 \times 10^{-5}$$

2. Determine the activity coefficients for calcium and bicarbonate using Eq. (2–9).
   a. For calcium

$$\log \gamma_{\mathrm{Ca}^{2+}} = -0.5(Z_i)^2\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I\right)$$

$$= -0.5(2)^2\left[\frac{\sqrt{50 \times 10^{-5}}}{1+\sqrt{50 \times 10^{-5}}} - 0.3(50 \times 10^{-5})\right] = -0.0434$$

$$\gamma \mathrm{Ca}^{2+} = 0.905$$

   b. For bicarbonate

$$\log \gamma_{\mathrm{HCO}_3^-} = -0.5(Z_i)^2\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I\right)$$

$$= -0.5(1)^2\left[\frac{\sqrt{50 \times 10^{-5}}}{1+\sqrt{50 \times 10^{-5}}} - 0.3(50 \times 10^{-5})\right] = -0.0109$$

$$\gamma_{\mathrm{HCO}_3^-} = 0.975$$

3. Determine the saturation pH_s using Eq. (6–46).

$$\mathrm{pH}_s = -\log\left(\frac{K_{a2}\gamma_{\mathrm{Ca}^{2+}}[\mathrm{Ca}^{2+}]\gamma_{\mathrm{HCO}_3^-}[\mathrm{HCO}_3^-]}{K_{sp}}\right)$$

$$\mathrm{pH}_s = -\log\left[\frac{(4.17 \times 10^{-11})(0.905)(0.125 \times 10^{-3})(0.975)(0.164 \times 10^{-3})}{5.25 \times 10^{-9}}\right]$$

$$\mathrm{pH}_s = -\log(1.43 \times 10^{-10}) = 9.84$$

4. Determine the Langelier and Ryzner indexes.
   a. Langelier Saturation Index

   $\mathrm{LSI} = \mathrm{pH} - \mathrm{pH}_s = 7.7 - 9.84 = -2.14$

   $\mathrm{LSI} < 0$ (Water is undersaturated with respect to calcium carbonate)

   b. Ryzner Index

   $\mathrm{RSI} = 2\mathrm{pH}_s - \mathrm{pH} = 2(9.84) - 7.7 = 11.98$

   $(\mathrm{RSI} = 11.98) < 8.5$ (Water is very aggressive)

Comment Although both indexes are used, the Langelier index is used most commonly in the water and wastewater field, whereas the Ryzner index is used most commonly in industrial applications.

Scale Control

Usually, $\mathrm{CaCO_3}$ scale control can be achieved using one or more of the following methods:

- Acidifying to reduce pH and alkalinity
- Reducing calcium concentration by ion exchange or lime softening
- Adding a scale inhibitor chemical (antiscalant) to increase the apparent solubility of $\mathrm{CaCO_3}$ in the concentrate stream (see Chap. 11)
- Lowering the RO product recovery rate (see Chap. 11)

Because it is not possible to predict a priori the value of pH in water treated with reverse osmosis, it is usually necessary to conduct bench and/or pilot scale studies using the same modules that will be used in the full scale installation.

Stabilization

Wastewater effluent that is demineralized with reverse osmosis will generally require pH and calcium carbonate adjustment (stabilization) to prevent metallic corrosion, due to the contact of the demineralized water with metallic pipes and equipment. Corrosion occurs because material from the solid is removed (solubilized) to satisfy the various solubility products. Demineralized water typically is stabilized by adding lime to adjust the LSI, using the procedure outlined above.

6–11 CHEMICAL STORAGE, FEEDING, PIPING, AND CONTROL SYSTEMS

The design of chemical treatment operations involves not only the sizing of the various unit operations and processes but also the necessary appurtenances. Because of the corrosive nature of many of the chemicals used and the different forms in which they are available, special attention must be given to the design of chemical storage, feeding, piping, and control systems. The following discussion is intended to serve as an introduction to this subject.

In domestic wastewater treatment systems, the chemicals employed can be in a solid, liquid, or gaseous form. Coagulants in the dry solid form generally are converted to solution or slurry form prior to introduction into the wastewater. Coagulants in the liquid form are usually delivered to the plant in a concentrated form and have to be diluted prior to introduction into the wastewater. Chemicals in the gas form (generally stored as a liquid), typically used for disinfection purposes, are either dissolved in water before injection or are injected directly into the wastewater. The types of chemical feed systems used for these chemicals are termed *dry, liquid* (also known as wet), or *gas* feed. The various types of feeders are classified on Fig. 6–29. Chemical feeders are generally designed to be: (1) proportioning, feeding chemical in proportion to the influent wastewater flowrate and (2) constant feed, designed to deliver chemical at a fixed rate regardless of the influent flowrate.

Chemical Storage and Handling

General information on the handling, storage, and feeding requirements for various chemicals is presented in Table 6–22. The specific storage facilities required will depend on the

Figure 6–29

Classification of chemical feed systems.

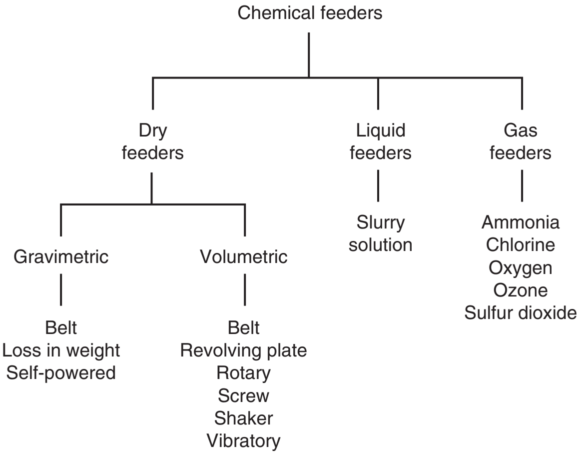


Table 6–22

Handling, storage and feeding requirements for various chemicals used in wastewater treatment[a]

Chemical	Formula	Shipping form	Feeding form	Feeding type	Accessory equipment	Handling materials
Chemicals used for precipitation						
Aluminum sulfate	$Al_2(SO_4)_3 \cdot 18H_2O$	Lump, ground or powdered solutions	Liquid	Metering pump	Slurry tank, slaker	Iron, steel
Aluminum chloride	$AlCl_3$	Liquid	Liquid	Metering pump	Storage tank	Hastelloy B, plastic
Calcium hydroxide (lime)	$Ca(OH)_2$	Bags, barrels, and bulk	Liquid	Metering pump	Slurry tank	Iron, steel
Ferric chloride	$FeCl_3$	Bags, carboys, and bulk	Liquid	Metering pump	Slurry tank	Iron, steel
Ferric sulfate	$Fe_2(SO_4)_3$	Bags, barrels, and bulk	Liquid	Metering pump	Slurry tank	Iron, steel
Copperas	$FeSO_4 \cdot 7H_2O$		Liquid	Metering pump	Slurry tank	Iron, steel
Chemicals used for neutralization						
Calcium carbonate	$CaCO_3$	Bags, drums or bulk	Slurry, dry slurry in fixed beds	Metering pump, Volumetric pump	Slurry tank	Iron, steel
Calcium oxide	CaO	Bags (22.5 kg), barrels, or bulk	Dry or slurry, slaked to $Ca(OH)_2$	Metering pump	Slurry tank, slaker	Iron, steel, plastic, rubber hose
Sodium bicarbonate	$NaHCO_3$	Bags or drums	Dry or slurry	Metering pump	Dissolving tank	Iron, steel, plastic, rubber hose
Sodium carbonate	Na_2CO_3	Bags (45.5 kg), bulk	Dry or slurry	Metering pump	Dissolving tank	Iron, steel, plastic, rubber hose
Sodium hydroxide	$NaOH$	Drum (45.5, 204.5, 367.5 kg)	Dry or slurry	Metering pump	Solution tank	Iron, steel, plastic, rubber hose
Carbonic acid	H_2C0_3		Gas (CO_2)	Metering pump		
Hydrochloric acid	HCl	Barrels, drums, bulk	Liquid	Metering pump	Dilution tank	Hastelloy A, plastic, rubber[b]
Sulfuric acid	H_2S0_4	Carboys, drums, and bulk	Liquid	Metering pump		Iron, steel, plastic, rubber hose

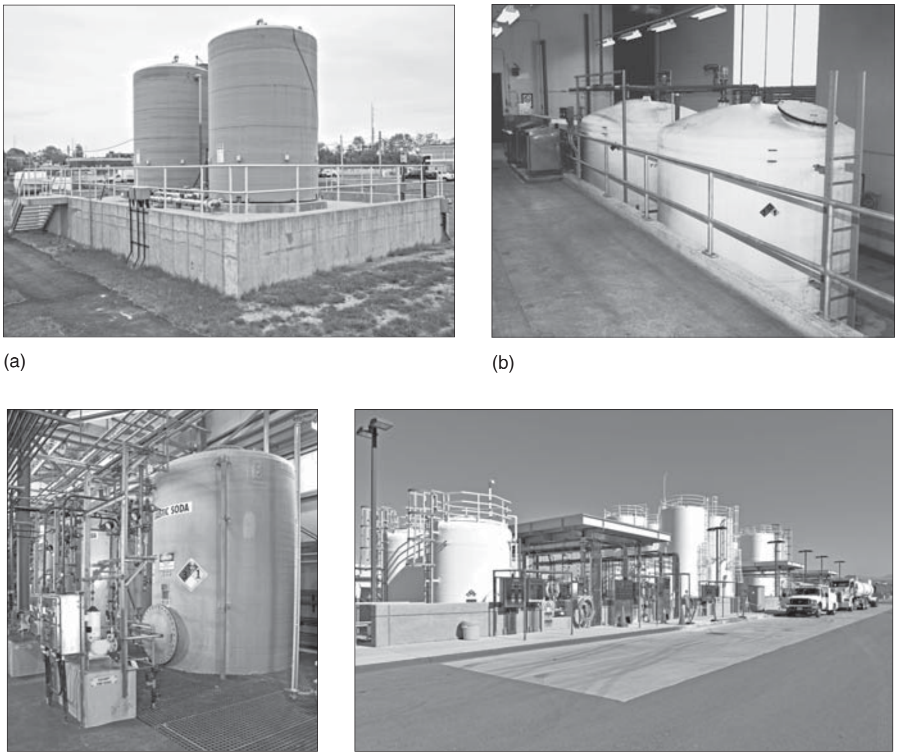
[b] Selected types.



(a) (b) (c) (d)

Figure 6–30

Typical chemical storage facilities: (a) outdoor facility at a small wastewater treatment plant. The chemical storage tanks are located within a containment structure in case of a chemical spill (b) chemical storage tanks located indoors in a containment area, (c) chemical storage tanks located indoors on grated floor over chemical containment area below, and (d) large chemical storage facilities located within chemical containment structures. The chemical feed station is located between storage tanks.

form in which the chemical is available locally. For small treatment plants the available forms are usually limited. Typical indoor and outdoor storage facilities for chemicals at wastewater treatment plants are shown on Fig. 6–30. In all cases some form of containment is provided to limit the spread of any chemical should any type of leak develop.

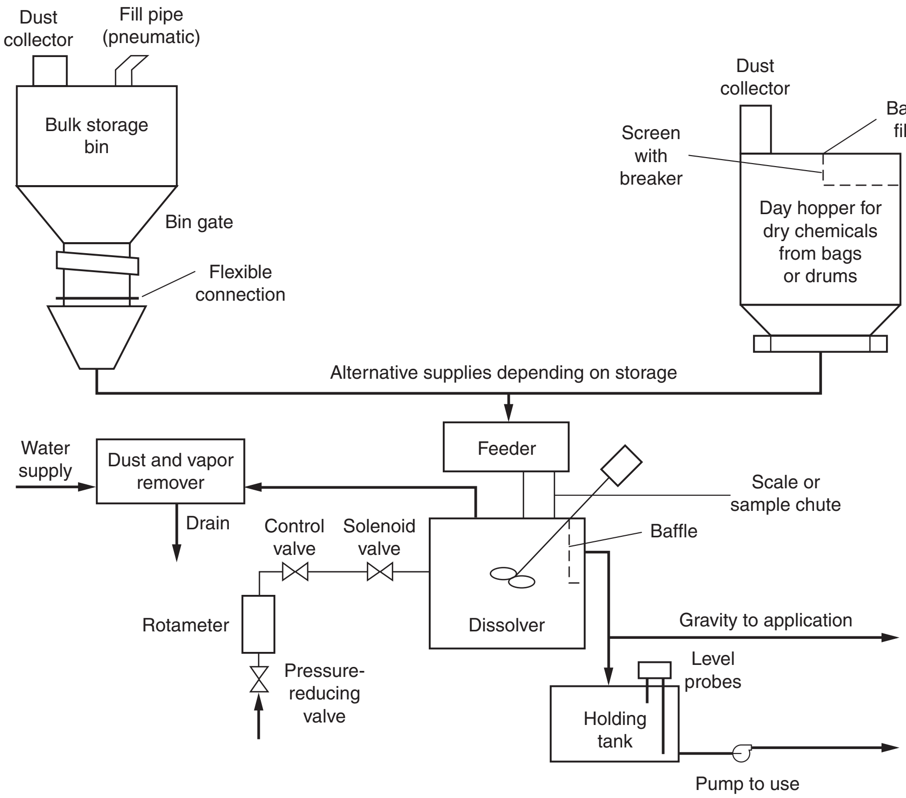
Dry Chemical Feed Systems

A dry chemical feed system typically consists of a storage hopper, dry chemical feeder, a dissolving tank, and a pumped or gravity distribution system (see Figs. 6–31 and 6–32). The units are sized according to the volume of wastewater, treatment rate, and optimum length of time for chemical feeding and dissolving. Hoppers used with powdered chemicals that are compressible and can form an arch such as lime are equipped with positive agitators and a dust collection system. Dry chemical feeders are either of the volumetric or gravimetric type. In the volumetric type the volume of the dry chemical fed is measured, whereas in the gravimetric type the weight of chemical fed is measured. A brief description and illustration of the chemical feeders used most commonly is presented in Table 6–23.

With a dry feed system, the dissolving operation is critical. The capacity of the dissolving tank is based on the detention time, which is directly related to the wettability or rate of solution of the chemical. When the water supply is controlled for the purpose of forming a constant strength solution, mechanical mixers should be used. Depending on the flow pattern within the mixing tank, it may be necessary to add baffles for effective mixing. In smaller mixing tanks, the mixer can be set at an angle to avoid the use of baffles. Solutions or slurries are often stored after dissolving and discharged to the application point at metered rates by chemical feed pumps.

Figure 6–31

Schematic of typical dry chemical-feed system.



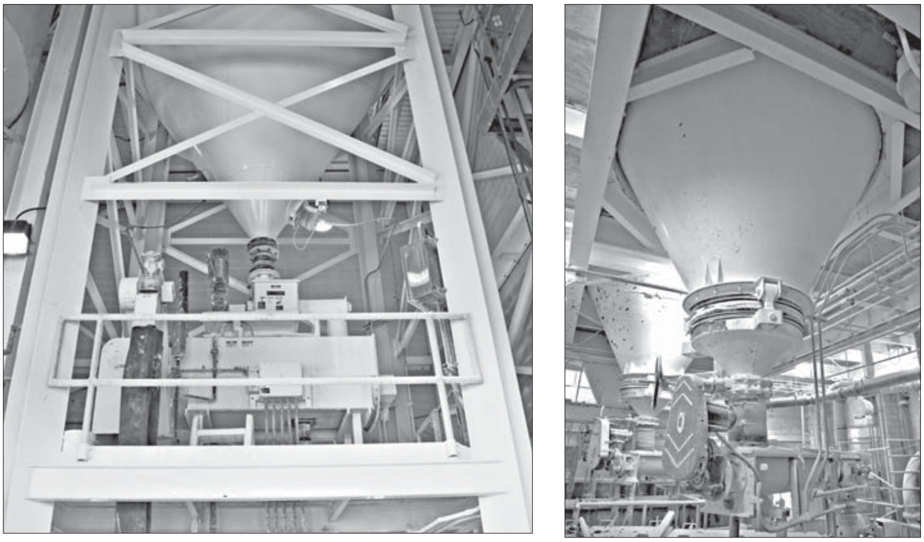


Figure 6–32

Typical dry chemical-feed system (a) single storage hopper and (b) two chemical storage hoppers coupled through flexible connectors to individual chemical feeders and dissolvers as illustrated schematically on Fig. 6–31.

Table 6–23

Typical characteristics of chemical feeders[a]

Type of feeder	Description	Illustration
Volumetric		
Conveyor belt	Consists of a belt located below a hopper. The feed rate is adjusted by varying the speed of the belt.	Revolving plate	Consists of a rotating plate below the storage hopper. As the plate is rotated, material to be feed is drawn from the hopper. The amount of material feed is controlled by the rate of rotation.	Rotary	Consists of rotating shaft with vanes that form pockets. The amount of material feed is controlled by the rate of rotation.	Screw	Consists of a variable pitch screw mounted below a feed hopper. The amount of material feed is controlled by the rate of rotation of the screw.	Shaker	Consists of a shaker pan mounted below a storage hopper. As the pan oscillates, the material to be feed is moved forward and dropped into the feed chute.	
(*continued*)

Table 6–23 (*Continued*)

Type of feeder	Description	Illustration
Vibratory	Consists of vibrating pan or chute positioned below a chemical storage hopper. The pan or chute which vibrates back and forth by the oscillating electromagnetic driver delivers the material to be feed forward. The amount of material feed can be controlled by adjusting the rate of oscillation.	Gravimetric		
Belt	Consists of volumetric feeder that transfers the material to be feed from the hopper to the weigh belt. The signal generated from the weigh belt is used to control the volumetric feeder.	Loss in weight	Consists of a feed hopper mounted on scale and a chemical feeder. The chemical feed rate can be controlled with a screw or vibratory feeder. The feed rate is controlled by the loss in weight measured by the scale.	Self-powered	Consists of a counter balanced control gate mounted below a storage hopper. The weight of the material in the hopper is counterbalanced by the setting on the beam balance. The rate at which material is feed is controlled by the impact pan. Although not accurate, this device does not require any power source.	
[a] Adapted from Liptak (1974).

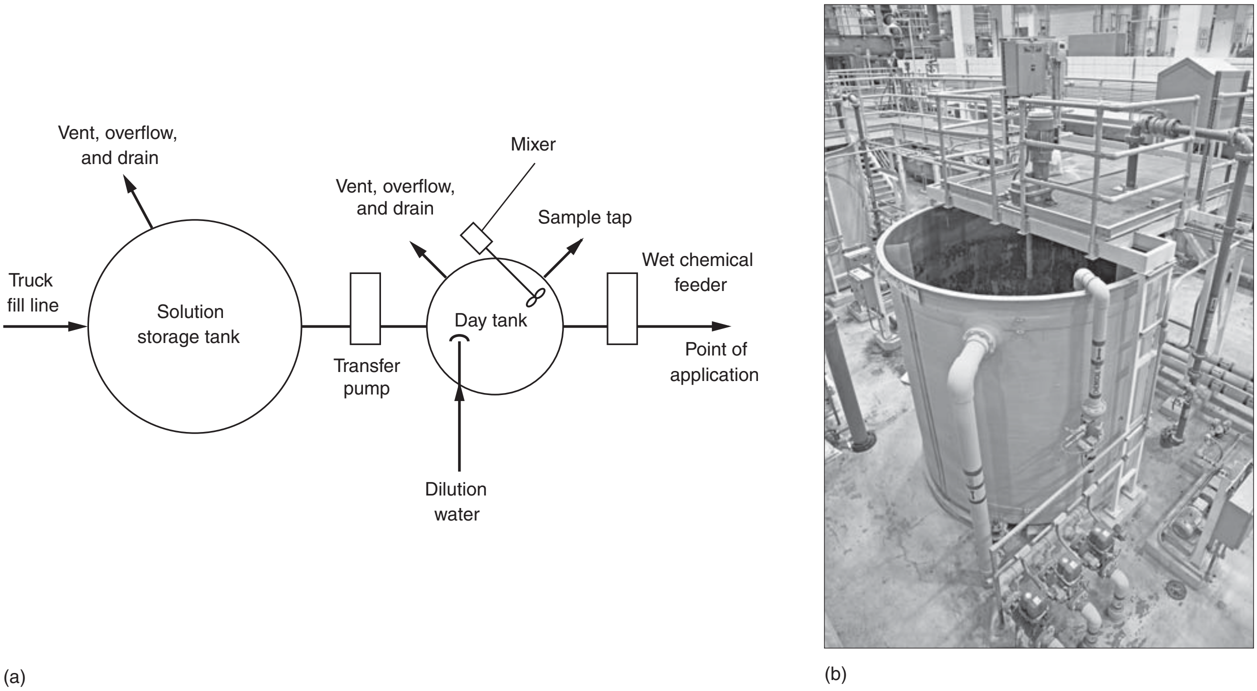

Figure 6–33

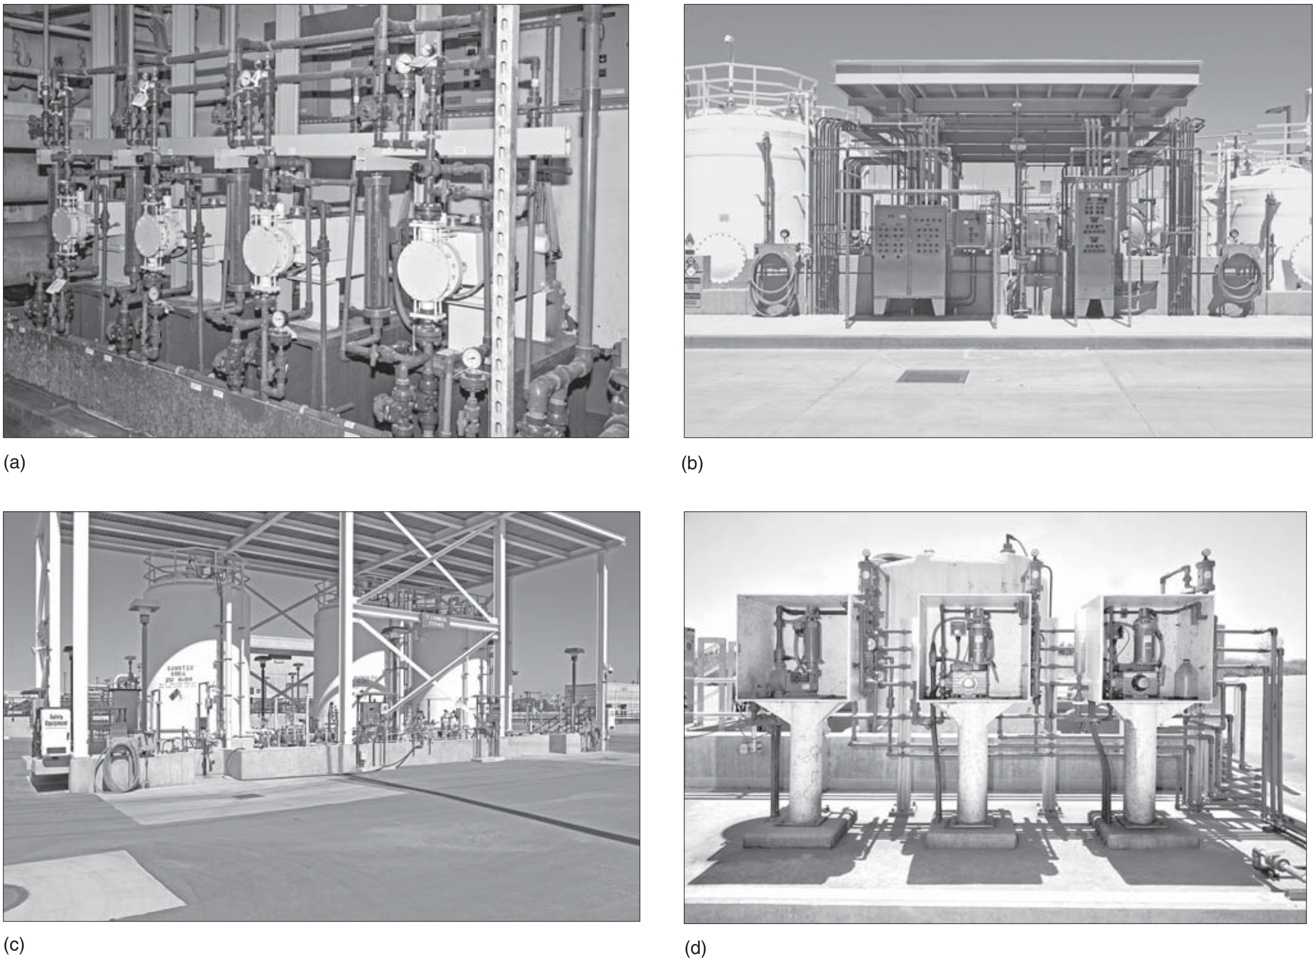
Typical liquid chemical-feed system (a) schematic and (b) view of large day tank with mixer. Also, note the internal deflection baffle to enhance mixing (see Fig. 5–14).

Liquid Chemical Feed Systems

Liquid chemical feed systems typically include a solution storage tank, transfer pump, day tank for diluting the concentrated solution, and chemical feed pump for distribution to the application point (see Figs. 6–33 and 6–34). In general, liquid feed systems provide for better initial contact and dispersion of the chemical and the wastewater. In systems where the liquid chemical does not require dilution, the chemical feed pumps draw liquid directly from the solution storage tank. The storage tank is sized based upon the stability of the chemical, feed rate requirements, regulatory requirements, delivery constraints (cost, size of tank truck, etc.), and availability of the supply. Solution feed pumps are usually of the positive displacement type for accurate metering of the chemical feed. Spill or secondary containment is usually required around the storage tanks; chemicals that are highly reactive should not be stored next to each other.

Gas Chemical Feed Systems

Chemicals that are used as a gas include ammonia, chlorine, oxygen, ozone, and sulfur dioxide. Gas feed systems are used mostly for feeding chemicals used for disinfection and dechlorination (see Chap. 12). Chlorine, a commonly used chemical for disinfection, is often supplied in a liquid form within the storage container and evaporates continuously as the gas is drawn from the headspace above the liquid in the storage container. Feed systems for disinfection chemicals are illustrated in Chap. 12 which deals with disinfection.



(a) (b) (c) (d)

Figure 6–34

Typical liquid chemical-feed systems (a) indoor chlorine metering pumps and (b), (c) and (d) typical outdoor shaded chemical feed stations.

Initial Chemical Mixing

Perhaps the least appreciated fact about chemical addition is the importance of both the initial and uniform mixing of the chemical with the wastewater to be treated. The optimal time for mixing can, as discussed in this section, vary from a fraction of a second to several seconds or more. Because of the difficulties in achieving rapid mixing in large treatment plants with a single mixing device, the use of multiple mixing devices is recommended. The particular mixing device selected for a given application must be based on a consideration of the reaction times and operative mechanisms for the chemicals that are being used. Typical mixing times for the chemicals used in wastewater treatment facilities are reported in Table 6–24. Typical devices used for mixing chemicals in wastewater treatment plants are discussed in Chap. 5. Approximate mixing times achievable with various mixing devices may be found in Table 5–9 in Chap. 5.

Table 6–24

Typical mixing times for various chemicals used in wastewater treatment facilities

Chemical	Applications	Recommended mixing times, s
Alum, Al^{3+}; Ferric chloride, Fe^{3+}	Coagulation of colloidal particles	<1
Alum, Al^{3+}; Ferric chloride, Fe^{3+}	Sweep floc precipitation	1–10
Lime, $Ca(OH)_2$	Chemical precipitation	10–30
Chlorine, Cl_2	Chemical disinfection	<1
Chloramine, NH_2Cl	Chemical disinfection	5–10
Cationic polymers	Destabilization of colloidal particles	<1
Anionic polymers	Particle bridging	1–10
Polymers, nonionic	Filter aids	1–10

PROBLEMS AND DISCUSSION TOPICS

6–1 To aid sedimentation in the primary settling tank, 15, 25, 40, or 60 g/m^3 value to be selected by instructor) of ferrous sulfate ($FeSO_4 \cdot 7H_2O$) is added to the wastewater. Determine the minimum alkalinity required to react initially with the ferrous sulfate. How many grams of lime should be added as CaO to react with $Fe(HCO_3)_2$ and the dissolved oxygen in the wastewater to form insoluble $Fe(OH)_3$?

6–2 Iron sulfate in the form ($FeSO_4 \cdot 7H_2O$) is to be added at a rate of 15, 25, 30, or 40 kg/1000 m^3 (value to be selected by instructor) to a wastewater to improve the efficiency of an existing primary sedimentation tank. Assuming sufficient alkalinity is present as $Ca(HCO_3)_2$ determine:

(a) How many kg of lime should be added as CaO to complete the reaction,

(b) The concentration of oxygen needed in the wastewater to oxidize the ferrous hydroxide that is formed,

(c) The mass of sludge that will result per 1000 m^3 of wastewater, and

(d) The amount (kg) of alum needed to obtain the same quantity of sludge as in Part (c), assuming $Al(OH)_3$ is the precipitate that is formed.

6–3 Assume that 40, 45, 50, and 55 kg (value to be selected by instructor) of (a) alum (mole wt 666.5) and (b) ferrous sulfate and lime as $Ca(OH)_2$ is added per 4000 m^3 of wastewater. Also assume that all insoluble and very slightly soluble products of the reactions, with the exception of 15 g/m^3 $CaCO_3$, are precipitated as sludge. How many kg of sludge/1000 m^3 will result in each case?

6–4 Raw wastewater is to be treated chemically for the removal of total suspended solids and phosphorus through coagulation, flocculation, and sedimentation. The wastewater characteristics are as follows: $Q = 0.75$ m^3/s; orthophosphate $= 10$ g/m^3 as P; alkalinity $= 200$ g/m^3 expressed as $CaCO_3$ [essentially all due to the presence of $Ca(HCO_3)_2$]; total TSS $= 220$ g/m^3.

a. Determine the sludge production in kg dry wt/d and m^3/d under the following conditions: (1) Alum [$Al_2(SO_4)_3 \cdot 14.3\ H_2O$] dosage of 120, 130, 140, or 150 g/m^3 (to be selected by instructor); (2) 100 percent removal of orthophosphate as insoluble $AlPO_4$; (3) 95 percent removal of original TSS; (4) all alum not required for reaction with phosphate reacts with alkalinity to form $Al(OH)_3$, which is 100 percent removed; (5) wet sludge has a water content of 93 percent and a specific gravity of 1.04.

b. Determine the sludge production in a kg dry wt/d and m^3/d under the following conditions: (1) Lime [$Ca(OH)_2$] dosage of 450 g/m^3 to give pH of approximately 11.2; (2) 100 percent removal of orthophosphate as insoluble hydroxylapatite [$Ca_{10}(PO_4)_6(OH)_2$]; (3) 95 percent removal of original TSS; (4) added lime (i) reacts with phosphate, (ii) reacts with all alkalinity to form $CaCO_3$, 20 g/m^3 of $CaCO_3$ is soluble and remains in solution and the rest is 100 percent removed, and (iii) remainder stays in solution; (5) wet sludge has a water content of 92 percent and a specific gravity of 1.05.

c. Determine the net increase in calcium hardness in g/m^3 as $CaCO^3$ for the treatment specified in part b.

6–5 Verify the correctness of one of the plots given on Fig. 6–8, using the equations given below the figures.

6–6 Obtain equilibrium values from the literature and verify one of the solubility curves given on Fig. 6–21.

6–7 Obtain equilibrium values from the literature and verify one of the solubility curves given on Fig. 6–22.

6–8 Using the potentials for the following two half reactions given in the Table 6–12, estimate the equilibrium constant for the ionization of water.

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^-$$

$$2H^+ + 2e^- \rightarrow H_2$$

6–9 Using the half reactions given in Table 6–12, evaluate the feasibility of the following reaction:

$$2Fe^{2+} + 2H_2O_2 \rightleftarrows 2Fe^{3+} + 2H_2O$$

6–10 Using the half reactions given in Table 6–12, evaluate the feasibility of the following reaction:

$$2Fe^{2+} + Cl_2 \rightleftarrows 2Fe^{3+} + 2Cl^-$$

6–11 Using the half reactions given in Table 6–12, evaluate the feasibility of the following reaction:

$$H_2S + Cl_2 \rightleftarrows S + 2HCl$$

6–12 Using the half reactions given in Table 6–12, evaluate the feasibility of the following reaction:

$$H_2S + O_3 \rightleftarrows S + O_2 + H_2O$$

6–13 Estimate the scaling potential of one of the treated wastewater samples (to be selected by instructor) using both the Langelier and Ryzner indexes. Use a temperature of 20°C.

		Wastewater sample			
Constituent	Unit	1[a]	2	3	4
Ca^{2+}	mg/L as $CaCo_3$	5	12	245	15
HCO_3^-	mg/L as $CaCO_3$	7	9	200	16
TDS	mg/L	30	275	600	500
pH	unitless	6.5	8.0	6.9	6.5

[a] Typical values are for runoff from snow melt (adapted from Benefield et al. (1982).

6–14 Estimate the scaling potential of one of the treated wastewater samples (to be selected by instructor) using both the Langelier and Ryzner indexes. The measured pH values for the four samples are 1 = 7.2, 2 = 6.9, 3 = 7.3, and 4 = 6.8.

	Concentration, mg/L					Concentration, mg/L			
Cation	1	2	3	4	Anion	1	2	3	4
Ca^{2+}	121.3	64.0	42.1	44.0	HCO_3^-	280	96.0	158.7	91.5
Mg^{2+}	36.2	15.1	14.6	25.2	SO_4^{2-}	116	80	48.0	57.6
Na^+	8.1	20.5	46.0	4.6	Cl^-	61	17.3	63.8	17.7
K^+	12	10.0	11.7		NO_3^-	15.6	5		
					H_2CO_3				8.8
					CO_3^{2-}			12.0	

6–15 Review the literature concerning the Langelier (1946) and Ryzner (1944) indexes and discuss the difference in approach to scaling used in the development of these two indexes.

6–16 Determine the hydroxyl radical concentration required to remove each of the following compounds using an advanced oxidation process with a contact time of 10 s. Comment on the feasibility of removing each of the compounds under the given conditions.

	Concentration, μg/L			
	Water 1		Water 2	
Compound	Influent	Effluent	Influent	Effluent
Clorobenzene	100	5	120	7
Chloroethene	100	5	150	5
TCE	100	5	180	10
Toluene	100	5	200	15

6–17 Design an advanced oxidation process to achieve a 95 percent reduction of one of the following compounds for a flowrate of 3800 m^3/d, specify reactor dimensions and hydroxyl radical concentration required for the process.

Compound	Initial concentration, μg/L
1	25
2	10
3	100
4	75

6–18 A water reclamation plant produces 1×10^5 m^3/d of effluent containing 100 ng/L of NDMA. Determine the number of photolysis reactors needed to reduce the NDMA concentration of the RO effluent to 10 ng/L prior to indirect potable reuse using absorptivity values of $k'(\lambda) = 0.01$, 0.05, and 0.1 cm^{-1} (measured at a wavelength of 254 nm). The photolysis reactors under evaluation are 0.5 m in diameter and 1.5 m long with an effective water volume of 250 L. Each reactor has 25 lamps rated at 500 W per lamp and an output efficiency of 30 percent at 254 nm. Assume that the reactors operate as four mixed tanks in series and neglect all other losses, lamp fouling, and process inefficiencies. Calculate EE/O and daily energy usage for the photolysis process. Comment on the importance of absorptivity and recommend an appropriate pretreatment process.

6–19 Estimate the electricity cost (based on the current price of electricity) to treat a flowrate of 3800 m^3/d with a NDMA concentration of 100 mg/m^3 using a photolysis unit.

6–20 For each compound in the following list, which of the treatment methods discussed in this chapter, if any, are suitable for use to reduce the concentration from 100 to 10 mg/L?

Benzene
Chloroform
Dieldrin
Heptachlor
N-Nitrosodimethylamine
Trichloroethylene (TCE)
Vinyl chloride

Fundamentals of Biological Treatment

WORKING TERMINOLOGY

Term	**Definition**
Acetogenesis	Biological conversion of volatile acids to acetic acid and hydrogen.
Activated sludge process	Biological treatment process that involves the conversion of organic matter and/or other constituents in the wastewater to gases and cell tissue by a large mass of aerobic microorganisms maintained in suspension by mixing and aeration. The microorganisms form flocculent particles that are separated from the process effluent in a sedimentation tank (clarifier) or by membranes and are returned subsequently to the aeration process or wasted.
Aerobic (oxic) process	Biological treatment process that occur in the presence of free dissolved oxygen; oxygen is consumed by aerobic microorganisms to drive metabolic reactions.
Anaerobic fermentation	See fermentation.
Anaerobic process	Biological treatment process that occur in the absence of free dissolved oxygen and oxidized compounds.
Anammox process	An anaerobic biological treatment process in which nitrite is used by specialized planctomycete bacteria as the electron acceptor to convert ammonia and nitrite to nitrogen gas primarily.
Anoxic process	Biological treatment process that occurs in the absence of free dissolved oxygen where oxidized compounds such as nitrate and nitrite are used to drive metabolic reactions; denitrification is an example of an anoxic process.
Attached-growth process (also known as fixed-film processes)	Biological treatment process in which the microorganisms responsible for the conversion of organic matter or other constituents in the wastewater to gases and cell tissue are attached to some inert medium such as rocks, slag or specially designed ceramic or plastic materials.

Term	Definition
Bioenergetics	The study of energy transformations that take place in living organisms.
Biological nutrient removal (BNR)	The term applied to the removal of nitrogen and phosphorus in biological treatment processes.
Biofilm	An accumulation of biological growth on the surface of an object such as attached-growth media.
Biomass	The mass of microorganisms in a biological treatment process.
Carbonaceous BOD removal	Biological conversion of the carbonaceous organic matter in wastewater to cell tissue and various gaseous end products. In the conversion, it is assumed that the nitrogen present in the various compounds is converted to ammonia.
Combined aerobic/ anoxic/anaerobic processes	Various combination of aerobic, anoxic and anaerobic biological treatment processes grouped together to achieve biological nitrogen and phosphorus removal.
Denitritation	Biological reduction of nitrite to nitrogen gas and other gaseous end products containing nitrogen.
Denitrification	Biological reduction of nitrate to nitrogen gas and other gaseous end products containing nitrogen.
Enhanced biological phosphorus removal	The term applied to phosphorus removal by certain bacteria with phosphorus storage capabilities greater than normally found in biological wastewater treatment.
Energetics	The scientific study of energy flows and transformations.
Facultative processes	Biological conversion processes which can occur in the presence or absence of molecular oxygen.
Fermentation (also referred to as acidogenesis)	The conversion of organic matter to carbon dioxide and other low molecular weight compounds.
Greenhouse gas	Gaseous compounds that contribute to global warming. Methane and nitrous oxide are potent greenhouse gases that can be produced in biological treatment processes.
Hybrid process	Term used to describe combined suspended and attached growth biological process.
Methanogenesis	Biological conversion of acetic acid or hydrogen and carbon dioxide to methane.
Nitratation	Biological oxidation of nitrite to nitrate.
Nitritation	Biological oxidation of ammonia to nitrite.
Nitrification	The two-step biological oxidation of nitrogen (mostly in the form of ammonia) to nitrite and then to nitrate.
Substrate	Wastewater or solids constituents used to promote biological growth.
Suspended growth process	Biological treatment process in which the microorganisms responsible for the conversion of the organic matter or other constituents in the wastewater to gases and cell tissues are maintained in suspension within the liquid.
Yield	The amount of biological solids produced relative to the amount of substrate removed.

With proper analysis and environmental control, almost all wastewaters containing biodegradable constituents can be treated biologically. Therefore, it is essential that the environmental engineer understand the characteristics of each biological process to ensure that the proper environment is produced and controlled effectively. The principal purposes of this chapter are (1) to provide fundamental background information on the microorganisms used to treat wastewater and (2) to consider the application of biological process fundamentals for the biological treatment of wastewater. The information presented in this chapter provides the necessary background material needed for the design of biological treatment processes discussed in Chaps. 8 through 10. For ease of computation, constituent concentrations in this chapter and in Chaps. 8, 9, and 10 are expressed in g/m^3 instead of mg/L because flowrate is given in units of m^3/s or m^3/d.

The fundamentals of biological treatment introduced in the first seven sections of this chapter include (1) an overview of biological wastewater treatment, (2) the composition and classification of the microorganisms used for wastewater treatment, (3) an introduction to important aspects of microbial metabolism, (4) bacterial growth and energetics, (5) microbial growth kinetics, (6) modeling suspended growth treatment processes, and (7) modeling attached-growth treatment processes. Following the presentation of fundamentals, the remaining eight sections deal with an introduction to the general classes of biological processes used for the treatment of wastewater. The material in these sections will also serve as an introduction to the material presented in Chaps. 8, 9 and 10. Because the focus of this book is on quantifiable treatment processes, the role of algae in wastewater treatment, principally in lagoon systems, is not considered. Information on algae is available in publications from the U.S. EPA, WEF, and several textbooks. Similarly, constructed wetlands are not considered because of space constraints and the fact that there are numerous publications including several books devoted solely to the analysis, design, and implementation of these systems.

7–1 OVERVIEW OF BIOLOGICAL WASTEWATER TREATMENT

The objectives of biological treatment, some useful definitions, the role of microorganisms in the biological treatment of wastewater, and biological processes used for wastewater treatment are introduced in this section to provide a perspective for the material to be presented in this chapter.

Objectives of Biological Treatment

The overall objectives of the biological treatment of domestic wastewater are to (1) transform (i.e., oxidize) dissolved and particulate biodegradable constituents into acceptable end products, (2) capture and incorporate suspended and nonsettleable colloidal solids into a biological floc or biofilm, (3) transform or remove nutrients, such as nitrogen and phosphorus, and (4) in some cases, remove specific trace organic constituents and compounds. For industrial wastewater, the objective is to remove or reduce the concentration of organic and inorganic compounds. Because some of the constituents and compounds found in industrial wastewater are toxic to microorganisms, pretreatment may be required before the industrial wastewater can be discharged to a municipal collection system. For agricultural irrigation return (drainage) water containing nutrients, the objective is to remove the nutrients, specifically nitrogen and phosphorus, that are capable of stimulating the growth of aquatic plants.

Role of Microorganisms in Wastewater Treatment

The removal of dissolved and particulate carbonaceous BOD and the stabilization of organic matter found in wastewater is accomplished biologically using a variety of microorganisms, principally bacteria. Microorganisms are used to oxidize (i.e., convert) the dissolved and particulate carbonaceous organic matter into simple end products and additional biomass, as represented by the following equation for the aerobic biological oxidation of organic matter.

$$v_1\ (\text{organic material}) + v_2\text{O}_2 + v_3\text{NH}_3 + v_4\text{PO}_4^{3-} \xrightarrow{\text{microorganisms}} v_5\ (\text{new cells}) + v_6\text{CO}_2 + v_7\text{H}_2\text{O} \tag{7–1}$$

where v_i = the stoichiometric coefficient, as defined previously in Sec. 1–9 in Chap. 1.

In Eq. (7–1), oxygen (O_2), ammonia (NH_3), and phosphate (PO_4^{3-}) are used to represent oxygen and the nutrients needed for the conversion of the organic matter to simple end products [i.e., carbon dioxide (CO_2) and water]. The term shown over the directional arrow is used to denote the fact that microorganisms are needed to carry out the oxidation process. The term *new cells* is used to represent the biomass produced as a result of the oxidation of the organic matter. Microorganisms are also used to remove nitrogen and phosphorus in wastewater treatment processes. Specific bacteria are capable of oxidizing ammonia (nitrification) to nitrite and nitrate, while other bacteria can reduce the oxidized nitrogen to gaseous nitrogen. For phosphorus removal, biological processes are configured to encourage the growth of bacteria with the ability to take up and store large amounts of inorganic phosphorus.

Because the biomass has a specific gravity slightly greater than that of water, the biomass can be removed from the treated liquid by gravity settling. It is important to note that unless the biomass produced from the organic matter is removed on a periodic basis, complete treatment has not been accomplished because the biomass, which itself is organic, will be measured as BOD in the effluent. Without the removal of biomass from the treated liquid, the only treatment achieved is that associated with the bacterial oxidation of a portion of the organic matter originally present.

Types of Biological Processes for Wastewater Treatment

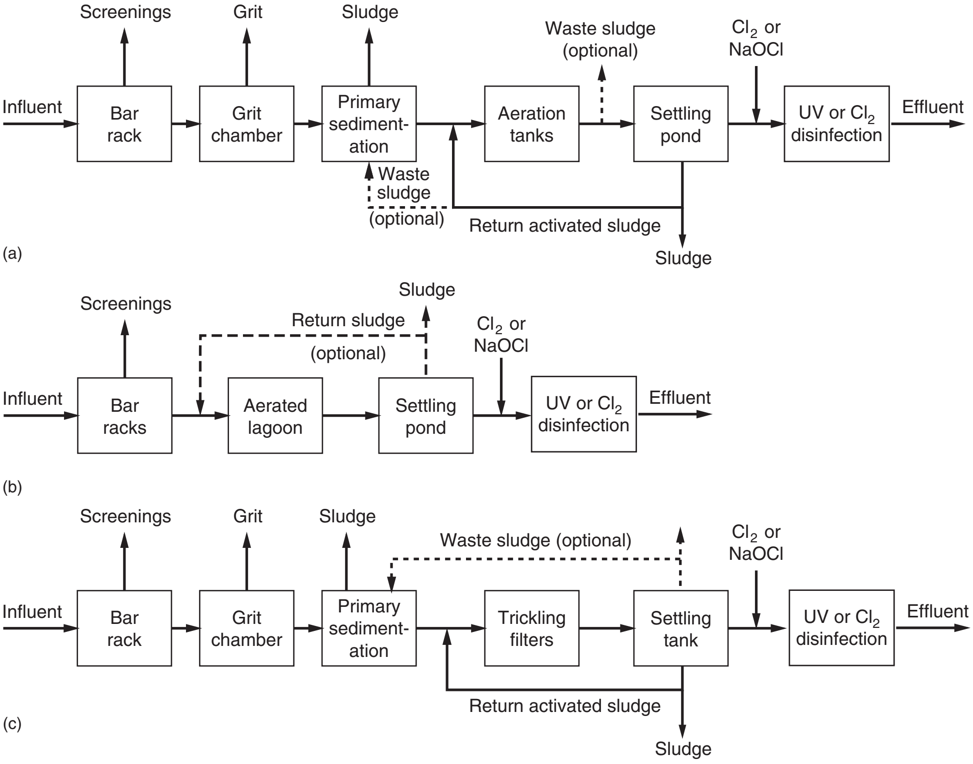
The principal biological processes used for wastewater treatment can be divided into two main categories: *suspended growth* and *attached growth* (or *biofilm*) processes. Examples of commonly used suspended and attached growth biological treatment processes are shown in Fig. 7–1. Typical process applications for suspended and attached growth biological treatment processes are given in Table 7–1, along with other treatment processes. The successful design and operation of the processes listed in Table 7–1 requires an understanding of the types of microorganisms involved, the specific reactions that they perform, the environmental factors that affect their performance, their nutritional needs, and their reaction kinetics. These subjects are considered in the sections that follow.

Suspended Growth Processes. In suspended growth processes, the microorganisms responsible for treatment are maintained in liquid suspension by appropriate mixing methods. Many suspended growth processes used in municipal and industrial wastewater treatment for biodegradation of organic substances are operated with dissolved oxygen (aerobic) or nitrate/nitrite (anoxic) utilization, but applications exist where suspended growth anaerobic (no oxygen present) reactors are used, such as for high organic concentration industrial wastewaters and organic sludges. The most common suspended growth process used for municipal wastewater treatment is the activated sludge process shown on Fig. 7–2 and discussed below.

Early Developments. The activated sludge process was developed around 1913 at the Lawrence Experiment Station in Massachusetts by Clark and Gage (Metcalf and Eddy, 1930)

Figure 7–1

Typical (simplified) flow diagrams for biological processes used for wastewater treatment:
(a) activated sludge process,
(b) aerated lagoons, and
(c) trickling filters.



and by Ardern and Lockett (1914) at the Davyhulme Sewage Works, in Manchester, England. The activated sludge process was so named because it involved the production of an activated mass of microorganisms capable of stabilizing a waste under aerobic conditions. In the aeration tank, contact time is provided for mixing and aerating influent wastewater with the microbial suspension, generally referred to as the mixed liquor suspended solids (MLSS) or mixed liquor volatile suspended solids (MLVSS). Mechanical equipment is used to provide the mixing and transfer of oxygen into the process (see Sec. 5–11, Chap. 5). The mixed liquor then flows to a clarifier where the microbial suspension is settled and thickened. The settled biomass, described as *activated sludge* because of the presence of active microorganisms, is returned to the aeration tank to continue biodegradation of the influent organic material. A portion of the thickened solids is removed daily or periodically as the process produces excess biomass that would accumulate with nonbiodegradable solids contained in the influent wastewater. If the accumulated solids are not removed, the solids level in the clarifier would increase until solids eventually exit via the system effluent flow.

An important feature of the activated sludge process is the formation of floc particles, ranging in size from 50 to 200 mm, which can be removed by gravity settling, leaving a relatively clear liquid as the treated effluent. Typically, greater than 99 percent of the suspended solids can be removed in the clarification step. As will be discussed in Chap. 8, the characteristics and thickening properties of the flocculent particles will affect the clarifier design and performance.

Treatment Objective and Process Developments. The treatment objectives and process configurations for the activated sludge process have changed considerably since its

Table 7–1

Major biological treatment processes used for wastewater treatment

Type	Common name	Use[a]
Aerobic processes:		
Suspended growth	Activated sludge process(es)	Carbonaceous BOD removal, nitrification
	Aerated lagoons	Carbonaceous BOD removal, nitrification
	Aerobic digestion	Stabilization, carbonaceous BOD removal
	Membrane bioreactor	Carbonaceous BOD removal, nitrification
	Nitritation process	Nitritation
Attached growth	Biological aerated filters	Carbonaceous BOD removal, nitrification
	Moving bed bioreactor	Carbonaceous BOD removal, nitrification
	Packed-bed reactors	Carbonaceous BOD removal, nitrification
	Rotating biological contactors	Carbonaceous BOD removal, nitrification
	Trickling filters	Carbonaceous BOD removal, nitrification
Hybrid processes	Trickling filter/activated sludge	Carbonaceous BOD removal, nitrification
	Integrated fixed film activated sludge (IFAS)	Carbonaceous BOD removal, nitrification
Anoxic processes:		
Suspended growth	Suspended-growth denitrification	Denitrification
Attached growth	Attached growth denitrification filter	Denitrification
Anaerobic processes:		
Suspended growth	Anaerobic contact processes	Carbonaceous BOD removal
	Anaerobic digestion	Stabilization, solids destruction, pathogen kill
	Anammox process	Denitritation, ammonia removal
Attached growth	Anaerobic packed and fluidized bed	Carbonaceous BOD removal, waste stabilization, denitrification
Sludge blanket	Upflow anaerobic sludge blanket	Carbonaceous BOD removal, especially high strength wastes
Hybrid	Upflow sludge blanket/attached growth	Carbonaceous BOD removal
Combined aerobic, anoxic, and anaerobic processes:		
Suspended growth	Single- or multi-stage processes, Various proprietary processes	Carbonaceous BOD removal, nitrification, denitrification, and phosphorus removal
Hybrid	Single- or multi-stage suspended growth processes with fixed film media	Carbonaceous BOD removal, nitrification, denitrification, and phosphorus removal
Lagoon processes:		
Aerobic lagoons	Aerobic lagoons	Carbonaceous BOD removal, nitrification
Maturation (tertiary) lagoons	Maturation (tertiary) lagoons	Carbonaceous BOD removal, nitrification
Facultative lagoons	Facultative lagoons	Carbonaceous BOD removal
Anaerobic-lagoons	Anaerobic-lagoons	Carbonaceous BOD removal (waste stabilization)

[a] Adapted from Tchobanoglous and Schroeder (1985).

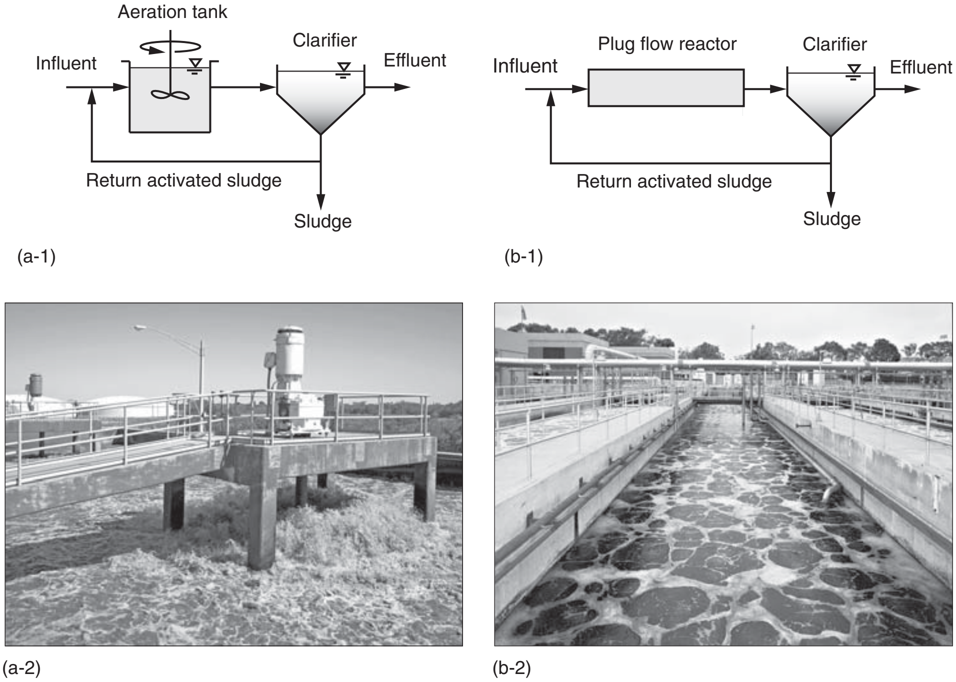


Figure 7–2

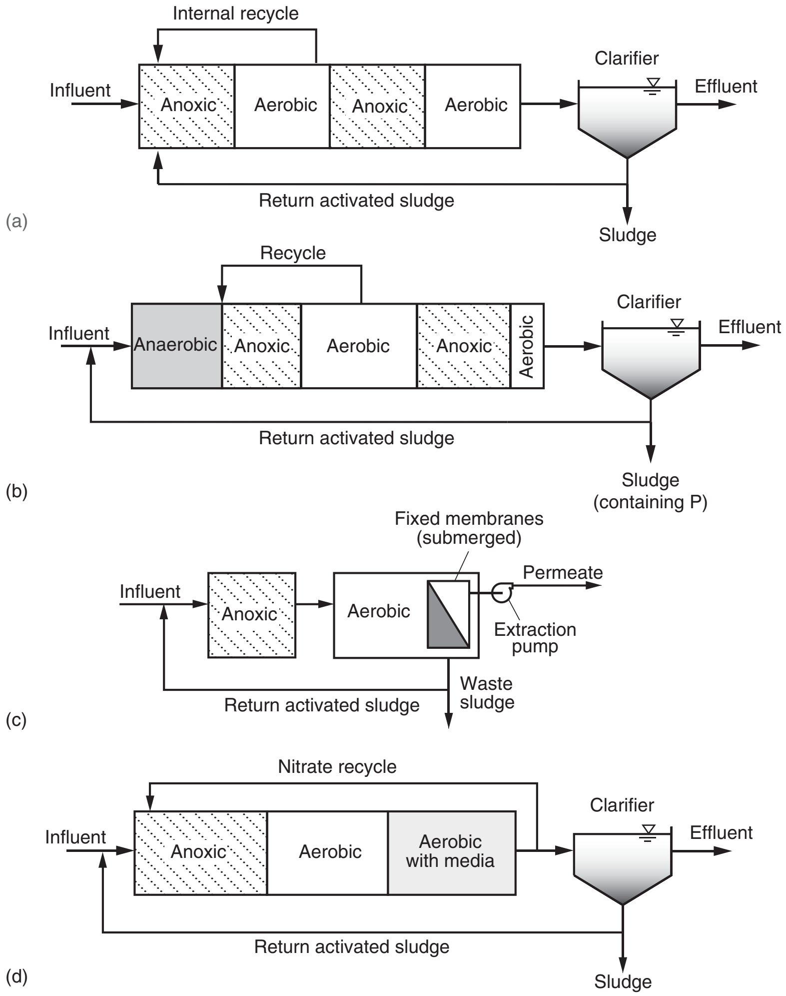
development and application in the early 1900s. Significant changes have been brought about by enhanced understanding of the process microbiology, improved characterization of the individual microorganisms involved, improvements in aeration technology, and new equipment innovations. As a result of these discoveries and innovations, the process capabilities have been expanded and treatment objectives have become more rigorous. In the late 1950s, Pasveer developed a race track configuration for activated sludge treatment (Hao et al., 1997) that led to the popular oxidation ditch system with biological nitrogen removal that is employed at hundreds of wastewater treatment plants around the world today. A common hindrance to operation and performance over the first 60 y of using activated sludge was settling problems associated with the growth of filamentous bacteria. Work by Chudoba et al. (1973) led to the concept of biological selectors and staged reactor configurations to prevent filamentous growth. Staged activated sludge reactor configurations proposed by Barnard (1974) led to activated sludge process applications for biological removal of nitrogen and phosphorus in addition to carbonaceous BOD removal.

Processes with a sequence of anoxic-aerobic-anoxic-aerobic zones for biological nitrogen removal and the addition of an anaerobic contact zone to promote enhanced biological phosphorus removal are shown on Figs. 7–3(a) and (b). Another major change in activated sludge process design occurred in the late 1990s when membrane materials and manufacturing technology had advanced sufficiently so that membranes could be used in activated sludge for effluent liquid-solids separation instead of clarifiers. A membrane bioreactor (MBR) system is depicted in Fig. 7–3(c). The membrane separation unit is immersed in an aerated activated sludge compartment and a sufficient head is provided by gravity or pumping so that the effluent or permeate can be discharged essentially free of suspended solids. As will be shown in Chap. 8, the MBR process can also be incorporated with biological nutrient removal designs.

Figure 7–3

Progression of activated sludge processes: (a) anoxic-aerobic activated sludge for nitrogen removal, (b) anaerobic-anoxic-aerobic-anoxic-aerobic process for nitrogen and phosphorus removal, (c) anoxic-aerobic treatment in membrane bioreactor process with nitrogen removal, and (d) integrated fixed film activated sludge process with nitrogen removal.



Attached Growth Processes. In attached growth processes, the microorganisms responsible for the conversion of organic material or nutrients are attached to an inert packing material. The organic material and nutrients are removed from the wastewater flowing past the attached growth, also known as a biofilm. Packing materials used in attached growth processes include rock, gravel, slag, sand, redwood, and a wide range of plastic and other synthetic materials. Attached growth processes can also be operated as aerobic or anaerobic processes. The packing can be submerged completely in liquid or partially submerged, with air or gas space above the biofilm liquid layer.

The most common aerobic attached growth process used is the trickling filter in which wastewater is distributed over the top area of a vessel containing nonsubmerged packing material (see Fig. 7–4). Historically, rock was used most commonly as the packing material for trickling filters [see Fig. 7–4(a)], with typical depths ranging from 1.25 to 2 m (4 to 6 ft). Most modern trickling filters vary in height from 5 to 10 m (16 to 33 ft) and are filled with a plastic packing material for biofilm attachment [see Fig. 7–4(b)]. The plastic packing material is designed such that about 90 to 95 percent of the volume in the tower consists of void space. Air circulation in the void space, by either natural draft or blowers,

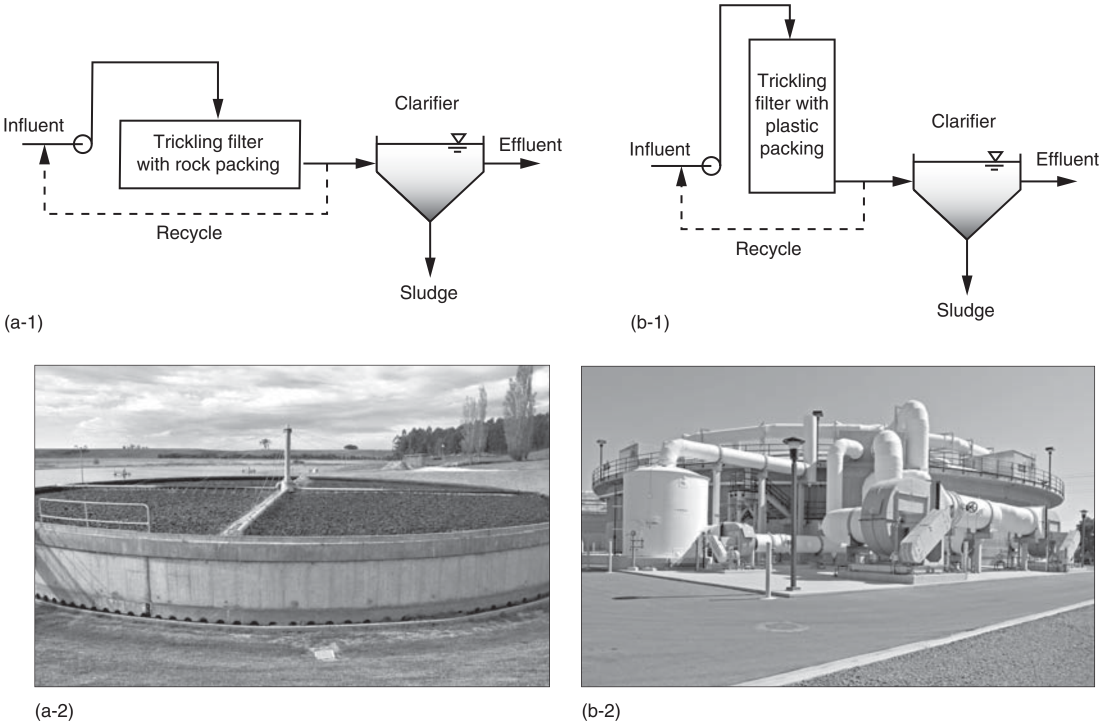


Figure 7–4

Attached growth biological treatment process: (a-1) schematic and (a-2) view of trickling filter with rock packing; and (b-1) schematic and (b-2) view of covered tower trickling filter with plastic packing. The air injection and odor control facilities are shown on the foreground. The tower filter is 10 m high and 50 m in diameter.

provides oxygen for the microorganisms growing as an attached biofilm. Influent wastewater is distributed over the packing and flows as a nonuniform liquid film over the attached biofilm. Excess biomass sloughs from the attached growth periodically and some form of liquid/solids separation is needed to provide an effluent with an acceptable suspended solids concentration. The solids are collected at the bottom of the clarifier and removed for waste-sludge processing.

The popularity of trickling filters had declined with the increasing applications for biological nutrient removal. Advances in the 1990s involved the combination of fixed film and activated sludge treatment, termed an integrated fixed film activated sludge process (IFAS) [see Fig. 7–3(d)]. Other fixed film processes that save space and/or can be used with biological nutrient removal have received more attention and are presented in Chap. 9.

7–2 COMPOSITION AND CLASSIFICATION OF MICROORGANISMS

Biological processes for wastewater treatment consist of mixed microbial communities which may include bacteria, archaea, protozoa, fungi, rotifers, and possibly algae. The basic characteristics and important roles of these organisms have been described in Chap. 2. In some cases, biological treatment goals can only be accomplished by the presence of a specific microbial species. To provide a basic understanding of the nature of microorganisms, the topics introduced in this section are (1) cell components, (2) cell composition, (3) environmental factors that affect microbial activity, and (4) methods used to identify and classify microorganisms. The focus here is mainly on prokaryotes, bacteria and archaea (see Sec. 2–8 in Chap. 2), because of their major role in biological wastewater treatment.

Cell Components

The important components of the prokaryotic cell and their functions were illustrated on Fig. 2–28(a) and are described in Table 7–2; the eukaryotic cell is illustrated on Fig. 2–28(b). Key components that relate to the cell's genetic information and specific enzymes produced, which determine the capability of the microorganism in wastewater treatment, are deoxyribose nucleic acid (DNA) and the ribosomes. Ribosomes are the sites of protein synthesis, which are necessary for enzyme production, and the DNA provides the genetic information used to determine the protein structure synthesized. To understand how DNA codes for the cell proteins, the DNA structure and nucleotide sequence and the structure and role of ribose nucleic acid (RNA) are reviewed.

Nucleic Acids. The nucleic acids, DNA and RNA, are composed of a series of nucleotides. Each nucleotide consists of a five-carbon sugar compound, a nitrogen base,

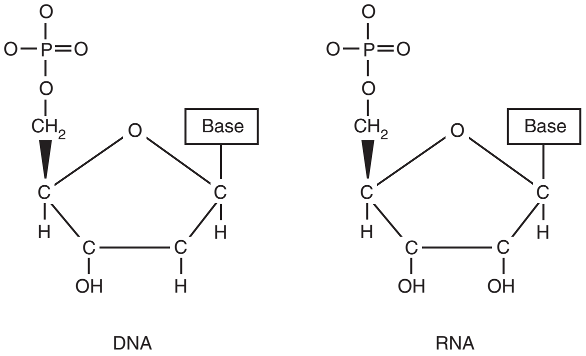
Table 7–2

Description of prokaryote cell components

Cell Component	Function
Cell wall	Provides strength to maintain the cell shape and protects the cell membrane. Some bacteria can produce a sticky polysaccharide layer outside the cell wall, called a capsule or slime layer.
Cell membrane	Controls the passage of dissolved organics and nutrients into the cell and the waste materials and metabolic by products out of the cell.
Cytoplasm	Contains the material within the cell to carry out cell functions and includes water, nutrients, enzymes, ribosomes, and small organic molecules.
Cytoplasmic inclusions	Contains storage material that can provide carbon, nutrients, or energy. These may be carbohydrate deposits, such as polyhydroxybutyrate (PHB) or glycogen, polyphosphates, lipids, and sulfur granules.
Deoxyribonucleic acid (DNA)	A double-stranded helix-shaped molecule that contains genetic information which determines the nature of the cell protein and enzymes that are produced.
Plasmid DNA	Small circular DNA molecules that can also provide genetic characteristics for the bacteria.
Ribosomes	Particles in the cytoplasm that are composed of ribonucleic acid (RNA) and protein and are the sites where proteins are produced.
Flagella	Protein hair-like structures that extend from the cytoplasm membrane several bacteria lengths out from the cell and provide mobility by rotating at high speeds.
Fimbriae and pili	Short protein hair-like structures (Pili is longer) that enable bacteria to stick to surfaces. Pili also enable bacteria to attach to each other.

Figure 7–5

Nucleotide structure of deoxyribose nucleic acid (DNA) and ribose nucleic acid (RNA).



and a phosphate molecule (see Fig. 7–5). To form the nucleotide chain of DNA or RNA, the phosphate group bonds to the third carbon (clockwise from the oxygen bond) of the sugar molecule. The nitrogen bases for DNA can be one of four pyrimidine or purine compounds: cytosine (C), thymine (T), adenine (A), and guanine (G). For RNA, four nitrogen bases are also involved, including A, C, and G, and thymine is replaced with uracil (U). The DNA is a double-strand helix structure with bonding between the nitrogen bases of each strand. Base bonding is very specific with bonds only between G and C, and A and T. The RNA is a single strand of a nucleotide sequence of various combinations of A, C, G, and U. The sequence of nucleotides in DNA contains the necessary genetic codes for the cell, which determine the specific proteins and enzymes that the microorganism can produce. The number of nucleotides in DNA is very high, and the size of the DNA molecule is described in terms of the number of thousands of nucleotide bases (kilobase) per molecule. The bacterium *Escherichia coli* has 4.7 million nucleotides in each DNA strand or 4700 kilobase pairs.

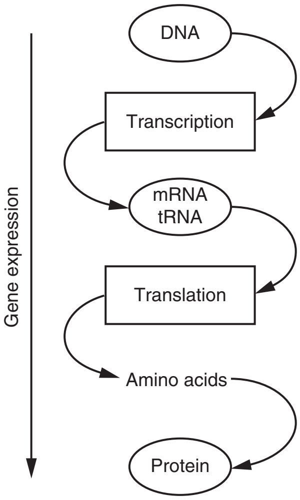


Figure 7–6

Gene expression leads to the formation of proteins by transcription of a segment of the DNA genetic code and translation in the ribosome via messenger RNA (mRNA) and transfer RNA (tRNA) to form a series of amino acids, which form polypeptides and finally protein.

Gene Expression. Gene expression as illustrated on Fig. 7–6 involves the transcription and translation of a segment (gene) of the DNA to form a specific protein. The first step in the process is transcription, in which a small segment of the DNA is unraveled to form a single strand that is used to form a single strand of RNA by complementing base pairing of the nitrogen bases in the DNA nucleotides. For example, adenine (A) in the DNA strand pairs with uracil (U), and guanine (G) with cytosine (C) in the mRNA. The order of the nucleotides in the mRNA will determine the order of amino acids that form polypeptides and the protein structure produced. Translation of the mRNA occurs in the ribosome by tRNA. Each of the nucleotides on the mRNA in series is matched by complementary base pairing with the tRNA in the ribosome, and for each match, another segment of the tRNA, containing three nucleotides, selects a specific amino acid. The three nucleotide sequences in the mRNA are called *codons*. In essence, each codon selects for a specific amino acid, and there is more than one codon for each of the possible 21 amino acids that can be found in living cells. Thus, the length and nucleotide sequence expressed in the DNA represents a gene that determines what specific protein is formed. Because protein is an essential component of cellular enzymes, the DNA gene composition then determines the microbial cell functions and degradative capabilities. Additional details on gene expression may be found in Madigan et al. (2012).

Cell Enzymes. Cell enzymes, consisting of protein and a cofactor such as a metal ion (e.g., zinc, iron, copper, manganese, or nickel), determine the metabolic capability of microorganisms in wastewater treatment. Enzymes are large organic molecules with molecular weights in the range of 10,000 to 1,000,000. Enzymes catalyze biological reactions necessary for cell functions, such as hydrolysis, oxidation-reduction reactions, and cell synthesis reactions. Cells may also produce enzymes for activity outside the cell wall (extracellular enzymes). An example of the function of extracellular enzymes is the hydrolysis of particulates and large molecules so that the material can be transported across the cell membrane for use by the cell. Enzymes can be *constitutive* or *inducible*. Constitutive enzymes are produced continuously by the cell, while inducible enzymes are produced in response to the presence of a particular compound. The rate of enzyme activity is affected by temperature and pH.

Cell Composition

To support microbial growth in biological systems, appropriate nutrients must be available. Reviewing the composition of a typical microbial cell will provide a basis for understanding the nutrients needed for growth. Prokaryotes are composed of about 80 percent water and 20 percent dry material, of which 90 percent is organic and 10 percent is inorganic. Typical values for the composition of prokaryote cells are reported in Table 7–3. The most widely used empirical formula for the organic fraction of cells is $C_5H_7O_2N$, first proposed by Hoover and Porges (1952). About 53 percent by weight of the organic fraction is carbon. The formulation $C_{60}H_{87}O_{23}N_{12}P$ can be used when phosphorus is also considered. It should be noted that both formulations are approximations and may vary with time and species, but they are used for practical purposes. Nitrogen and phosphorus are considered macronutrients because they are required in comparatively large amounts. Prokaryotes also require trace amounts of metallic ions, or micronutrients, such as zinc, manganese, copper, molybdenum, iron, and cobalt. Because all of these elements and compounds must be derived from the environment, a shortage of any of these substances would limit and, in some cases, alter growth.

Environmental Factors

Environmental conditions such as temperature and pH have an important effect on the selection, survival, and growth of microorganisms. In general, optimal growth for a particular microorganism occurs within a fairly narrow range of temperature and pH, although most microorganisms can survive within much broader limits. Temperatures below the optimum typically have a more significant effect on growth rate than temperatures above the optimum; it has been observed that growth rates double with approximately every 10°C increase in temperature until the optimum temperature is reached. According to the temperature range in which they function best, prokaryotes may be classified as *psychrophilic*, *mesophilic*, or *thermophilic*. Typical temperature ranges for microorganisms in each of these categories are presented in Table 7–4. For a more detailed discussion of the organisms in the various temperature ranges, see Madigan et al. (2012).

The pH of the environment is also a key factor in the growth of organisms. Most bacteria cannot tolerate pH levels above 9.5 or below 4.0. Generally, the optimum pH for bacterial growth lies between 6.5 and 7.5. Different archaea are able to grow at thermophilic and ultrathermophilic (60 to 80°C) temperatures, extremely low pH, and high salinity.

Table 7–3

Typical composition of bacteria cells[a]

Constituent or element	Percent of dry weight
Major cellular material	
Protein	55.0
Polysaccharide	5.0
Lipid	9.1
DNA	3.1
RNA	20.5
Other (sugars, amino acids)	6.3
Inorganic ions	1.0
As cell elements	
Carbon	50.0
Oxygen	22.0
Nitrogen	12.0
Hydrogen	9.0
Phosphorus	2.0
Sulfur	1.0
Potassium	1.0
Sodium	1.0
Calcium	0.5
Magnesium	0.5
Chlorine	0.5
Iron	0.2
Other trace elements	0.3

Temperature classification of biological processes

Type	Temperature range, °C	Optimum range, °C
Psychrophilic	10–30	12–18
Mesophilic	20–50	25–40
Themophilic	35–75	55–65

Microorganism Identification and Classification

With the use of more sophisticated biological treatment processes and developments in the use of molecular tools for microbial applications, environmental engineers have expanded their interests from the general functionality of microorganisms to understanding the presence and role of specific microbial species in biological treatment systems. For example, engineered systems can be controlled to create selective pressures that will favor the growth of preferred microorganisms. Thus, the identification of microorganisms and their metabolic characteristics is very important and is described here along with molecular methods used in biological processes.

In the past, the methods used to identify microorganisms relied on physical taxonomic (morphologic) and metabolic characteristics (phenotypic analysis). With modern tools from molecular biology, microorganims identification is now based on cellular genetic information. The basic taxonomic unit in the identification of bacteria, for example, is the species, which represents a collection of similar strains of bacteria that exhibit characteristics significantly different from other groups of bacteria. Species that share one or more major properties are placed in a group termed a genus (plural genera). All bacteria are given a genus and species name. The genus name is capitalized and placed before the species name and can be abbreviated ahead of the species name after first identified. The genus and species names are italicized. For example, the genus *Bacillus* contains several species including *B. subtilis*, *B. cerus*, and *B. stearothermophilis*, based on different morphological, physiological, and ecological traits (Madigan et al., 2012).

Taxonomic Classification. Conventional taxonomic methods used to identify a bacterium, for example, rely on physical properties of the bacteria and metabolic characteristics. To apply this approach, a pure culture must first be isolated. The culture may be isolated by serial dilution and growth in selective growth media. The cells are harvested and grown as pure culture using sterilization techniques to prevent contamination. In some cases, isolation of a species is not possible, which may be due to the need for synergistic growth with other species or the lack of a specific growth factor. Historically, the types of tests that are used to characterize a pure culture include (1) microscopic observations, to determine morphology (size and shape); (2) gram staining, to determine if the bacteria cell wall will absorb crystal violet dye; (3) the type of electron acceptor (i.e., oxygen, CO_2, etc.) used in oxidation-reduction reactions; (4) the type of carbon source used for cell growth; (5) the ability to use various nitrogen and sulfur sources; (6) nutritional needs; (7) cell wall chemistry; (8) cell characteristics including pigments, segments, cellular inclusions, and storage products; (9) resistance to antibiotics; and (10) environmental effects of temperature and pH. An alternative to taxonomic classification is a newer method, termed *phylogeny*.

Phylogenetic Classification. In the late 1970s, microbiologists began to use tools that allowed them to study microorganisms at the molecular level and to observe genetic relationships related to the evolutionary history of living cells. The characterization of microorganisms based on genetic information and evolutionary location in time is termed *phylogeny*, which is the more current method of identification and classification. To identify accurately the microbes and determine the true evolutionary relationships among species, the choice of cellular genetic material is critical. The genetic code for ribosomal RNA was chosen as the evolutionary chronometer for cell identification because the code (1) is of evolutionary significance, (2) is present in all known forms of life, (3) is well conserved across broad phylogenetic distances, and (4) contains sufficient nucleotide sequences so that similarity in sequences between two organisms indicates a phylogenetic relationship (Pace et al., 1986).

Ribosomal RNA. Ribosomal RNA can be separated into two components, 30S (Svedberg units) and 50S, based on different centrifugal forces in ultracentrifugation. The 30S units consist of 16S rRNA (18S rRNA in eukaryotes), containing about 1500 nucleotides and 21 proteins. While the 16S rRNA can be extracted from cells for nucleotide sequencing using molecular techniques, more often the section of DNA that encodes the rRNA genes is used. This method includes genomic DNA extraction from the cell material, followed by a polymerase chain reaction (PCR) procedure that uses DNA primers and a thermally-stable DNA polymerase enzyme to reproduce and amplify artificially a section of the DNA material by a factor of 10^6 or more from the small amount of DNA extracted from the cell. The amplified 16S rRNA gene is then sequenced to determine the order of nucleotide bases in 16S rRNA gene. The sequencing result is compared to the ribosome sequences available in a database to determine its phylogenetic relationship to known organisms.

Molecular Phylogeny. Molecular phylogeny involves a systematic organization and classification of microorganisms based on their genetic traits. The phylogenetic tree of life as determined from 16S and 18S rRNA sequencing is shown on Fig. 7–7. Life is divided into three basic domains, two composed of prokaryotic cells (Archaea and Bacteria), as discussed previously, and the third composed of Eukarya cells. The gene used to build the tree of life is highly conserved, meaning that changes to the genomic sequence that encode this gene occur slowly. Thus, the similarity of 16S rRNA gene sequences can be used as an evolutionary timeline to estimate the distance to a common ancestor (defined as the nodes or branches in the tree of life). The evolutionary history of the organisms does not necessarily indicate the evolution of the organisms' full set of genes, which can be passed between unrelated species by several mechanisms. Therefore, metabolism of the organisms cannot always be inferred by position on the tree of life. This situation has been shown to be particularly true for genes encoding sulfate reduction and ammonia oxidation, which are found in discrete branches within both the bacterial and archaeal domains. In addition to having different rRNA sequencing properties, the archaea have a number of different phenotypic properties compared to bacteria. These differences are found in cell wall composition, cell membrane lipid chemistry, RNA polymerase composition, and protein synthesis mechanisms in the ribosome.

Domains of Life. Representatives from all three domains of life are involved in wastewater treatment. Nitification (Sec. 7–9) is an important process in biological nutrient

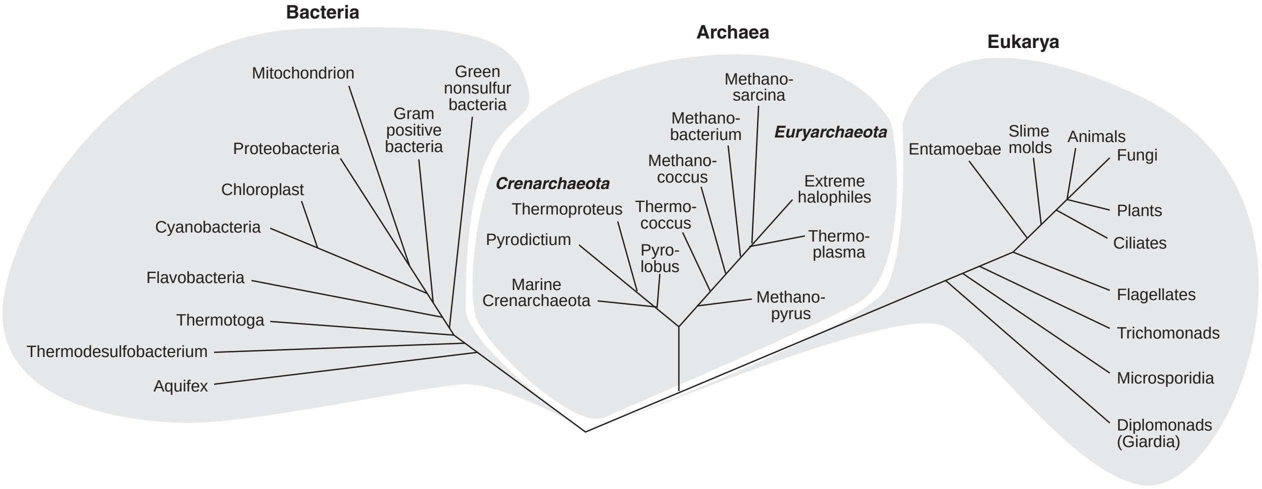

Figure 7–7

Phylogenetic tree of life.

removal and involves a first step of biological oxidation of ammonium. Aerobic ammonia oxidizing prokaryotes (AOP) are found within the Bacteria and Archaea domains with the ammonia oxidizing bacteria (AOB) in the genus *Nitrosomonas* and *Nitrosospira* within the β-proteobacteria class of the phylum, Proteobacteria. The ammonia oxidizing archaea (AOA) were originally recognized as Crenarchaeota and have now been reclassified to a new phylum named Thaumarchaeota.

The more recently found "anammox" bacteria (Sec. 7–11), which can oxidize ammonia under anaerobic conditions, have been classified within the phylum Planctomycetes. Bacteria that are important for the removal of phosphorus without chemical addition in enhanced biological phosphorus removal (EBPR) processes (Sec. 7–12) appear to be similar to the phosphate accumulating bacteria Candidatus *Accumulibacter phosphatis*, also a member of the β-proteobacteria. Nitrite oxidizing bacteria (NOB) within the genus *Nitrobacter* are within the α-proteobacteria and *Nitrospira* are within the phylum Nitrospirae. Methylotrophic bacteria important for using methanol in denitrification applications include the proteobacteria *Hyphomicrobium spp*. and *Methyloversatilis spp*. All the methanogens are Archaea within the phylum Euryarchaeaota. Eukaryotes within wastewater treatment include amoebae, ciliates, and rotifers.

Use of Molecular Tools

In addition to identifying and classifying microorganisms, molecular tools are used to provide information about active microbial communities and to monitor water or wastewater treatment plant effluents for specific pathogenic organisms. Molecular techniques use DNA, RNA, and proteins to identify, track, and quantify the presence and activities of microorganisms. Some common molecular tools that are applied to understand relationships between microbial community composition and biological process performance are considered below. The use of molecular tools is a rapidly growing area of microbiology. The continual development of new tools in the next few years for application to research and operations of biological wastewater treatment processes may be expected.

Polymerase Chain Reaction (PCR). Many molecular tools are based on the polymerase chain reaction (PCR) process in which small sections of DNA are amplified using naturally occurring enzymes involved in cellular DNA replication. The DNA is recovered from the complex microbial communities that comprise biological processes by first disrupting the cells either physically (e.g., shaking with glass micro-beads) or chemically (e.g., by adding phenol, lysozyme, or detergent). The recovered DNA is cleaned and concentrated by sorption to a column in the presence of ethanol. The clean DNA is eluted into purified water (see Fig. 7–8). The PCR process proceeds by mixing the sample (i.e., template) DNA, PCR primers (short oligonucleotides that complement a section of the target DNA sequence), DNA polymerase (a naturally occurring enzyme that creates copies of DNA during cell replication), a mixture of nucleotides (the molecular building-blocks for constructing new DNA), and a pH buffer containing Mg^{2+}.

A typical PCR reaction uses three temperature steps (see Fig. 7–9): (1) the temperature is increased to about 95°C causing the double stranded DNA to separate into two single strands, (2) the temperature is lowered to allow PCR primers to anneal to the DNA template, and (3) the temperature is increased to about 72°C and DNA polymerase extends the copy of the template DNA. The amount of amplified DNA doubles with each repeated temperature cycle. The process is done in instruments, called thermocyclers, specifically designed to modulate rapidly between the required temperatures, allowing much greater process precision. The most commonly used DNA polymerase was originally obtained

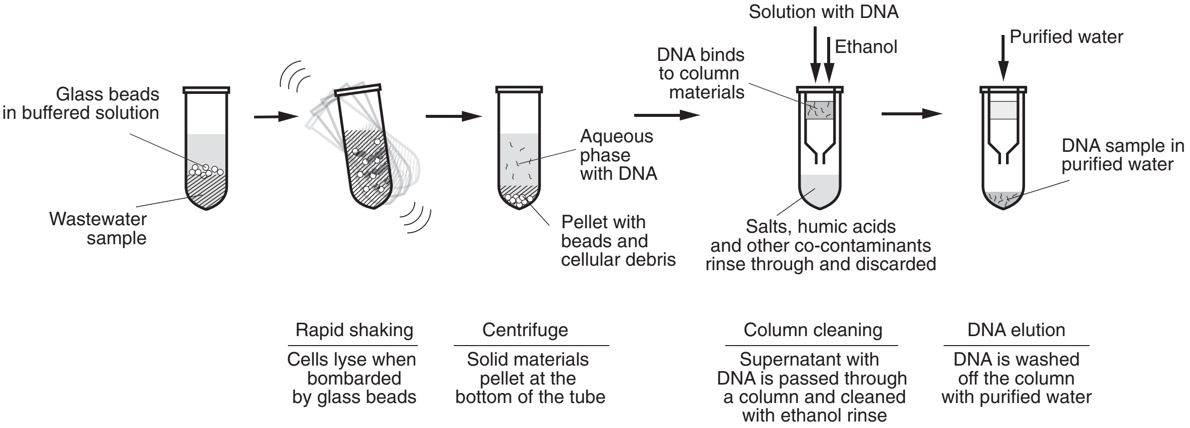

Figure 7–8

Extraction of DNA from wastewater samples. A vortex mixer or an instrument specifically designed for cell disruption by rapid shaking is used for the rapid shaking process.

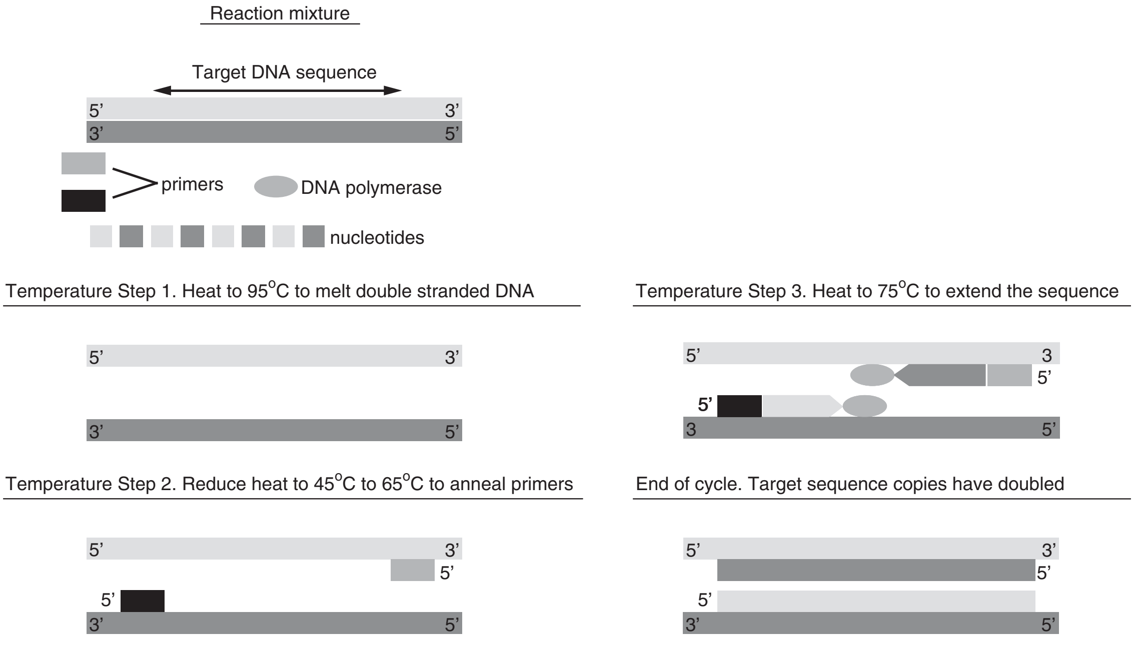

Figure 7–9

Sequence of a polymerase chain reaction (PCR) process.

from the thermophilic Bacteria *Thermus aquaticus* (Taq) and remains active when exposed to the high temperatures used to melt the template DNA. A great advantage of the PCR process is that the primers can be designed to target DNA sequences that are either conserved across domains or are unique to individual species. For example, primers have been designed that target all Bacteria, all Archaea, *dsr* genes (associated with sulfate reduction), *amoA* genes (associated with ammonia oxidation), or even 16S rRNA gene sequences of a single species.

Modifications of PCR Technologies. PCR allows genetic identification without requiring prior knowledge of a microbial community composition and has led to the discovery that less than 1 percent of microbial diversity was previously documented. Even now, studies of biological processes lead to new species discoveries. Some applications of PCR to wastewater treatment processes are described in the following paragraphs.

Quantification of Microbial Populations in Mixed Communities. By modifying the PCR approach, different microbial populations within mixed communities can be quantified using quantitative PCR (qPCR). The qPCR procedure uses a dye that fluoresces when bound to double-stranded DNA, which allows measurement of the amount of PCR product at the end of each PCR cycle. Through comparison to standards with known DNA concentrations, qPCR is used to quantify relative bacterial or functional gene concentrations.

Profiles of Mixed Communities. Another modification of the PCR technique can be used to generate profiles of mixed microbial communities, sometimes called community "finger prints." For example, terminal restriction fragment length polymorphism (TRFLP) modifies PCR by adding a fluorescent tag to one of the primers. The PCR products are cut using a restriction enzyme. The distance from the PCR priming site to the restriction enzyme cut site will differ among microbial populations. The resulting fragments are size separated using conventional sequencing instruments and a chromatogram of florescence intensities is recorded corresponding to the differing fragment lengths.

Sequencing PCR Products. Sequencing PCR products can provide information about microbial phylogenetic identity. When the PCR product is from a mixed microbial community, cloning reactions of the PCR products can be used to separate amplified DNA from individual organisms. The PCR product is incorporated into plasmid vectors (small circular DNA). The vectors are transformed into "competent" *E. coli* cells. When the *E. coli* are grown on solid media, each colony starting from a single *E. coli* cell will have identical copies of one original PCR product strand. These strands can then be sequenced and the sequence results compared to public databases, such as the Basic Local Alignment Search Tool (BLAST) at the National Center for Biotechnology Information (NCBI) website (http://blast.ncbi.nlm.nih.gov), to reveal the microorganisms that comprised the original mixed community.

Other Molecular Methods. Several molecular methods do not require a PCR step. One such method is fluorescent in-situ hybridization (FISH). An oligonucleotide probe (similar in design to PCR primers) is labeled so that it can be detected by fluorescence. The probes are allowed to penetrate intact cells, where they hybridize to the rRNA of active microorganisms. Multiple probes can be applied with each, using different fluorescens. When viewed through a microscope with fluorescence capabilities, FISH allows visual observation of how different microbial populations interact and allows quantification of the population through cell counting (Maier et al., 2000). The use of the FISH technique to identify dense clusters (up to 3000 cells) of ammonia-oxidizing (*Nitrosomonas*) bacteria in several activated sludge plant sample using the NEU probe was demonstrated by Wagner et al. (1995). A probe targeting *E. coli* that was developed to study UV disinfection was illustrated previously on Fig. 2–36 in Chap. 2.

One of the distinct advantages of FISH is that the distribution of a species in its environment can be observed. When FISH techniques are employed with more than one nucleic acid probe added to the sample, a number of bacterial species or strains can be identified and their relative distribution within the matrix can be observed. Microradiography-FISH (MAR-FISH) modifies the approach to provide a link between phylogeny and physiology by first incubating an active culture in the presence of a C^{14}-labeled substrate. Following fluorescence to identify bacteria, microscope slides are overlaid onto film and bacteria that took up the labeled compounds are identified based on film exposure.

Metagenomics. As sequencing technologies have become more efficient and affordable, it has become possible to sequence community DNA without first requiring a PCR step. This technique is known as metagenomics and provides information not only on 16S rRNA sequence data but also on all genomics data (much of which still has no assigned function). This approach was used to obtain a full genome sequence of "Candidatus *Accumulibacter phosphatis"* (Martín et al., 2006), a bacterium involved in enhanced biological phosphorus removal (EBPR) that has thus far eluded culture attempts. By studying the genome sequence, new hypotheses have been generated about the physiological and adaptive capabilities of this important bacterium that will help direct future EBPR designs.

Proteomics. Another method that has been applied to many environments is proteomics, used to examine protein profiles from mixed samples. The amino acids that comprise each protein are compared to genome sequence information to identify which genes were active at the time the sample was collected. Comparing protein profiles obtained under a different set of conditions (for example, with and without a contaminant or at different reactor temperatures) may provide insights into how operational changes impact microbial activities.

7–3 INTRODUCTION TO MICROBIAL METABOLISM

Basic to the design of a biological treatment process, or to the selection of the type of biological process to be used, is an understanding of the biochemical activities of microorganisms. The classification of microorganisms by sources of cell carbon, electron donor, electron acceptor, and end products is summarized in Table 7–5. Different microorganisms can use a wide range of electron acceptors, including oxygen, nitrite, nitrate, iron (III), sulfate, organic compounds, and carbon dioxide. The two major topics considered in this section are (1) the general nutritional requirements of the microorganisms commonly encountered in wastewater treatment, and (2) the nature of microbial metabolism based on the need for molecular oxygen.

Carbon and Energy Sources for Microbial Growth

To continue to reproduce and function properly, an organism must have sources of energy, carbon for the synthesis of new cellular material, and inorganic elements (nutrients) such as nitrogen, phosphorus, sulfur, potassium, calcium, and magnesium. Organic nutrients (growth factors) may also be required for cell synthesis. Carbon and energy sources, usually referred to as *substrates*, and nutrient and growth factor requirements for various types of organisms are considered in the following discussion.

Table 7–5

Classification of microorganisms by electron donor, electron acceptor, sources of cell carbon, and end products. All reactions shown support new biomass growth

Type of bacteria	Common reaction name	Carbon source	Electron Donor (substrate oxidized)	Electron acceptor	Products
Aerobic heterotrophic	Aerobic oxidation	Organic compound	Organic compound	O_2	CO_2, H_2O
Aerobic autotrophic	Nitrification	CO_2	NH_4^+, NO_2^-	O_2	NO_2^-, NO_3^-
	Iron oxidation	CO_2	Fe (II)	O_2	Ferric Iron Fe (III)
	Sulfur oxidation	CO_2	H_2S, S°, $S_2O_3^{2-}$	O_2	SO_4^{2-}
Facultative heterotrophic	Denitrification anoxic reaction	Organic compound	Organic compounds	NO_2^-, NO_3^-	N_2, CO_2, H_2O
Anaerobic heterotrophic	Acid fermentation	Organic compound	Organic compounds	Organic compounds	Volatile fatty acids (VFAs) (acetate, propionate, butyrate)
	Iron reduction	Organic compound	Organic compounds	Fe (III)	Fe (II), CO_2, H_2O
	Sulfate reduction	Organic compound	Organic compounds	SO_4	H_2S, CO_2, H_2O
	Methanogenesis	Organic compound	Volatile fatty acids (VFAs)	CO_2	Methane
Anaerobic autotrohpic	Anammox	CO_2	NH_4^+	NO_2^-	N_2, NO_3^-

Carbon Sources. Microorganisms obtain their carbon for cell growth from either organic matter or carbon dioxide. Organisms that use organic carbon for the formation of new biomass are called *heterotrophs*, while organisms that derive cell carbon from carbon dioxide are called *autotrophs*. The conversion of carbon dioxide to cellular carbon compounds is an anabolic process, which requires a net input of energy. Autotrophic organisms must therefore spend more of their energy for synthesis than do heterotrophs, resulting in generally lower yields of cell mass and growth rates.

Energy Sources. The energy needed for cell synthesis may be supplied by light or by a chemical oxidation reaction. Organisms that are able to use light as an energy source are called *phototrophs*. Phototrophic organisms may be either heterotrophic (certain sulfur-reducing bacteria) or autotrophic (algae and photosynthetic bacteria). Organisms that derive their energy from chemical reactions are known as *chemotrophs*. As with the phototrophs, chemotrophs may be either heterotrophic (protozoa, fungi, and most bacteria) or autotrophic (i.e., nitrifying bacteria). *Chemoautotrophs* obtain energy from the oxidation of reduced *inorganic* compounds, such as ammonia, nitrite, ferrous iron, and sulfide. *Chemoheterotrophs* usually derive their energy from the oxidation of *organic* compounds.

Oxidation-Reduction Reaction. The energy-producing chemical reactions by chemotrophs are oxidation-reduction reactions that involve the transfer of electrons from an electron donor to an electron acceptor. The electron donor is oxidized and the electron acceptor is reduced. The electron donors and acceptors can be either organic or inorganic compounds, depending on the microorganism. The electron acceptor may be available within the cell during metabolism (endogenous), or it may be obtained from outside the cell (i.e., dissolved oxygen) (exogenous). Organisms that generate energy by enzyme-mediated electron transport to an external electron acceptor are said to have a *respiratory metabolism*. The use of an internal electron acceptor is termed *fermentative metabolism* and is a less efficient energy-yielding process than respiration. Heterotrophic organisms that are strictly fermentative are characterized by lower growth rates and cell yields than respiratory heterotrophs.

Utilization of Oxygen. When oxygen is used for the electron acceptor the reaction is termed *aerobic*, and reactions involving other electron acceptors are considered anaerobic. The term *anoxic* is used to distinguish the use of nitrite or nitrate for electron acceptors from the others under anaerobic conditions. Under anoxic conditions nitrite or nitrate reduction to gaseous nitrogen occurs, and this reaction is also referred to as biological denitrification. Organisms that can only meet their energy needs with oxygen are called *obligate aerobic* microorganisms. Some bacteria can use oxygen or nitrate/nitrite as electron acceptors when oxygen is not available. These bacteria are called *facultative aerobic* bacteria.

Energy for Fermentation. Organisms that generate energy by fermentation and that can exist only in an environment that is devoid of oxygen are *obligate anaerobes*. *Facultative anaerobes* have the ability to grow in either the presence or absence of molecular oxygen and fall into two subgroups, based on their metabolic abilities. True facultative anaerobes can shift from fermentative to aerobic respiratory metabolism, depending upon the presence or absence of molecular oxygen. *Aerotolerant anaerobes* have a strictly fermentative metabolism but are relatively insensitive to the presence of molecular oxygen.

Nutrient and Growth Factor Requirements

Nutrients, rather than carbon or energy sources, may at times be the limiting material for microbial cell synthesis and growth. The principal inorganic nutrients needed by microorganisms are N, S, P, K, Mg, Ca, Fe, Na, and Cl. Minor nutrients of importance include Zn, Mn, Mo, Se, Co, Cu, and Ni (Madigan et al., 2012). Required organic nutrients, known as growth factors, are compounds needed by an organism as precursors or constituents of organic cell material, which cannot be synthesized from other carbon sources. Although growth factor requirements differ from one organism to another, the major growth factors fall into the following three classes: (1) amino acids, (2) nitrogen bases (i.e., purines and pyrimidines), and (3) vitamins.

For municipal wastewater treatment sufficient nutrients are generally present, but for industrial wastewaters nutrients may need to be added to the biological treatment processes. The lack of sufficient nitrogen and phosphorus is common especially in the treatment of food-processing wastewaters or wastewaters high in organic content. Using the formula $C_{12}H_{87}O_{23}N_{12}P$ (given previously) for the composition of cell biomass, about 12.2 g of nitrogen and 2.3 g of phosphorus are needed per 100 g of cell biomass.

7–4 BACTERIAL GROWTH, ENERGETICS, AND DECAY

In the description of microbial metabolism it was noted that as microorganisms consume substrate and carry out oxidation-reduction reactions, growth occurs by the production of additional cells. Thus, in wastewater treatment applications biomass is produced continuously as the substrate in the wastewater is consumed and biodegraded. Topics considered in this section include (1) bacterial reproduction, (2) bacterial growth patterns in a batch reactor, (3) bacterial growth and biomass yield, (4) methods used to measure biomass growth, (5) estimating cell yield and oxygen requirements from stoichiometry, (6) estimating cell yield from bioenergetics, and (7) observed versus synthesis yield. The material presented in this section will serve as a basis for the sections that follow and the material presented in Chaps. 8, 9, and 10 on the various treatment processes.

Bacterial Reproduction

Bacteria can reproduce, as noted in Chap. 2, by binary fission, by asexual mode, or by budding. Generally, bacteria reproduce by binary fission, in which the original cell becomes two new organisms. The time required for each division, which is termed the generation time, can vary from days to less than 20 min. For example, if the generation time is 30 min, one bacterium would yield 16,777,216 (i.e., 2^{24}) bacteria after a period of 12 h. Assuming spherical-shaped bacteria with a 1 μm diameter and specific gravity of 1.0, the weight of 1 cell is approximately 5.0×10^{-13} g. In 12 h the bacteria mass would be about 8.4×10^{-6} g or 8.4 μg; thus the number of cells is quite large compared to the mass. This rapid change in biomass with time is a hypothetical example. In biological treatment systems bacteria would not continue to divide indefinitely because of environmental limitations, such as substrate and nutrient availability.

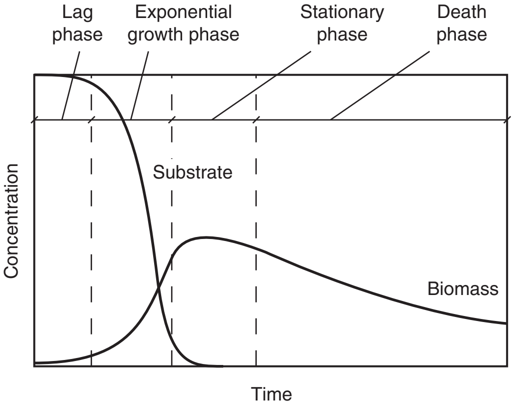
Bacterial Growth Patterns in a Batch Reactor

Bacterial growth in a batch reactor (see Sec. 1–7) is characterized by identifiable phases as illustrated on Fig. 7–10. The curves shown on Fig. 7–10 represent what occurs in a batch reactor in which, at time zero, substrate and nutrients are present in excess and only a very small population of biomass exists. As substrate is consumed, four distinct growth phases develop sequentially.

1. The lag phase. Upon addition of the biomass, the lag phase represents the time required for the organisms to acclimate to their new environment before significant cell division and biomass production occur. During the lag phase enzyme induction may be occurring and/or the cells may be acclimating to changes in salinity, pH, or temperature. The apparent extent of the lag phase may also be affected by the ability to measure the low biomass concentration during the initial batch phase.
2. The exponential-growth phase. During the exponential-growth phase, bacterial cells are multiplying at their maximum rate, as there is no limitation due to substrate

Figure 7–10

Batch process biomass growth phases with changes in substrate and biomass versus time.



or nutrients. The biomass growth curve increases exponentially during this period. With unlimited substrate and nutrients the only factor that affects the rate of exponential growth is temperature.

3. The stationary phase. During this phase, the biomass concentration remains relatively constant with time. In this phase, bacterial growth is no longer exponential, and the amount of growth is offset by the death of cells.
4. The death phase. In the death phase, the substrate has been depleted so that no growth is occurring, and the change in biomass concentration is due to cell death. An exponential decline in the biomass concentration is often observed as an approximate constant fraction of the biomass remaining that is lost each day.

Bacterial Growth and Biomass Yield

In biological treatment processes, cell growth occurs concurrent with the oxidation of organic or inorganic compounds, as described above. The ratio of the amount of biomass produced to the amount of substrate consumed (g biomass/g substrate) is defined as the *biomass synthesis yield* and typically is defined relative to the electron donor used.

$$\text{Biomass synthesis yield, } Y = \frac{\text{g biomass produced}}{\text{g substrate consumed}} \tag{7–2}$$

For example, for aerobic heterotrophic reactions with organic substrates, the yield is expressed as g biomass/g organic substrate; for nitrification the yield is expressed as g biomass/g NH_4-N oxidized; and for the anaerobic degradation of volatile fatty acids (VFAs) to produce methane, the yield is expressed as g biomass/g VFAs used. Where specific compounds are measured and known, such as ammonia, the yield is quantified relative to the amount of compound used. For aerobic or anaerobic treatment of municipal and industrial wastewater containing a large number of organic compounds, the yield is based on a measurable parameter reflecting the overall organic compound consumption, such as COD or BOD. Thus, the yield would be g biomass/g COD removed or g biomass/g BOD removed.

Measuring Biomass Growth

Because biomass is mostly organic material, an increase in biomass can be measured by volatile suspended solids (VSS) or particulate COD (total COD minus soluble COD). Other more direct parameters that are used to indicate biomass growth are protein content, DNA, and adenosine triphosphate (ATP), a cellular nucleotide compound involved in energy transfer. Of these growth measurement parameters, VSS is the parameter used most commonly to follow biomass growth in full-scale biological wastewater treatment systems because its measurement is simple, and minimal time is required for analysis. It should be noted that the VSS measured includes other particulate organic matter in addition to biomass. Most wastewaters contain some amount of nonbiodegradable VSS and possibly influent VSS that may be degraded slowly in the biological reactor. These solids are included with biomass in the VSS measurement. Nevertheless the VSS measurement is used as an apparent indicator of biomass production and also provides a useful measurement of reactor solids in general.

For laboratory research on biological treatment processes, growth parameters that can be related to true microbial mass are often used. Of these, protein is the most popular growth parameter due to the relative ease of measurement and the fact that about 50 percent of biomass dry weight is protein. Both ATP and DNA have also been used, especially where the reactor solids contain proteins and other solids that are not associated with biomass. Where very low biomass concentrations are involved, turbidity measurements may be used to provide a rapid and simple means of observing cell growth. Bacterial cell counts have also been used to enumerate the biomass population. A portion of a diluted sample is applied to an agar growth plate, and after incubation, the number of colonies formed are counted and used to determine the number of bacterial cells in the culture. It should be noted, however, that not all bacteria are culturable.

Estimating Biomass Yield and Oxygen Requirements from Stoichiometry

As given by Eq. (7–1), a definite stoichiometric relationship exists between the substrate removed, the amount of oxygen consumed during aerobic heterotrophic biodegradation, and the observed biomass yield. The most common approach used to define the fate of the substrate is to prepare a COD mass balance. The COD is used because the substrate concentration in the wastewater can be defined in terms of its oxygen equivalence, which can be accounted for by being conserved in the biomass or oxidized.

Biomass Yield. In general, the exact stoichiometry involved in the biological oxidation of a mixture of wastewater compounds is never known. However, for the purpose of illustration, it is assumed that organic matter can be represented as $C_6H_{12}O_6$ (glucose) and new cells can be represented as $C_5H_7NO_2$ (Hoover and Porges, 1952). Thus, neglecting nutrients other than nitrogen, Eq. (7–1) can be written as

$$\underset{3(180)}{3C_6H_{12}O_6} + \underset{8(32)}{8O_2} + \underset{2(17)}{2NH_3} \rightarrow \underset{2(113)}{2C_5H_7NO_2} + 8CO_2 + 14H_2O \tag{7–3}$$

As given by the above equation, the substrate used (glucose in this case) is divided between that found in new cells and that oxidized to produce CO_2 and H_2O. The yield based on the glucose consumed can be obtained as follows:

$$Y = \frac{\Delta(C_5H_7NO_2)}{\Delta(C_6H_{12}O_6)} = \frac{2(113\text{ g/mole})}{3(180\text{ g/mole})}$$
$$= 0.42\text{ g cells/g glucose used}$$

In practice, COD and VSS are used to represent the organic matter and the new cells, respectively. To express the yield on a COD basis, the COD of glucose must be determined. The COD of glucose can be determined by writing a balanced stoichiometric reaction for the oxidation of glucose to carbon dioxide as follows:

$$\underset{(180)}{C_6H_{12}O_6} + \underset{(32)}{6O_2} \rightarrow 6CO_2 + 6H_2O \tag{7–4}$$

The COD of glucose is

$$\text{COD} = \frac{\Delta(O_2)}{\Delta(C_6H_{12}O_6)} = \frac{6(32\text{ g/mole})}{(180\text{ g/mole})} = 1.07\text{ g }O_2\text{/g glucose}$$

The theoretical yield expressed in terms of COD, accounting for the portion of the substrate converted to new cells, is

$$Y = \frac{\Delta(C_5H_7NO_2)}{\Delta(C_6H_{12}O_6\text{ as COD})} = \frac{2(113\text{ g/mole})}{3(180\text{ g/mole})(1.07\text{ g COD/g glucose})}$$
$$= 0.39\text{ g cells/g COD used or }0.39\text{ g VSS/g COD used}$$

It should be noted that the actual observed yield in a biological treatment process will be less than the value given above, because a portion of the substrate incorporated into the cell mass will be later oxidized with time by the bacteria to obtain energy for cell maintenance.

Oxygen Requirements. The quantity of oxygen utilized can be accounted for by considering (1) the oxygen used for substrate oxidation to CO_2 and H_2O, (2) the COD of the biomass, and (3) the COD of any substrate not degraded. For the formula $C_5H_7NO_2$, the oxygen equivalent of the biomass (typically measured as VSS) is approximately 1.42 g COD/g biomass VSS, as given below.

$$\underset{(113)}{C_5H_7NO_2} + \underset{5(32)}{5O_2} \rightarrow 5CO_2 + NH_3 + 2H_2O \tag{7–5}$$

The COD of cell tissue is

$$\frac{\Delta(O_2)}{\Delta(C_5H_7NO_2)} = \frac{5(32\text{ g/mole})}{(113\text{ g/mole})} = 1.42\text{ g }O_2/\text{g cells} = 1.42\text{ g COD/g VSS}$$

Based on the above relationships, the oxygen consumed per unit of COD utilized for the reaction given by Eq. (7–3) can be determined from a mass balance on COD.
The COD removed is oxidized or accounted for in cell growth.

$$\text{COD}_r = \text{COD}_{\text{cells}} + \text{COD}_{ox} \tag{7–6}$$

where COD_r = COD utilized, g COD/d
$\text{COD}_{\text{cells}}$ = COD incorporated into cell synthesis, g COD/d
COD_{ox} = COD oxidized, g COD/d

The COD of oxidized substrate is equal to the oxygen consumed; thus

$$\text{Oxygen consumed} = \text{COD utilized} - \text{COD cells} \tag{7–7}$$

$$\begin{aligned} &= \left(\frac{1.07\text{ g }O_2}{\text{g glucose}}\right)\left(3\text{ mole} \times \frac{180\text{ g glucose}}{\text{mole}}\right) \\ &\quad - \left(\frac{1.42\text{ g }O_2}{\text{g cells}}\right)\left(2\text{ mole} \times \frac{113\text{ g cells}}{\text{mole}}\right) \\ &= 577.8\text{ g }O_2 - 320.9\text{ g }O_2 = 256.9\text{ g }O_2 \end{aligned}$$

Thus, the oxygen consumed per unit of COD used is

$$\begin{aligned} \frac{\text{Oxygen consumed}}{\text{Glucose as COD}} &= \frac{256.9\text{ g }O_2}{3\text{ mole}\,(1.07\text{ g COD/g glucose})(180\text{ g glucose/mole})} \\ &= 0.44\text{ g }O_2/\text{g COD used} \end{aligned}$$

The amount of oxygen required based on the COD balance, as given above, is in agreement with the oxygen use based on the stoichiometry as defined by Eq. (7–3) in which 8 moles of oxygen are required for 3 moles of glucose.

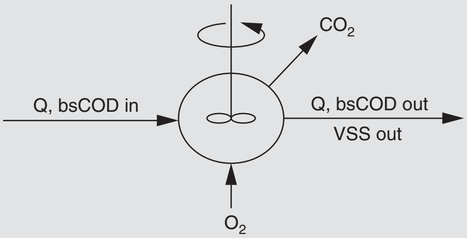
$$\begin{aligned} \frac{\text{Oxygen used}}{\text{Glucose as COD}} &= \frac{8(32\text{ g }O_2/\text{mole})}{3(180\text{ g/mole})(1.07\text{ g COD/g glucose})} \\ &= 0.44\text{ g }O_2/\text{g COD used} \end{aligned}$$

Note that the cell yield as 0.39 g VSS/gCOD used is equal to 0.56 g cells as COD/g COD used, and the sum of the g oxygen used for energy yielding oxidation/g COD used (0.44) plus the g cells as COD/g COD used = 1.0 g COD/g COD used. The COD is accounted for by the oxygen used and by the COD of biomass produced.

The relationship of the observed biomass yield to the oxygen consumed for substrate oxidation by aerobic heterotrophic biomass based on typical measurements made at wastewater-treatment plants is illustrated in Example 7–1.

EXAMPLE 7–1 **Observed Biomass Yield and Oxygen Consumption** An aerobic complete-mix biological treatment process without recycle, as shown below, receives wastewater with a biodegradable soluble COD (bsCOD) concentration of 500 g/m^3. The flowrate is 1000 m^3/d and the reactor effluent bsCOD and VSS concentrations are 10 and 200 g/m^3, respectively. Based on these data, determine the:

1. Observed yield in g VSS/g COD removed?
2. Amount of oxygen used in g O_2/g COD removed and in g/d?



Solution

1. Determine the observed yield. Assume the following general reaction is applicable.

$$\underset{500\ \text{g COD/m}^3}{\text{Organic matter}} + O_2 + \text{nutrients} \rightarrow \underset{200\ \text{g VSS/m}^3}{C_5H_7NO_2} + CO_2 + H_2O$$

   a. The g VSS/d produced is:

$$\text{g VSS/d} = 200\ \text{g/m}^3\ (1000\ \text{m}^3/\text{d}) = 200{,}000\ \text{g VSS/d}$$

   b. The g bsCOD/d removed is:

$$\begin{aligned}\text{g COD/d} &= (500 - 10)\ \text{g COD/m}^3\ (1000\ \text{m}^3/\text{d})\\ &= 490{,}000\ \text{g COD/d}\end{aligned}$$

   c. The observed yield is:

$$Y_{obs} = \frac{(200{,}000\ \text{g VSS/d})}{(490{,}000\ \text{g COD/d})} = 0.41\ \text{g VSS/g COD removed}$$

2. Determine the amount of oxygen used per g bsCOD removed.
   a. Prepare a steady-state COD mass balance around the reactor

$$\text{accumulation} = \text{inflow} - \text{outflow} + \text{conversion}$$

$$0 = \text{COD}_{in} - \text{COD}_{out} - \text{oxygen used (expressed as COD)}$$

$$\text{Oxygen used} = \text{COD}_{in} - \text{COD}_{out}$$

$$\text{COD}_{in} = 500\ \text{g COD/m}^3\ (1000\ \text{m}^3/\text{d}) = 500{,}000\ \text{g COD/d}$$

$$\text{COD}_{out} = \text{bsCOD}_{out} + \text{biomass COD}_{out}$$

$$\text{bsCOD}_{out} = 10\ \text{g/m}^3\ (1000\ \text{m}^3/\text{d}) = 10{,}000\ \text{g COD/d}$$

$$\text{Biomass COD}_{\text{out}} = 200{,}000\ \text{g VSS/d}\,(1.42\ \text{g COD/g VSS})$$
$$= 284{,}000\ \text{g COD/d}$$

$$\text{Total COD}_{\text{out}} = 10{,}000\ \text{g/d} + 284{,}000\ \text{g/d} = 294{,}000\ \text{g COD/d}$$

b. The oxygen used is

$$\text{Oxygen used} = 500{,}000\ \text{g COD/d} - 294{,}000\ \text{g COD/d}$$
$$= 206{,}000\ \text{g COD/d} = 206{,}000\ \text{g O}_2\text{/d}$$

c. Amount of oxygen used per unit COD removed is

$$\text{Oxygen/COD} = (206{,}000\ \text{g/d})/(490{,}000\ \text{g/d}) = 0.42\ \text{g O}_2\text{/g COD}$$

Comment The general COD balance that accounts for the cell yield fraction of COD oxidized is

$$\text{g COD cells} + \text{g COD oxidized} = \text{g COD removed}$$

$$(0.41\ \text{g VSS/g COD})(1.42\ \text{g O}_2\text{/g VSS}) + 0.42\ \text{g O}_2\text{/g COD} = 1.0\ \text{g O}_2\text{/g COD}$$

Estimating Biomass Yield from Bioenergetics

Most cell yield values are based on measurements from laboratory reactors, pilot plants, or full-scale systems. However, an approach that has been developed to estimate cell yield, based on bioenergetics, involves the application of thermodynamic principles to biological reactions. An introduction to bioenergetics and the application of bioenergetics to estimate the biomass yield for different types of biological reactions is provided in this section (McCarty 1971, 1975).

Gibbs Free Energy. Chemical reactions, which involve changes in energy, can be described thermodynamically by a change in the free energy G°, known as the *Gibbs free energy*. The change in energy due to the reaction is termed ΔG°. The superscript is used to indicate that the free energy values were obtained at standard conditions of $\text{pH} = 7.0$ and 25°C. The net Gibbs free energy, positive or negative, can be evaluated for reactants and products based on standard free energy values available for the half reactions. Half reactions describe the transfer of 1 mole of electron in oxidation-reduction and synthesis reactions. Free energy changes for various half reactions are listed in Table 7–6. Reactions that result in a negative change in the free energy are those that release energy and are called *exergonic* reactions. These reactions will proceed spontaneously in the direction shown. However, if the free energy change results in a positive value, the reaction is termed *endergonic*, and such a reaction will not occur spontaneously. Reactions with positive free energy values require energy to proceed in the direction indicated.

The basis of the analysis of free energy changes for reactions is that in oxidation-reduction reactions one compound loses electrons (electron donor) and the other compound gains electrons (electron acceptor) (see discussion in Sec. 6–6 in Chap. 6). The moles of compound used as an electron acceptor and electron donor per mole of electron (e^-) transferred from the half reactions along with the change in free energy are used to develop energy balances in bioenergetic analyses. Determination of the free energy change resulting from the oxidation of hydrogen by oxygen is illustrated in Example 7–2.

Table 7–6

Half-reactions for biological systems[a]

Reaction number		Half-reaction	ΔG^o (W),[b] kJ per electron equivalent
Reactions for bacterial cell synthesis (R_s)			
	Ammonia as nitrogen source:		
1.	$\frac{1}{5}CO_2 + \frac{1}{20}HCO_3^- + \frac{1}{20}NH_4^+ + H^+ + e^-$	$= \frac{1}{20}C_5H_7O_2N + \frac{9}{20}H_2O$	
	Nitrate as nitrogen source:		
2.	$\frac{1}{28}NO_3^- + \frac{5}{28}CO_2 + \frac{29}{28}H^+ + e^-$	$= \frac{1}{28}C_5H_7O_2N + \frac{11}{28}H_2O$	
Reactions for electron acceptors (R_a)			
	Nitrite:		
3.	$\frac{1}{3}NO_2^{2-} + \frac{4}{3}H^+ + e^-$	$= \frac{1}{6}N_2 + \frac{2}{3}H_2O$	−93.23
	Oxygen:		
4.	$\frac{1}{4}O_2 + H^+ + e^-$	$= \frac{1}{2}H_2O$	−78.14
	Nitrate:		
5.	$\frac{1}{5}NO_3^- + \frac{6}{5}H^+ + e^-$	$= \frac{1}{10}N_2 + \frac{3}{5}H_2O$	−71.67
	Sulfite:		
6.	$\frac{1}{6}SO_3^{2-} + \frac{5}{4}H^+ + e^-$	$= \frac{1}{12}H_2S + \frac{1}{12}HS^- + \frac{1}{2}H_2O$	13.60
	Sulfate:		
7.	$\frac{1}{8}SO_4^{2-} + \frac{19}{16}H^+ + e^-$	$= \frac{1}{16}H_2S + \frac{1}{16}HS^- + \frac{1}{2}H_2O$	21.27
8.	$\frac{1}{8}CO_2 + H^+ + e^-$	$= \frac{1}{8}CH_4 + \frac{1}{4}H_2O$	24.11
Reactions for electron donors (R_d)			
	Organic donors (heterotrophic reactions)		
	Domestic wastewater:		
9.	$\frac{9}{50}CO_2 + \frac{1}{50}NH_4^+ + \frac{1}{50}HCO_3^- + H^+ + e^-$	$= \frac{1}{50}C_{10}H_{19}O_3N + \frac{9}{25}H_2O$	31.80
	Protein (amino acids, proteins, nitrogenous organics)		
10.	$\frac{8}{33}CO_2 + \frac{2}{33}NH_4^+ + \frac{31}{33}H^+ + e^-$	$= \frac{1}{66}C_{16}H_{24}O_5N_4 + \frac{27}{66}H_2O$	32.22
	Formate		
11.	$\frac{1}{2}HCO_3^- + H^+ + e^-$	$= \frac{1}{2}HCOO^- + \frac{1}{2}H_2O$	48.07
	Glucose		
12.	$\frac{1}{4}CO_2 + H^+ + e^-$	$= \frac{1}{24}C_6H_{12}O_6 + \frac{1}{4}H_2O$	41.96
	Carbohydrate (cellulose, starch, sugars):		
13.	$\frac{1}{4}CO_2 + H^+ + e^-$	$= \frac{1}{4}CH_2O + \frac{1}{4}H_2O$	41.84

(*Continued*)

Table 7–6 (*Continued*)

Reaction number	Half-reaction	ΔG° (W),[b] kJ per electron equivalent
	Methanol:	
14.	$\frac{1}{6}CO_2 + H^+ + e^- = \frac{1}{6}CH_3OH + \frac{1}{6}H_2O$	37.51
	Pyruvate	
15.	$\frac{1}{5}CO_2 + \frac{1}{10}HCO_3 + H^+ + e^- = \frac{1}{10}CH_3COCOO^- + \frac{2}{5}H_2O$	35.78
	Ethanol:	
16.	$\frac{1}{6}CO_2 + H^+ + e^- = \frac{1}{12}CH_3CH_2OH + \frac{1}{4}H_2O$	31.79
	Propionate:	
17.	$\frac{1}{7}CO_2 + \frac{1}{14}HCO_3^- + H^+ + e^- = \frac{1}{14}CH_3CH_2COO^- + \frac{5}{14}H_2O$	27.91
	Acetate:	
18.	$\frac{1}{8}CO_2 + \frac{1}{8}HCO_3 + H^+ + e^- = \frac{1}{8}CH_3COO^- + \frac{3}{8}H_2O$	27.68
	Grease (fats and oils):	
19.	$\frac{4}{23}CO_2 + H^+ + e^- = \frac{1}{46}C_8H_{16}O + \frac{15}{46}H_2O$	27.61
	Inorganic donors (autotrophic reactions):	
20.	$Fe^{3+} + e^- = Fe^{2+}$	−74.40
21.	$\frac{1}{2}NO_3^- + H^+ + e^- = \frac{1}{2}NO_2^- + \frac{1}{2}H_2O$	−40.15
22.	$\frac{1}{8}NO_3^- + \frac{5}{4}H^+ + e^- = \frac{1}{8}NH_4^+ + \frac{3}{8}H_2O$	−34.50
23.	$\frac{1}{6}NO_2^- + \frac{4}{3}H^+ + e^- = \frac{1}{6}NH_4^+ + \frac{1}{3}H_2O$	−32.62
24.	$\frac{1}{6}SO_4^{2-} + \frac{4}{3}H^+ + e^- = \frac{1}{6}S + \frac{2}{3}H_2O$	19.48
25.	$\frac{1}{8}SO_4^{2-} + \frac{19}{16}H^+ + e^- = \frac{1}{16}H_2S + \frac{1}{16}HS^- + \frac{1}{2}H_2O$	21.28
26.	$\frac{1}{4}SO_4^{2-} + \frac{5}{4}H^+ + e^- = \frac{1}{8}S_2O_3^{2-} + \frac{5}{8}H_2O$	21.30
27.	$\frac{1}{6}N_2 + \frac{4}{3}H^+ + e^- = \frac{1}{3}NH_4^+$	27.47
28.	$H^+ + e^- = \frac{1}{2}H_2$	40.46
29.	$\frac{1}{2}SO_4^{2-} + H^+ + e^- = SO_3^{2-} + H_2O$	44.33

EXAMPLE 7–2 Free Energy Change from Hydrogen Oxidation by Molecular Oxygen

Determine the free energy change resulting from the oxidation of hydrogen by molecular oxygen.

Solution

1. Identify the electron donor and acceptor.
   Electron donor: hydrogen
   Electron acceptor: oxygen

2. Determine the change in free energy. From Table 7–6, the free energy change values for the half reactions are

		G^o, kJ/mole e^-
Reaction No. 28	$\frac{1}{2}H_2 \rightarrow H^+ + e^-$	-40.46
Reaction No. 4	$\frac{1}{4}O_2 + H^+ + e^- \rightarrow \frac{1}{2}H_2O$	-78.14
Overall	$\frac{1}{2}H_2 + \frac{1}{4}O_2 \rightarrow \frac{1}{2}H_2O$	$\Delta G = -118.60$

Because the ΔG value is negative for this oxidation-reduction reaction, energy is released, and the overall reaction will proceed as written.

Exergonic Reactions. Exergonic reactions are catalyzed by enzymes within the microbial cell, making energy available to support cell growth. Only a portion (40 to 80 percent) of the energy produced is captured by the bacteria, while the rest escapes as heat. McCarty (1971) assumed 60 percent energy capture efficiency, but the exact amount varies. The energy that is not captured or released can result in an elevated temperature in the surrounding liquid, where high biomass concentrations exist and high reaction rates are occurring. An example is autothermal aerobic digestion in which liquid temperatures are increased from 20°C to as high as 60°C due to biological oxidation and energy release. The volatile solids concentration in autothermal aerobic digesters may be in the range of 20 to 40 g/L.

Bioenergetic Methods of Analysis. The key steps in bioenergetics analysis are to (1) identify the electron donor (substrate oxidized) and electron acceptor, (2) determine the energy produced from the bacteria oxidation-reduction reaction, (3) determine the amount of energy needed for converting the growth carbon source into cell matter, and (4) calculate the cell yield based on a balance between energy produced and energy needed for cell yield. The energy production step was illustrated above for oxidation of hydrogen with oxygen as the electron acceptor.

The amount of energy required for cell synthesis depends on the specific carbon and nitrogen compounds used for growth. The bioenergetics analysis discussed here is for heterotrophic bacteria. A different procedure is used for the case of autotrophic bacteria, and additional details can be found in McCarty (1971, 1975) and Rittman and McCarty (2001). For heterotrophic bacteria, many carbon sources may be used for growth with different energetic effects. In the analysis it is assumed that pyruvate is the intermediate organic compound used for cell synthesis, and energy will be either produced or consumed depending on the free energy of the organic compound relative to pyruvate. Pyruvate was selected by McCarty (1971) because it is at the end of the glycolysis pathway and just ahead of the Krebs cycle. When CO_2 is used for the carbon source, as for autotrophic bacteria, a considerable amount of energy is needed to incorporate CO_2 into cell mass. If nitrogen is not available in the form of ammonia, additional energy is needed to convert the nitrogen source to ammonia.

The energy required for cell synthesis is estimated as follows, with pyruvate as the organic intermediate for cellular carbon constituents:

$$\Delta G_s = \frac{\Delta G_P}{K^m} + \Delta G_c + \frac{\Delta G_N}{K} \tag{7–8}$$

where ΔG_s = free energy to convert 1 electron equivalent (e^- eq) of the carbon source to cell material

ΔG_P = free energy to convert 1 e^- eq of the carbon source to the pyruvate intermediate

K = fraction of energy transfer captured

m = $+1$ if ΔG_P is positive and -1 if energy is produced

ΔG_c = free energy to convert 1 e^- eq of pyruvate intermediate to 1 e^- eq of cells

ΔG_N = free energy per e^- eq of cells to reduce nitrogen to ammonia

The value for ΔG_c is $+31.41$ kJ/e^- eq of cells (McCarty, 1971) and the ΔG_N for the following nitrogen sources are $+17.46$, $+13.61$, $+15.85$, and 0.00 kJ/e^- eq of cells for NO_3^-, NO_2^-, N_2, and NH_4^+, respectively. The value for ΔG_P is estimated by using the free energy half reactions to convert the carbon source to the pyruvate intermediate.

The electron donor used for heterotrophic reactions is divided between portions oxidized to produce energy or used in cell synthesis. The energy balance relative to the substrate used is illustrated in the following equation in which the energy made available (on the left side of the equation) equals the energy used for cell growth (right side of the equation).

$$K\Delta G_R\left(\frac{f_e}{f_s}\right) = -\Delta G_S \tag{7–9}$$

$$f_e + f_s = 1 \tag{7–10}$$

where K = fraction of energy captured

ΔG_R = energy released from oxidation-reduction reactions, kJ/mole e^- transferred

f_e = e^- mole of substrate oxidized per e^- mole of substrate used

f_s = e^- mole of substrate used for cell synthesis per e^- mole of substrate used

ΔG_S = energy used for cell growth, kJ/mole e^- transfer for cell growth

Equations (7–9) and (7–10) are used with half reactions and their free energy values to estimate cell yield by solving for f_e and f_s. The terms f_e and f_s represent the fraction of substrate oxidized or used in cell synthesis, respectively. The substrate is expressed as COD because a mole of COD contains a set quantity of electron moles of oxygen transfer. Thus, the values for f_e and f_s can also be expressed as COD fractions. The oxidation of acetate by heterotrophic bacteria with different acceptors is used in Example 7–3 to illustrate the bioenergetics analysis.

EXAMPLE 7–3 Estimate Biomass Yield Using Energetics

Compare the cell yield in g cells as COD/g COD used and g cells as VSS/g COD used for acetate utilization by heterotrophic bacteria with oxygen and then carbon dioxide as the electron acceptor, and ammonia as the nitrogen source. Assume 60 percent energy capture efficiency.

Solution

Part A—Oxygen as the electron acceptor

1. Solve for the energy produced and captured ($K\Delta G_R$) using reaction No. 18 for acetate oxidation and reaction No. 4 for oxygen reduction from Table 7–6.

		kJ/mole e^-
No. 18	$\frac{1}{8}CH_3COO^- + \frac{3}{8}H_2O \rightarrow \frac{1}{8}CO_2 + \frac{1}{8}HCO_3^- + H^+ + e^-$	−27.68
No. 4	$\frac{1}{4}O_2 + H^+ + e^- \rightarrow H_2O$	−78.14
	$\frac{1}{8}CH_3COO^- + \frac{3}{8}H_2O \rightarrow \frac{1}{8}CO_2 + \frac{1}{8}HCO_3^- + \frac{1}{8}H_2O$	$\Delta G = -105.82$

Energy captured by cell:

$K(\Delta G_R) = 0.60(-105.82) = -63.42$ kJ/mole e^-

2. Solve for the energy needed per electron mole of cell growth (ΔG_S).

$\Delta G_C = 31.41$ kJ/mole e^- cells

$\Delta G_N = 0$

ΔG_P [acetate (reaction No. 18) to pyruvate (reaction No. 15)]

		ΔG kJ/mole e^-
No. 18	$\frac{1}{8}CH_3COO^- + \frac{3}{8}H_2O \rightarrow \frac{1}{8}CO_2 + \frac{1}{8}HCO_3^- + H^+ + e^-$	−27.68
No. 15	$\frac{1}{5}CO_2 + \frac{1}{10}HCO_3^- + H^+ + e^- \rightarrow \frac{1}{10}CH_3COCOO^- + \frac{2}{5}H_2O$	+35.78
	$\frac{1}{8}CH_3COO^- + \frac{3}{40}CO_2 \rightarrow \frac{1}{10}CH_3COCOO^- + \frac{1}{40}HCO_3^- + \frac{1}{40}H_2O$	$\Delta G_p = +8.10$

Because ΔG_P is positive, energy is required and m = +1

$$\Delta G_S = \left[\frac{+8.10}{(0.6)^{1.0}} + 31.41 + 0\right] = 44.91 \text{ kJ/mole e}^-$$

3. Determine f_e and f_s using Eq. (7–9).

$$\frac{f_e}{f_s} = \frac{-\Delta G_S}{K\Delta G_R} = \frac{(-44.91 \text{ kJ/mole e}^-)}{(-63.42 \text{ kJ/mole e}^-)}$$

$$\frac{f_e}{f_s} = 0.708$$

$$f_e + f_s = 1.0$$

Solve for f_e and f_s:

$$f_e = 0.41$$

$$f_s = 0.59 \frac{\text{g cell COD}}{\text{g COD used}}$$

4. Determine the yield based on COD.

For biomass ($C_5H_7NO_2$), 1 g cells = 1.42 g COD

Thus, the yield is

$$Y = \frac{(0.59 \text{ g COD/g COD})}{(1.42 \text{ g COD/g VSS})} = 0.42 \text{ g VSS/g COD}$$

5. Determine the yield based on BOD assuming a conversion factor of 1.6 g COD/g BOD (see discussion in Sec. 8–2 in Chap. 8).

Thus, the yield is

$$Y = \frac{(0.42 \text{ g VSS/g COD})}{(\text{g BOD}/1.6 \text{ g COD})} = 0.67 \text{ g VSS/g BOD}$$

Solution Part B—Carbon dioxide as the electron acceptor

1. Solve for energy produced and captured ($K\Delta G_R$) using reaction No. 18 for acetate oxidation and reaction No. 8 for CO_2 reduction to methane from Table 7–6.

		kJ/mole e^-
No. 18	$\frac{1}{8}CH_3COO^- + \frac{3}{8}H_2O \rightarrow \frac{1}{8}CO_2 + \frac{1}{8}HCO_3^- + H^+ + e^-$	-27.68
No. 8	$\frac{1}{8}CO_2 + H^+ + e^- \rightarrow \frac{1}{8}CH_4 + \frac{1}{4}HCO_3^-$	$+24.11$
	$\frac{1}{8}CH3COO^- + \frac{1}{8}H_2O \rightarrow \frac{1}{8}CH_4 + \frac{1}{8}HCO_3^-$	$\Delta G = -3.57$

Energy captured by cell:

$(K\Delta G_R) = 0.60(-3.57) = -2.142$ kJ/mole e^-

2. Solve for the energy needed per electron mole at cell growth ΔG_S.

$\Delta G_C = 31.41$ kJ/mole e^- cells

$\Delta G_N = 0$

ΔG_P (same as for acetate/O_2)

$\Delta G_S = 44.94$ kJ/mole e^-

3. Determine the values of fe and fs using Eq. (7–9).

$$\frac{f_e}{f_s} = \frac{-\Delta G_S}{K\Delta G_R} = \frac{-44.94}{-2.142} = 21.0$$

$f_e + f_s = 1.0$

Solve for f_e and f_s.

$f_e = 0.954 \qquad f_s = 0.046$ g cell COD/g COD used

4. Determine the yield based on COD.

$$Y = \frac{(0.046 \text{ g cell COD/g COD used})}{(1.42 \text{ g COD/g VSS})} = 0.032 \text{ g VSS/g COD}$$

5. Compare yields for acetate oxidation.

Electron acceptor	Yield, g VSS/g COD	Product
O_2	0.42	CO_2, H_2O
CO_2	0.032	CH_4

Comment Based on bioenergetics calculations, estimated yield values for anaerobic reactions using carbon dioxide as the electron acceptor are much lower as compared to oxygen. The lower yield values are due to the much lower energy production with carbon dioxide as the electron acceptor in lieu of oxygen. The cell synthesis yield values calculated for these electron acceptors are very similar to yield values reported in the literature.

Stoichiometry of Biological Reactions

With the values determined for f_e and f_s, the stoichiometry of the biological reactions can be described according to the following relationship (McCarty, 1971, 1975):

$$R = f_e R_a + f_s R_{CS} - R_d \tag{7–11}$$

where R = overall balanced reaction
f_e = fraction of electron donor used for energy
R_a = half reaction for electron acceptor
f_s = fraction of electron donor used for cell synthesis
R_{cs} = half reaction for synthesis of cell tissue
R_d = half reaction for electron donor
$f_s + f_e = 1$

The minus sign in Eq. (7–11) means that the electron donor equation given in Table 7–6 must be reversed and then added to the other two equations. In the first equation given in Table 7–6, the term $C_5H_7O_2N$ (Hoover and Porges, 1952), is used to represent bacterial cell tissue. Application of Eq. (7–11) is illustrated in Example 7–4.

EXAMPLE 7–4 **Write a Balanced Reaction for the Biological Oxidation of Acetate Using Oxygen** Using Eq. (7–11) and the half reactions given in Table 7–6, write a balanced reaction for the biological oxidation of acetate with oxygen. Use the values for f_e and f_s determined in Example 7–3, Part A ($f_e = 0.41$ and $f_s = 0.59$). The COD of acetate is 1.07 g COD/g acetate, computed as illustrated in Eq. (7–4).

Solution

1. Develop the balanced stoichiometric reaction for the oxidation of acetate.

$$R = f_e R_a + f_s R_{CS} - R_d$$

$$R = 0.41(\text{No. } 4) + 0.59(\text{No. } 1) - \text{No. } 18$$

$$(0.41)(\text{No. } 4) = 0.103O_2 + 0.41H^+ + 0.4e^- + 0.205H_2O$$

$$(0.59)(\text{No. } 1) = 0.118CO_2 + 0.0295HCO_3^- + 0.0295NH_4^+ + 0.59H^+ + 0.59e^-$$
$$\rightarrow 0.0295C_5H_7O_2N + 0.2655H_2O$$

$$-\text{No. } 18 = \quad 0.125CH_3COO^- + 0.375H_2O \rightarrow 0.125CO_2 + 0.125HCO_3^- + H^+ + e^-$$

$$R = \quad 0.125CH_3COO^- + 0.0295NH_4^+ + 0.103O_2$$
$$\rightarrow 0.0295C_5H_7O_2N + 0.0955H_2O + 0.095HCO_3^- + 0.007CO_2$$

2. Determine the cell yield from the stoichiometry.
   a. Cells produced from oxidation of acetate

      Cells produced = 0.0295 mole (113 g VSS/mole) = 3.334 g VSS

   b. Acetate utilized for cell production

      Acetate used = 0.125 mole acetate (60 g/mole)(1.07 g COD/g acetate)
      = 8.03 g COD

c. Determine the cell yield

$$Y = \frac{3.334 \text{ g VSS}}{8.03 \text{ g COD}} = 0.42 \text{ g VSS/g COD}$$

The results are the same as in Example 7–3.

If nitrate (NO_3^-) is used for the electron acceptor instead of oxygen for acetate degradation, denitrification occurs with the NO_3^- reduced to nitrogen gas (N_2). The energetics calculation using the same procedure as above results in an f_s value of 0.57, only slightly less than that for oxygen as the electron acceptor (Rittman and McCarty, 2001). This f_s value leads to a biomass yield coefficient determination very close to that with oxygen (0.41 versus 0.42 g VSS/g COD). However, Muller et al. (2004) showed that the heterotrophic bacteria yield coefficient under anoxic conditions is much lower, approximately 80 percent of the aerobic yield. A similar ratio is recommended in the IWA ASM3 model (Gujer et al., 1999). In denitrification studies with pure cultures of *Paracoccus denitrificans* and *Pseudomonas stutzeri*, Strohm et al. (2007) found that much less energy is converted via ATP into cell mass than expected from energetic calculations. For acetate degradation with NO_3^- as the electron acceptor a cell yield of 0.28 to 0.32 g VSS/g COD was observed, which is 67 to 78 percent of that predicted by the above energetic calculation. Henze et al. (2008) applied a lower biomass yield by about 70 percent for NO_3^- reduction versus aerobic degradation in considering carbon addition for nitrate removal.

Biomass Synthesis Yields for Different Growth Conditions

In Example 7–3, it was demonstrated that the biomass synthesis yield is related to the energy produced by the electron transfer from the electron donor (acetate) to the electron acceptor (oxygen). From a review of the half reaction ΔG° values in Table 7–6, it can be seen that the energy production that occurs from the oxidation-reduction reactions is reduced as the electron acceptor is changed from oxygen to nitrate to sulfate and to carbon dioxide. Accordingly, a lower cell yield would be predicted using the half reactions given in Table 7–6. A range of typical synthesis yield coefficients are given in Table 7–7 for common electron donors and acceptors in wastewater treatment.

Biomass Decay

As shown for the batch process in Fig. 7–10, after the substrate is depleted and with continual aeration, the biomass concentration decreases. Terms used to define this biomass

Table 7–7

Typical bacteria synthesis yield coefficients for common biological reactions in wastewater treatment

Growth Condition	Electron Donor	Electron acceptor	Synthesis yield
Aerobic	Organic compound	Oxygen	0.45 g VSS/g COD
Aerobic	Ammonia	Oxygen	0.12 g VSS/g NH_4-N
Anoxic	Organic compound	Nitrate	0.30 g VSS/g COD
Anaerobic	Organic compound	Organic compound	0.06 g VSS/g COD
Anaerobic	Acetate	Carbon dioxide	0.05 g VSS/g COD

decrease are *decay*, *endogenous decay*, or *endogenous respiration*. A number of factors contribute to the biomass loss, including cell maintenance energy needs, cell lysis due to death or stress from environmental factors, and predation (Hao et al., 2010). Examples of maintenance energy needs are energy for resynthesis of essential cell components and for controlling osmotic pressure. Energy may come from oxidation of cellular organic material or substrates from the bulk liquid. If substrate is not available, the cell mass may decrease and cellular activity can approach a resting state. Cell death and lysis can be due to virus, environmental stress (pH, temperature and toxins), or to program cell death related to cell age (Rice and Bayle 2008).

Cell lysis results in the release of cellular substrates, which are mainly biodegradable proteins and polysaccharides. In addition, cell debris, which remains after cell lysis, has generally been assumed as inert volatile solids that accumulate in the bioreactor, but more recently cell debris has been found to have a very slow biodegradation rate (Ramdani et al., 2012). Protozoan and rotifers consume bacteria that are not well captured in activated sludge floc. Predation losses by protozoan and rotifers are greater for systems with free bacteria or more dispersed growth conditions. The parameter, specific endogenous decay, is commonly used to account for all of these biomass loss mechanisms, which may be occurring to a varying degree, depending on cell age and operating conditions. The specific endogenous decay coefficient is used to describe a specific rate of biomass loss, which can be in the range from 0.08 to 0.20 g biomass loss/g biomass present.

Observed versus Synthesis Yield

In the evaluation and modeling of biological treatment systems a distinction is made between the observed yield and the synthesis yield (or true yield). The observed biomass yield is based on the actual measurements of the net biomass production and substrate consumption and is actually less than the synthesis yield, because of cell loss by biomass decay (Sec. 7–6) concurrent with cell growth. In full-scale wastewater treatment processes the term solids production (or solids yield) is also used to describe the amount of VSS generated in the treatment process. The term is different from the synthesis biomass yield values because it contains other organic solids from the wastewater that are measured as VSS and have not been biologically degraded.

The synthesis yield is the amount of biomass produced immediately upon consumption of the growth substrate or oxidation of the electron donor in the case of autotrophic bacteria. The synthesis yield is seldom measured directly and is often interpreted from evaluating biomass production data for reactors operating under different conditions. Synthesis yield values for bacterial growth are affected by the energy that can be derived from the oxidation-reduction reaction, by the growth characteristics of the carbon source, by the nitrogen source, and by environmental factors such as temperature, pH, and osmotic pressure. As illustrated in this section, the synthesis yield can be estimated if the stoichiometry or the amount of energy produced in the oxidation-reduction reaction is known.

7–5 MICROBIAL GROWTH KINETICS

The performance of biological processes used for wastewater treatment depends on the dynamics of substrate utilization and microbial growth. Effective design and operation of such systems requires an understanding of the biological reactions occurring and an understanding of the basic principles governing the growth of microorganisms. Further, the need to understand all of the environmental conditions that affect the substrate utilization and microbial growth rate cannot be overemphasized, and it may be necessary to control such conditions as pH, dissolved oxygen (DO), and nutrients to provide effective treatment.

The purpose of this section is to present an introduction to microbial growth kinetics. The topics considered in this section include (1) microbial growth kinetics terminology, (2) rate of utilization of soluble substrate, (3) other rate expressions for the utilization of soluble substrate, (4) rate of soluble substrate production from biodegradable particulate organic matter, (5) the rate of biomass growth with soluble substrates, (6) kinetic coefficients for substrate utilization and biomass growth, (7) oxygen utilization rates, (8) effects of temperature, (9) total volatile suspended solids and active biomass, (10) rate of biomass decay and soluble substrate production, and (11) net biomass growth and observed yield.

Microbial Growth Kinetics Terminology

The kinetics of microbial growth govern the oxidation (i.e., utilization) of substrate and the production of biomass, which contributes to the total suspended solids concentration in a biological reactor. Common terms used to describe the transformations that occur in substrate oxidation and biomass growth as well as in biological treatment processes are defined in the Working Terminology. Because municipal and industrial wastewaters contain numerous substrates, the concentration of organic compounds is defined, most commonly, by the *biodegradable COD* (bCOD) or UBOD, both of which are comprised of soluble (dissolved), colloidal, and particulate biodegradable components. Both bCOD and UBOD represent measurable quantities that apply to all of the compounds. In the formulation of kinetic expressions in this chapter *biodegradable soluble COD* (bsCOD) will be used to quantify the fate of biodegradable organic compounds because it is related to the stoichiometry of substrate oxidized or used in cell growth [see Eq. (7–7)]. Some of the biodegradable COD in wastewater is in particulate or colloidal form, which must be hydrolyzed to bsCOD first before biological consumption. Kinetic expressions are also used to describe the rate of bsCOD production from particulate and colloidal material.

The biomass solids in a laboratory bioreactor fed only bsCOD are commonly measured as *total suspended solids* (TSS) and *volatile suspended solids* (VSS). These measurements are not equal to the active biomass, as the solids will contain cell debris material from bacteria decay.

In activated sludge systems used to treat municipal and industrial wastewater, the mixture of solids resulting from combining recycled sludge with influent wastewater in the bioreactor is termed *mixed liquor suspended solids* (MLSS) and *mixed liquor volatile suspended solids* (MLVSS). The solids are comprised of biomass, *nonbiodegradable volatile suspended solids* (nbVSS), and *inert inorganic total suspended solids* (iTSS). The nbVSS is derived from the influent wastewater and is also produced as cell debris from bacteria decay. The iTSS originates in the influent wastewater. Additional wastewater characterization terminology is considered in Sec. 8–2 in Chap. 8.

Rate of Utilization of Soluble Substrates

In the introduction to this chapter, it was noted that one of the principal concerns in wastewater treatment is the removal of substrate. Stated another way, the goal in biological wastewater treatment is, in most cases, to reduce the electron donor (i.e., organic compounds in aerobic oxidation) to minimal levels. For heterotrophic bacteria the electron donors are the organic substances being degraded; for autotrophic nitrifying bacteria it is ammonia or nitrite or other reduced inorganic compounds. The substrate utilization rate for soluble substrates in biological systems can be modeled with Eq. (7–12), in which the rate of substrate utilization increases as the reactor substrate concentration increases for a given biomass concentration.

$$r_{su} = \frac{kXS}{K_s + S} \tag{7–12}$$

where r_{su} = substrate utilization rate per unit of reactor volume, g/m^3·d
k = maximum specific substrate utilization rate, g substrate/g microorganisms·d
X = biomass (microorganism) concentration, g/m^3
S = growth-limiting substrate concentration in solution, g/m^3
K_s = half-velocity constant, substrate concentration at one-half the maximum specific substrate utilization rate, g/m^3

Equation (7–12) will be recognized as a saturation-type equation, as described previously in Chap. 1. Though Eq. (7–12) is an empirical model, based on using coefficients derived from biological reactor data, it is often referred to as the Michaelis-Menten equation (Bailey and Ollis, 1986), which was formulated from an enzymatic-substate model. A plot of r_{su} versus the substrate concentration is shown on Fig. 7–11. As shown on Fig. 7–11, the maximum substrate utilization rate occurs at high substrate concentrations. Further, as the substrate concentration decreases below some critical value, the value of r_{su} also decreases almost linearly. In practice, biological treatment systems are designed to produce an effluent with extremely low substrate concentrations.

Equation (7–12) is also of the form proposed by Monod for the specific growth rate of bacteria in which the limiting substrate is available to the microorganisms in a dissolved form (Monod, 1942, 1949).

$$r_g = \frac{\mu_m XS}{(K_s + S)} \tag{7–13}$$

where r_g = bacteria growth rate from substrate utilization, g/m^3·d
μ_m = maximum specific bacteria growth rate, g biomass/g biomass·d

As bacteria consume the substrate (electron donor), the energy produced from the substrate oxidation is used to process carbon and nutrients to produce new biomass. The new growth is directly proportional to the substrate used and is termed the true yield or synthesis yield coefficient as g biomass produced/g substrate used. The bacteria growth rate can thus be equated to the substrate utilization rate as follows:

$$r_g = Yr_{su} \tag{7–14}$$

and $$r_{su} = \frac{\mu_m XS}{Y(K_s + S)} \tag{7–15}$$

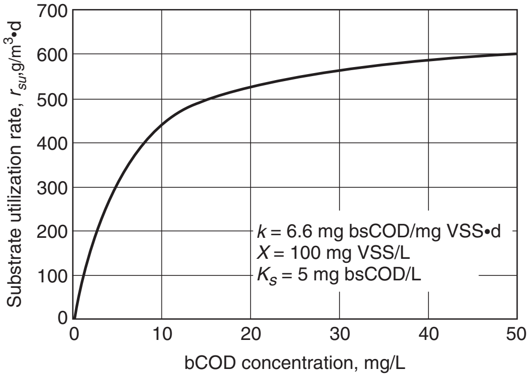
where Y = synthesis yield coefficient, g biomass/g substrate used

When the substrate is being used at its maximum rate, the bacteria are also growing at their maximum rate. The maximum specific growth rate of the bacteria is thus related to the maximum specific substrate utilization rate as follows.

$$\mu_m = kY \tag{7–16}$$

Figure 7–11

Rate of change of substrate utilization versus biodegradable soluble COD concentration based on the saturation-type model [see Eq. (7–12)].



Other Rate Expressions for Soluble Substrate Utilization

In reviewing kinetic expressions used to describe substrate utilization and biomass growth rates, it is important to remember that the expressions used to model biological processes are all empirical, based on coefficient values determined experimentally. Besides the substrate limited relationship presented above, other expressions that have been used to describe soluble substrate utilization rates include the following:

$$r_{su} = kS \tag{7–17}$$

$$r_{su} = kXS \tag{7–18}$$

$$r_{su} = kX\frac{S}{S_o} \tag{7–19}$$

The particular rate expression used to define kinetics of substrate utilization depends mainly on the experimental data available to fit the kinetic equations and the application of the kinetic model. In many cases, the pseudo first-order model as given by Eq. (7–18) is satisfactory for describing substrate utilization rates when the biological treatment process is operated at relatively low substrate concentrations. Fundamental in the use of any rate expression is its application in a mass-balance analysis as discussed in the following section. Also, with regard to modeling biological treatment processes, kinetic models should not be applied outside of the range of the conditions used to develop model coefficients.

Rate of Soluble Substrate Production from Biodegradable Particulate Organic Matter

The rate expressions for substrate utilization and biomass growth presented thus far are based on the utilization of soluble substrates. In municipal wastewater treatment only about 20 to 50 percent of the degradable organic material enters as soluble compounds, and for some industrial wastewaters the soluble organic material may be a low to moderate fraction of the total degradable organic substrates. Bacteria cannot consume the particulate substrates directly and must employ extracellular enzymes to hydrolyze the particulate organics to soluble substrates. The particulate substrate conversion rate is also a rate-limiting process that is dependent on the particulate substrate and biomass concentrations. A rate expression for particulate substrate conversion is shown as follows (Gujer et al., 1999):

$$r_{X_s} = -\frac{k_h(X_S/X_H)X_H}{(K_X + X_S/X_H)} \tag{7–20}$$

where r_{X_s} = rate of hydrolysis of particulate substrate to conversion to soluble substrate, g/m^3·d
k_h = maximum specific hydrolysis rate, g X_S/g X_H·d
X_S = particulate substrate concentration, g/m^3
X_H = heterotrophic biomass concentration, g/m^3
K_X = half-velocity hydrolysis coefficient, g/g

The particulate degradation concentration is expressed relative to the biomass concentration, because the particulate hydrolysis is related to the relative contact area between the nonsoluble organic material and the biomass. The effect of particulate organic constituents is considered further in Chap. 8.

Net Biomass Growth Rate

The net biomass growth rate is the biomass growth rate less the endogenous respiration rate. In Sec. 7–4, the biomass growth rate was shown to be proportional to the substrate utilization rate by the synthesis yield coefficient, and biomass decay was shown to be proportional to the biomass present. Thus, the following relationship between the net biomass growth rate and the substrate utilization rate is applicable in both batch and continuous culture systems.

$$r_X = Yr_{su} - bX \tag{7–21}$$

$$r_X = Y\frac{kXS}{K_s + S} - bX \tag{7–22}$$

where r_X = net biomass growth rate per unit reactor volume, g VSS/m^3·d
b = specific endogenous decay coefficient, g VSS/g VSS·d
Other terms are as defined above.

If both sides of Eq. (7–22) are divided by the biomass concentration *X*, the net specific growth rate is defined as follows:

$$\mu_{net} = \frac{r_X}{X} = Y\frac{kS}{K_s + S} - b \tag{7–23}$$

where μ_{net} = net specific biomass growth rate, g VSS/g VSS·d

As shown, the net specific growth rate corresponds to the change in biomass per day relative to the amount of biomass present and is a function of the reactor substrate concentration and the specific endogenous decay coefficient.

As noted in Sec. 7–4, the specific endogenous decay coefficient accounts for the loss in cell mass due to oxidation of internal storage products for energy for cell maintenance, cell death, and predation by organisms higher in the food chain. These factors are usually lumped together under endogenous decay, and it is assumed that the decrease in cell mass caused by them is proportional to the biomass concentration present. In Eq. (7–21), the coefficient *b* is the *specific endogenous decay* rate coefficient. An alternative approach used to describe the endogenous decay known as a *lysis-regrowth* model is described in Sec. 8–10 in Chap. 8. In biological treatment processes, both the substrate utilization and biomass growth rates are controlled by some limiting substrate, as given by Eqs. (7–12) and (7–22). The growth limiting substrate can be any of the essential requirements for cell growth (i.e., electron donor, electron acceptor, or nutrients), but often it is the electron donor that is limiting, as other requirements are usually available in excess. Thus, when the term substrate is used to describe growth kinetics, it generally refers to the electron donor.

For many substrate utilization modeling applications, it is convenient to use a general equation that includes factors other than the electron donor substrate and the substrate utilization rate. In some cases, low dissolved oxygen concentration or low nutrient concentrations can be of concern. For general model applications it is convenient to describe these effects as a multiple of rate expressions for each important factor affecting the soluble substrate utilization rate. For example, Eq. (7–24), used in the International Water Association ASM2d and ASM3 (Gujer et al., 1999) models, is used to account for possible effects of low dissolved oxygen and ammonia-nitrogen concentrations limiting the bacteria growth rate and thus the substrate utilization rate. At very low ammonia-nitrogen concentrations (less than 0.05 mg/L), the availability of nitrogen for cell synthesis may limit the biomass growth rate.

$$r_{su} = \left[\frac{\mu_{H,\max} S_S}{Y_H(K_s + S_S)}\right]\left(\frac{S_o}{K_o + S_o}\right)\left(\frac{S_{NH}}{K_{NH} + S_{NH}}\right)X_H \qquad (7\text{–}24)$$

where r_{su} = substrate utilization rate, g/m^3·d
$\mu_{H,\max}$ = maximum specific growth rate of heterotrophic bacteria, g VSS/g VSS·d
Y_H = heterotrophic bacteria synthesis yield coefficient, g VSS/g COD used
S_S = bsCOD concentration, g/m^3
S_o = dissolved oxygen concentration, g/m^3
S_{NH} = ammonia-nitrogen concentration, g/m^3
K_S = bsCOD half-velocity constant, g/m^3
K_o = dissolved oxygen half-velocity constant, g/m^3
K_{NH} = ammonia-nitrogen half-velocity constant, g/m^3
X_H = heterotrophic bacteria concentration, g VSS/m^3

Kinetic Coefficients for Substrate Utilization and Biomass Growth

The values used for the coefficients k, K_s, Y, and b to predict the rate of substrate utilization and biomass growth can vary as a function of the wastewater source, microbial population, and temperature. Kinetic coefficient values are determined from bench-scale testing or by fitting a model to full-scale plant test results. For modeling substrate removal in municipal and industrial wastewater, the coefficient values represent the net effect of microbial kinetics on the simultaneous degradation of a variety of different wastewater constituents by a variety of microorganisms. Typical values for kinetic coefficients are reported in Table 7–8 for the aerobic oxidation of BOD in domestic wastewater. Additional kinetic coefficient values are given in Chaps. 8, 9, and 10.

Rate of Oxygen Uptake

The rate of oxygen uptake is related stoichiometrically to the organic utilization rate and growth rate (see Sec. 7–4). Thus, the oxygen uptake rate can be defined as

$$r_o = r_{su} - 1.42 r_x \qquad (7\text{–}25)$$

where r_o = oxygen uptake rate, g O$_2$/m^3·d
r_{su} = substrate utilization rate per unit of reactor volume, g bsCOD/m^3·d
1.42 = the COD of biomass, g COD/g VSS
r_x = rate of biomass growth, g VSS/m^3·d

The factor 1.42 represents the COD of biomass as defined previously by Eq. (7–5).

Table 7–8

Typical kinetic coefficients for the activated sludge process for the removal of BOD from domestic wastewater

Coefficient	Unit	Value[a] Range	Value[a] Typical
k	g bsCOD/g VSS·d	4–12	6
K_s	mg/L BOD	20–60	30
	mg/L bsCOD	5–30	15
Y	mg VSS/mg BOD	0.4–0.8	0.6
	mg VSS/mg COD	0.4–0.6	0.45
b	g VSS/g VSS·d	0.06–0.15	0.10

[a] Values reported are for 20°C.

Effects of Temperature

The temperature dependence of the biological reaction-rate constants is very important in assessing the overall efficiency of a biological treatment process. Temperature not only influences the metabolic activities of the microbial population but also has a profound effect on such factors as gas-transfer rates and the settling characteristics of the biological solids. The effect of temperature on the reaction rate of a biological process is expressed using the same type of relationship developed previously in Chap. 1 [see Eq. (1–44)] and repeated here for ease of reference.

$$k_T = k_{20}\theta^{(T-20)} \tag{1–44}$$

where k_T = reaction-rate coefficient at temperature T, °C
k_{20} = reaction-rate coefficient at 20°C
θ = temperature-activity coefficient
T = temperature, °C

Values for θ in biological systems can vary from 1.02 to 1.25. Temperature correction factors for various kinetic coefficients are given in Chap. 8.

Total Volatile Suspended Solids and Active Biomass

The kinetic expressions used to describe biological kinetics and growth are related to the active biomass concentration X in the treatment reactor. In reality the VSS in a reactor consists of more than active biomass, and the fraction of active biomass can vary depending on the wastewater characteristics and operating conditions. The other components that contribute to the VSS concentration are cell debris, resulting from endogenous decay, and non-biodegradable VSS (nbVSS) in the influent wastewater fed to the biological reactor.

During cell death, cell lysis occurs with the release of cellular materials into the liquid for consumption by other bacteria. A portion of the cell mass (cell wall) is not dissolved and remains as nonbiodegradable particulate matter in the system. The remaining nonbiodegradable material is referred to as cell debris and represents about 10 to 15 percent of the original cell weight. Cell debris is also measured as VSS and contributes to the total VSS concentration measured in the reactor mixed liquor. The rate of production of cell debris is directly proportional to the endogenous decay rate.

$$r_{x,i} = f_d(b)X \tag{7–26}$$

where $r_{x,i}$ = rate of cell debris production, g VSS/m³·d
f_d = fraction of biomass that remains as cell debris, 0.10 – 0.15 g VSS/g biomass VSS depleted by decay

Other terms as defined previously.

The inert VSS concentration resulting from cell debris is typically a relatively small fraction of the VSS in a bioreactor used to treat municipal and some industrial wastewaters. As noted above, a variable amount of MLVSS that is not biomass originates from the nbVSS in the influent wastewater. For typical untreated municipal wastewaters the nbVSS concentration may be in the range from 60 to 100 mg/L, and following primary treatment may range from 10 to 40 mg/L.

Total Volatile Suspended Solids. The VSS production rate in the aeration tank can be defined as the sum of the biomass production rate given by Eq. (7–21), the nbVSS production given by Eq. (7–26), and the nbVSS in the influent wastewater:

$$r_{X_T,\text{VSS}} = \underbrace{Yr_{su} - bX}_{\substack{\text{net biomass}\\ \text{VSS from}\\ \text{soluble bCOD}}} + \underbrace{f_d(b)X}_{\substack{\text{nbVSS}\\ \text{from cells}}} + \underbrace{QX_{o,i}/V}_{\substack{\text{nbVSS}\\ \text{in influent}}} \tag{7–27}$$

where $r_{X_T,\text{VSS}}$ = total VSS production rate, g/m^3·d
Q = influent flowrate, m^3/d
$X_{o,i}$ = influent nbVSS concentration, g/m^3
V = volume of reactor, m^3
Other terms are as defined previously.

Active Biomass. From Eq. (7–27), the fraction of active biomass in the mixed liquor VSS (MLVSS) is the ratio of the net active biomass production rate, r_X in Eq. (7–21) divided by the total MLVSS production:

$$F_{X,\text{act}} = (Yr_{su} - bX)/r_{X_T,\text{VSS}} \tag{7–28}$$

where $F_{X,\text{act}}$ = active fraction of biomass in MLVSS, g VSS/g VSS

Net Biomass Yield and Observed Yield

The term true yield was defined in Sec. 7–4 as the amount of biomass produced during cell synthesis relative to the amount of substrate degraded. In the design and analysis of biological treatment processes, two other yield terms are important: (1) the net biomass yield and (2) the observed solids yield. The first is used as an estimate of the amount of active microorganisms in the system, and the second as the amount of sludge production.

Net Biomass Yield. The net biomass yield is the ratio of the net biomass growth rate in Eq. (7–21), and the substrate utilization rate:

$$Y_{\text{bio}} = r_x/r_{su} \tag{7–29}$$

where Y_{bio} = net biomass yield, g biomass/g substrate used

Observed Yield. The observed yield accounts for the actual solids production that would be measured for the system and is shown as follows:

$$Y_{\text{obs}} = r_{X_T,\text{VSS}}/r_{su} \tag{7–30}$$

where Y_{obs} = observed yield, g VSS produced/g substrate removed

A determination of the net biomass is considered in Example 7–5.

EXAMPLE 7–5 **Determine Biomass and Solids Yields** An aerobic complete-mix treatment process is used to treat an industrial wastewater. The amount of bsCOD in the influent wastewater is 300 g/m^3 and the influent nbVSS concentration is 50 g/m^3. The influent flowrate is 1000 m^3/d, the aerobic tank biomass concentration is 2000 g/m^3, the reactor bsCOD concentration is 2.4 g/m^3, and the reactor volume is 335 m^3. If the cell debris fraction f_d is 0.10, determine the net biomass yield, the observed solids yield, and the biomass fraction in the MLVSS. Use the kinetic coefficients given in Table 7–8.

Solution

1. Determine the net biomass yield using Eq. (7–29).

$$Y_{\text{bio}} = r_X / r_{su}$$

a. Solve for r_{su} using Eq. (7–12) and the information given in Table 7–8

$$\begin{aligned} r_{su} &= \frac{kXS}{K_s + S} \\ &= -\frac{(6/d)(2000\ \text{g/m}^3)(2.4\ \text{g bsCOD/m}^3)}{(15 + 2.4)\ \text{g/m}^3} \\ &= 1655.2\ \text{g bsCOD/m}^3\cdot\text{d} \end{aligned}$$

b. Determine the net biomass production rate r_X using Eq. (7–21)

$$\begin{aligned} r_X &= Yr_{su} - bX \\ &= (0.45\ \text{g VSS/g bsCOD})(1655.2\ \text{g bsCOD/m}^3\cdot\text{d}) \\ &\quad -(0.10\ \text{g VSS/g VSS}\cdot\text{d})(2000\ \text{g VSS/m}^3) \\ &= 544.8\ \text{g VSS/m}^3\cdot\text{d} \end{aligned}$$

c. Calculate the net biomass yield

$$\begin{aligned} Y_{\text{bio}} &= r_X/r_{su} = (544.8\ g\ \text{VSS/m}^3\cdot\text{d})/(1655.2\ g\ \text{bsCOD/m}^3\cdot\text{d}) \\ &= 0.33\ g\ \text{VSS/g bsCOD} \end{aligned}$$

2. Determine VSS production rate using Eq. (7–26).

$$\begin{aligned} r_{X_T,VSS} &= Yr_{su} - bX + f_d(b)X + QX_{o,i}/V \\ &= 544.8\ \text{g VSS/m}^3\cdot\text{d} \\ &\quad + (0.10\ \text{g VSS/g VSS})(0.10\ \text{g VSS/g VSS}\cdot\text{d})(2000\ \text{g VSS/m}^3) \\ &\quad + (1000\ \text{m}^3\text{/d})(50\ \text{g VSS/m}^3)/335\ \text{m}^3 \\ &= (544.8 + 20 + 149.3)\ \text{g VSS/m}^3\cdot\text{d} \\ &= 714\ \text{g VSS/m}^3\cdot\text{d} \end{aligned}$$

3. Calculate the observed solids yield using Eq. (7–30).

$$\begin{aligned} Y_{\text{obs}} &= r_{X_T,\text{VSS}}/r_{su} \\ &= (714\ g\ \text{VSS/m}^3\cdot\text{d})/(1655.2\ g\ \text{bsCOD/m}^3\cdot\text{d}) \\ &= 0.43\ g\ \text{VSS/g bsCOD} \end{aligned}$$

4. Calculate the active biomass fraction in the MLVSS. Using Eq. (7–28).

$$\begin{aligned} F_{X,\text{act}} &= (Yr_{su} - bX)/r_{X_T,\text{VSS}} \\ &= (544.8\ \text{g VSS/m}^3\cdot\text{d})/(714\ \text{g VSS/m}^3\cdot\text{d}) \\ &= 0.76 \end{aligned}$$

Comment Thus, accounting for the nbVSS in the wastewater influent and cell debris produced, the MLVSS contains 76 percent active biomass.

7–6 MODELING SUSPENDED GROWTH TREATMENT PROCESSES

Before discussing the individual biological processes used for the treatment of wastewater as given in Secs. 7–8 through 7–15, it will be helpful to review the general application of the kinetics of biological growth and substrate removal. The purpose here is to illustrate (1) the development of biomass and substrate balances, (2) the prediction of effluent biomass and soluble substrate concentrations, (3) the prediction of the reactor biomass and MLSS/MLVSS concentrations and amount of waste sludge produced daily, and (4) the prediction of the oxygen requirements. Attached growth processes are considered in Sec. 7–7.

Description of Suspended Growth Treatment Processes

The complete-mix reactor with recycle will be considered in the following discussion as a model for suspended growth processes. The schematic flow diagrams shown on Fig. 7–12 include the nomenclature used in the following mass-balance equations. A similar complete-mix reactor may be used in laboratory studies to assess wastewater treatability and to obtain model kinetic coefficients.

All biological treatment reactor designs are based on using mass balances across a defined volume for each specific constituent of interest (i.e., biomass, substrate, etc.). The mass balance includes the flowrates for the mass of the constituent entering and/or leaving the system and appropriate reaction rate terms for the depletion or production of the constituent within the system. The units for a mass balance are usually given in mass per volume per time. For all mass balances a check of the units is recommended to assure that the mass-balance equations are correct.

Solids Retention Time

Before proceeding with the mass balance for biomass and substrate in the completely mixed activated sludge (CMAS) process shown on Fig. 7–12, it is important to first select the system solids retention time (SRT) that will impact the solids production and is a key

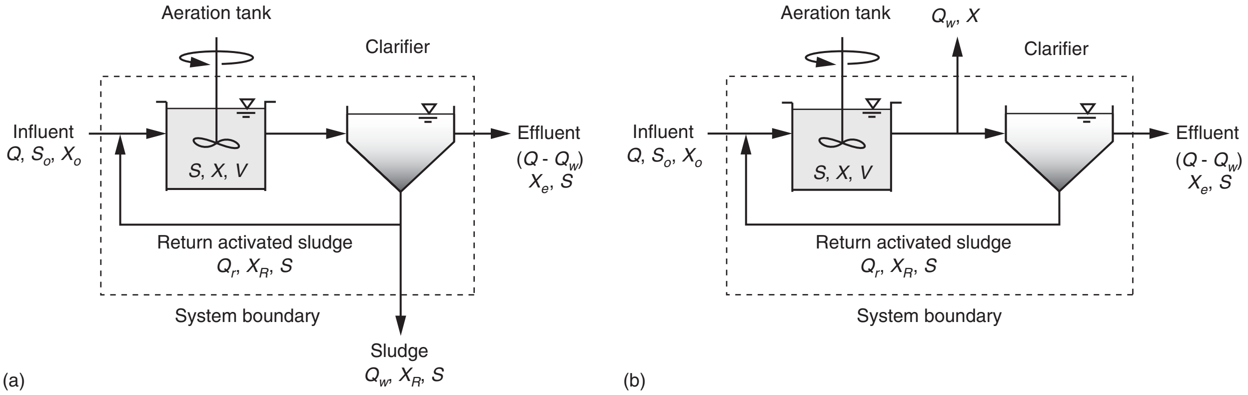


Figure 7–12

Schematic diagram of activated sludge process with model nomenclature: (a) with wasting from the sludge return line and (b) with wasting from the aeration tank.

operating and design parameter for activated sludge processes (Lawrence and McCarty, 1970). The SRT is the average time the activated sludge solids are in the system. Assuming that the solids inventory in the clarifier shown on Fig. 7–12(a) is negligible compared to that in the aeration tank, the SRT is determined by dividing the mass of solids in the aeration tank by the solids removed daily via the effluent and by wasting for process control. For many activated sludge processes, where good flocculation occurs and the clarifier is designed properly, the effluent VSS is typically less than 15 g/m^3. Where the effluent VSS is low, excess solids must be removed from the system by wasting. Wasting is accomplished most commonly by removing biomass (sludge) from the clarifier underflow recycle line as shown on Fig. 7–12(a). Alternatively, wasting can be accomplished from the aeration tank as shown on Fig. 7–12(b).

The average SRT for the process flow diagram shown on Fig. 7–12(a) is given as

$$\text{SRT} = \frac{VX}{(Q - Q_w)X_e + Q_w X_R} \tag{7–31}$$

where SRT = solids retention time, d
V = reactor volume (i.e., aeration tank), m^3
Q = influent flowrate, m^3/d
X = concentration of biomass in the aeration tank, g VSS/m^3
Q_w = waste sludge flowrate, m^3/d
X_e = concentration of biomass in the effluent, g VSS/m^3
X_R = concentration of biomass in the return activated sludge line from the clarifier, g VSS/m^3

Based on Eq. (7–31), the SRT can be controlled by the wasting rate. Increasing the value for Q_w in Eq. (7–31) results in a lower SRT. Similarly, it can be shown that by wasting from the aeration tank, the SRT can be controlled by wasting a given percentage of the aeration tank volume each day.

The inverse of the SRT is the solids wasted per day divided by the solids present.

$$\frac{1}{\text{SRT}} = \frac{(Q - Q_w)X_e + Q_w X_R}{VX} \tag{7–32}$$

At steady state operation, where the influent flowrate and substrate concentration is constant, the reactor biomass concentration is constant, and the net biomass growth rate per day is equal to the solids wasting rate, [the numerator in Eq. (7–32)]. If the product of r_x, the net biomass growth rate per unit volume (g/m^3·d) [see Eq (7–21)] and the volume, V, is substituted for the numerator in Eq. (7–32), it can be shown that the inverse of the SRT is the net specific biomass growth rate.

$$\frac{1}{\text{SRT}} = \frac{Vr_X}{VX} = \frac{r_X}{X} = \mu_{\text{net}} \tag{7–33}$$

Thus, based on Eq. (7–33), controlling the SRT by sludge wasting affects the net specific biomass growth rate, and the reactor substrate concentration. For a CMAS system the reactor effluent dissolved substrate concentration is equal to the reactor concentration.

Biomass Mass Balance

A mass balance for the mass of microorganisms in the complete-mix reactor shown on Fig. 7–12(a) can be written as follows:

1. General word statement:

$$\begin{array}{c} \text{Rate of accumulation} \\ \text{of microorganism} \\ \text{within the system} \\ \text{boundary} \end{array} = \begin{array}{c} \text{rate of flow of} \\ \text{microorganism} \\ \text{into the system} \\ \text{boundary} \end{array} - \begin{array}{c} \text{rate of flow of} \\ \text{microorganism} \\ \text{out of the system} \\ \text{boundary} \end{array} + \begin{array}{c} \text{net growth of} \\ \text{microorganism} \\ \text{within the} \\ \text{boundary} \end{array} \qquad (7\text{–}34)$$

2. Simplified word statement:

Accumulation = inflow – outflow + net growth (7–35)

3. Symbolic representation:

$$\frac{dX}{dt}V = QX_o - \ [(Q - Q_w)X_e] - (Q_w X_R) + r_x V \qquad (7\text{–}36)$$

where dX/dt = rate of change of biomass concentration in reactor measured as g VSS/m^3·d
V = reactor volume (i.e., aeration tank), m^3
Q = influent flowrate, m^3/d
X_o = concentration of biomass in influent, g VSS/m^3
Q_w = waste sludge flowrate, m^3/d
X_e = concentration of biomass in effluent, g VSS/m^3
X_R = concentration of biomass in return line from clarifier, g VSS/m^3
r_x = net rate of biomass production, g VSS/m^3·d

If it is assumed that the concentration of microorganisms in the influent can be neglected and that steady-state conditions exist (dX/dt =0), Eq. (7–36) can be simplified to

$$(Q - Q_W)X_e + Q_W X_R = r_X V \qquad (7\text{–}37)$$

If Eq. (7–37) is combined with Eq. (7–21), the result is

$$\frac{(Q - Q_w)X_e + Q_w X_R}{VX} = Y\frac{r_{su}}{X} - b \qquad (7\text{–}38)$$

where X = concentration of the biomass in the reactor, g/m^3

The inverse of the term on the left-hand side of Eq. (7–38) is defined as the average solids retention time (SRT) as given above in Eq. (7–31). Thus,

$$\frac{1}{\text{SRT}} = Y\frac{r_{su}}{X} - b \qquad (7\text{–}39)$$

The term, r_{su}, defined as the substrate utilization rate per unit of reactor volume [see Eq. (7–12)] is the amount of substrate removed in the reactor divided by the reactor volume:

$$r_{su} = \frac{Q(S_o - S)}{V} \qquad (7\text{–}40)$$

Combining Eq. (7–39) and (7–40):

$$\frac{1}{\text{SRT}} = \frac{YQ(S_o - S)}{XV} - b \qquad (7\text{–}41)$$

If Eq. (7–41) is rearranged as given by Eq. (7–42), the reactor biomass concentration is a function of the system SRT, the aerobic aeration tank hydraulic retention time, τ (V/Q), the synthesis yield coefficient, the amount of substrate removed ($S_o - S$), and the specific endogenous decay coefficient.

$$X = \left(\frac{\text{SRT}}{\tau}\right)\left[\frac{Y(S_o - S)}{1 + b(\text{SRT})}\right] \tag{7–42}$$

A substrate mass balance is needed to determine the effluent substrate concentration as a function of the reactor influent feed and operating conditions.

Substrate Mass Balance

The mass balance for substrate utilization in the aeration tank [see Fig. 7–12(a)] is

Accumulation = inflow − outflow + generation − utilization

$$\frac{dS}{dt}V = QS_o - QS + r_{su}V \tag{7–43}$$

where S_o = influent soluble substrate concentration, g/m^3

Substituting the value for r_{su} [Eq. (7–12)] and assuming steady-state conditions ($dS/dt = 0$), Eq. (7–43) can be rewritten as

$$S_o - S = \left(\frac{V}{Q}\right)\left(\frac{kXS}{K_s + S}\right) \tag{7–44}$$

If Eq. (7–41) is substituted for X in Eq. (7–44), the resulting expression is

$$S_o - S = \left(\frac{V}{Q}\right)\left(\frac{kS}{K_s + S}\right)\left(\frac{\text{SRT}}{V}\right)\left[\frac{QY}{1 + b(\text{SRT})}\right]S_o - S \tag{7–45}$$

Eliminating terms and solving for S yields

$$S = \frac{K_s[1 + b(\text{SRT})]}{\text{SRT}(Yk - b) - 1} \tag{7–46}$$

It should be noted that in Eq. (7–46), the effluent soluble substrate concentration for a complete-mix activated sludge process is only a function of the SRT and the kinetic coefficients for growth and decay. The effluent substrate concentration is not related to the influent soluble substrate concentration, but as shown previously in Eq. (7–42), the influent substrate concentration affects the reactor biomass concentration.

The same equations can be applied to describe an activated sludge process with no clarifier and thus no return sludge flow. For the case with no return sludge, all of the solids produced are present in the effluent from the aeration tank, and the SRT equals the τ.

$$\text{SRT} = VX/QX = \tau \tag{7–47}$$

The importance of the system SRT in determining the effluent soluble substrate concentration and aeration tank biomass concentration is clear from an examination of Eqs. (7–46) and (7–42).

Mixed Liquor Solids Concentration and Solids Production

The solids production from a biological reactor represents the mass of material that must be removed each day to maintain the process. It is of interest to quantify the solids production in terms of TSS, VSS, and biomass. By definition, the SRT also provides a convenient expression to calculate the total sludge produced daily from the activated sludge process:

$$P_{X_T,\text{VSS}} = \frac{X_T V}{\text{SRT}} \tag{7–48}$$

where $P_{X_T,\text{VSS}}$ = total solids wasted daily, g VSS/d
X_T = total MLVSS concentration in aeration tank, g VSS/m^3
V = volume of reactor, m^3
SRT = solids retention time, *d*

Because the 1/SRT in Eq. (7–32) represents the fraction of solids wasted per day and the mixed liquor can be assumed to be a homogeneous mixture of biomass and other solids, Eq. (7–48) can be used to calculate the amount of solids wasted for any of the mixed liquor components. For the amount of biomass wasted per day (P_X), the biomass concentration X can be used in place of X_T in Eq. (7–48).

Mixed Liquor Solids Concentration. The total MLVSS in the aeration tank equals the biomass concentration X plus the nbVSS concentration X_i:

$$X_T = X + X_i \tag{7–49}$$

A mass balance is needed to determine the nbVSS concentration in addition to the active biomass VSS concentration. The MLVSS nbVSS concentration is affected by the amount of nbVSS in the influent wastewater, the amount of nbVSS wasted per day, and the amount of cell debris produced from cell decay. A materials balance on the inert material is as follows:

Accumulation = inflow – outflow + generation

$$(dX_i/dt)V = QX_{o,i} - X_i V/\text{SRT} + r_{X,i}V \tag{7–50}$$

where $X_{o,i}$ = nbVSS concentration in influent, g/m^3
X_i = nbVSS concentration in aeration tank, g/m^3
$r_{X,i}$ = rate of nbVSS production from cell debris, g/m^3·d

At steady-state ($dX_i/dt = 0$) and substituting Eq. (7–26) for $r_{X,i}$ in Eq. (7–50) yields

$$0 = QX_{o,i} - X_i V/\text{SRT} + (f_d)(b)XV \tag{7–51}$$

$$X_i = X_{o,i}(\text{SRT})/\tau + (f_d)(b)X(\text{SRT}) \tag{7–52}$$

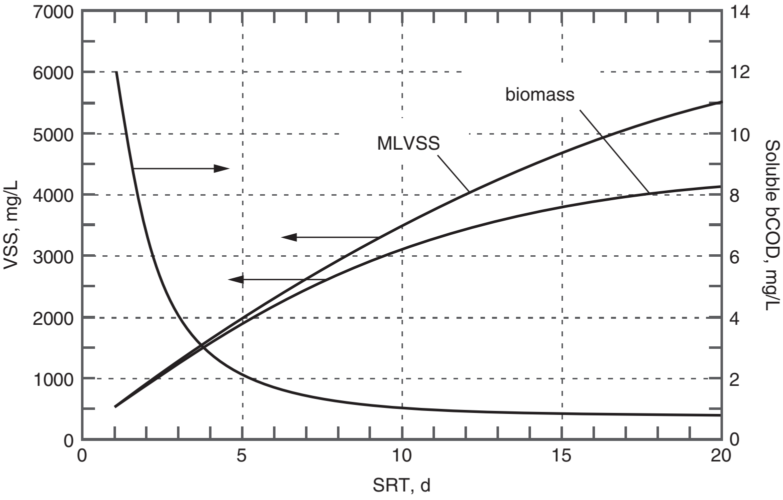
Substituting Eq. (7–42) for X and Eq. (7–52) for X_i in Eq. (7–49) produces the following equation that can be used to determine the total MLVSS concentration:

$$X_T = \underbrace{\left(\frac{\text{SRT}}{\tau}\right)\left[\frac{Y(S_o - S)}{1 + b(\text{SRT})}\right]}_{\substack{(A)\\ \text{Heterotrophic}\\ \text{biomass}}} + \underbrace{(f_d)(b)(X)(\text{SRT})}_{\substack{(B)\\ \text{Cell debris}}} + \underbrace{\frac{(X_{o,i})(\text{SRT})}{\tau}}_{\substack{(C)\\ \text{Nonbiodegradable}\\ \text{VSS in influent}}} \tag{7–53}$$

Solids Production. The amount of VSS produced and wasted daily can be estimated by substituting Eq. (7–53) into Eq. (7–48), and replacing τ with V/Q. The resulting

Figure 7–13

Biodegradable soluble COD, biomass, and MLVSS concentrations versus SRT for complete-mix activated sludge process.



equation is expressed as a function of substrate degraded, influent nbVSS, and kinetic coefficients.

$$P_{X,\text{VSS}} = \underbrace{\frac{QY(S_o - S)}{1 + b(\text{SRT})}}_{\substack{(A)\\ \text{Heterotrophic}\\ \text{Biomass}}} + \underbrace{\frac{(f_d)(b)YQ(S_o - S)\text{SRT}}{1 + b(\text{SRT})}}_{\substack{(B)\\ \text{Cell debris}}} + \underbrace{QX_{o,i}}_{\substack{(C)\\ \text{Nonbiodegradable}\\ \text{VSS in influent}}} \tag{7–54}$$

The effect of SRT on the performance of an activated sludge system for soluble substrate removal is illustrated on Fig. 7–13. In addition to the soluble substrate concentration, the total VSS concentration which includes nbVSS is also shown. As the SRT increases, more biomass decays and thus more cell debris accumulates, so that the difference between MLVSS and biomass VSS concentration increases with SRT. Also illustrated on Fig. 7–13 is the fact that the soluble substrate concentration is very low (bsCOD <5 mg/L) at SRTs above 2 d. The low substrate concentration is typical of the activated sludge process when used for the treatment of municipal wastewaters and illustrates how effectively the organic compounds are degraded in the activated sludge process. As will be shown in Chap. 8, organic substrate degradation is usually not the major factor in selecting a design SRT value.

The total mass of dry solids wasted per day is based on the TSS, which includes the VSS plus inorganic solids. Inorganic solids are present in the influent wastewater (TSS – VSS) and in the biomass, which contains 10 to 15 percent inorganic solids by dry weight. The influent inorganic solids are not soluble, and are assumed captured in the mixed liquor solids and removed in the wasted solids. To calculate the solids production in terms of TSS Eq. (7–54) is modified by adding the influent inorganic solids and by calculating the biomass in terms of TSS by assuming a typical biomass VSS/TSS ratio of 0.85. The ratio of VSS/TSS may vary from 0.80 to 0.90.

$$P_{X,\text{TSS}} = \frac{A}{0.85} + \frac{B}{0.85} + C + Q(\text{TSS}_o - \text{VSS}_o) \tag{7–55}$$

where $P_{X,\text{TSS}}$ = net waste activated sludge produced each day, measured in terms of total suspended solids, kg/d

TSS_o = influent wastewater TSS concentration, g/m^3

VSS_o = influent wastewater VSS concentration, g/m^3

A, *B*, and *C* are as defined in Eq. (7–54).

The mass of MLVSS and MLSS can be obtained by using Eqs. (7–54) and (7–55), respectively, with Eq. (7–48) as follows:

$$\text{Mass of MLVSS} = (X_{\text{VSS}})(V) = (P_{\text{X,VSS}})\,\text{SRT} \tag{7–56}$$

$$\text{Mass of MLSS} = (X_{\text{TSS}})(V) = (P_{\text{X,TSS}})\,\text{SRT} \tag{7–57}$$

By selecting an appropriate MLSS concentration, the aeration volume can be determined from Eq. (7–57). Typical MLSS concentrations in the range of 2000 to 4000 mg/L may be selected, and they must be compatible with the sludge settling characteristics and clarifier design as discussed in Secs. 8–10 and 8–11 in Chap. 8.

The Observed Yield

The observed yield Y_{obs} is based on the amount of solids production measured relative to the substrate removal, and may be calculated in terms of g TSS/g bsCOD or g BOD, or relative to VSS as g VSS/g bsCOD or g BOD. The measured solids production is the sum of the solids in the system effluent flow and the solids intentionally wasted, which equals the term P_X defined in Eqs. (7–54) and (7–55). The observed yield for VSS can be calculated by dividing Eq. (7–54) by the substrate removal rate, which is $Q(S_o - S)$:

$$Y_{\text{obs}} = \underbrace{\frac{Y}{1 + b(\text{SRT})}}_{\substack{(A)\\ \text{Heterotrophic}\\ \text{biomass}}} + \underbrace{\frac{(f_d)(b)(Y)(\text{SRT})}{1 + b(\text{SRT})}}_{\substack{(B)\\ \text{Cell debris}}} + \underbrace{\frac{X_{o,i}}{S_o - S}}_{\substack{(C)\\ \text{Nonbiodegradable}\\ \text{VSS in influent}}} \tag{7–58}$$

where Y_{obs} = g VSS/g substrate removed

For wastewaters with no nbVSS in the influent the solids production consists of only active biomass and cell debris, and the observed yield for VSS is as follows:

$$Y_{\text{obs}} = \frac{Y}{1 + b(\text{SRT})} + \frac{(f_d)(b)(Y)(\text{SRT})}{1 + b(\text{SRT})} \tag{7–59}$$

The impact of nonbiodegradable influent VSS in Eq. (7–58) on the observed yield depends on the wastewater characteristics and the type of pretreatment. The effluent substrate concentration is generally very low compared to S_o, and the term $X_{o,i}/(S_o - S)$ can be approximated by $X_{o,i}/S_o$, which is the g nbVSS/g BOD in the influent. For municipal wastewater $X_{o,i}/S_o$ values range from 0.10 to 0.30 g nbVSS/g BOD with primary treatment and 0.30 to 0.50 g nbVSS/g BOD without primary treatment. Sludge production is also addressed in Chap. 8.

Oxygen Requirements

The oxygen required for the biodegradation of carbonaceous material is determined from a mass balance using the bCOD concentration of the wastewater treated and the amount of biomass wasted from the system per day. If all of the bCOD were oxidized to CO_2 and H_2O, the oxygen demand would equal the bCOD concentration, but bacteria only oxidize a portion of the bCOD to provide energy and use a portion of the bCOD for cell growth. Oxygen is also consumed for endogenous respiration, and the amount will depend on the system SRT. For a given SRT, a mass balance on the system can be done where the bCOD removal equals the oxygen used plus the biomass VSS remaining (in terms of an oxygen equivalent), as given by Eq. (7–7). Thus, for a suspended growth process, the oxygen used is

$$\text{Oxygen used} = \text{bCOD removed} - \text{COD of waste sludge} \tag{7–60}$$

$$R_o = Q(S_o - S) - 1.42P_{X,\text{bio}} \tag{7–61}$$

where R_o = oxygen required, kg/d

$P_{X,\text{bio}}$ = biomass as VSS wasted per day, kg/d

It is important to note that $P_{X,\text{bio}}$ includes active biomass and cell debris derived from cell growth and is thus the sum of terms A and B in Eq. (7–54).

EXAMPLE 7–6 **Design of a Complete-mix Suspended Growth Process** A complete-mix suspended growth activated sludge process with recycle is used to treat municipal wastewater after primary sedimentation. The characteristics of the primary effluent are: flow = 1000 m^3/d, bsCOD = 192 g/m^3, nbVSS = 30 g/m^3, and inert inorganics = 10 g/m^3. The aeration tank MLVSS = 2500 g/m^3. Using these data and the kinetic coefficients given below, design a system with a 6-d SRT and determine the following:

1. What is the effluent bsCOD concentration?
2. What value of τ should be used so that the MLVSS concentration is 2500 g/m^3?
3. What is the daily sludge production in kg/d as VSS and TSS?
4. What is the fraction of biomass in the MLVSS?
5. What is the observed solids yield in g VSS/g bsCOD and g TSS/g bsCOD?
6. What is the oxygen requirement in kg/d?

Kinetic coefficients:

k = 12.5 g COD/g VSS·d　　K_s = 10 g COD/m^3

Y = 0.40 g VSS/g COD used　　f_d = 0.15 g VSS/g VSS

b = 0.10 g VSS/g VSS·d　　Biomass VSS/TSS = 0.85

Solution

1. Determine the effluent bsCOD concentration using Eq. (7–46).

$$S = \frac{K_s[1 + b(\text{SRT})]}{\text{SRT}(Yk - b) - 1}$$

$$= \frac{(10\text{ g bsCOD/m}^3)[1 + (0.10\text{ g VSS/g VSS·d})(6\text{ d})]}{(6\text{ d})[(0.40\text{ g VSS/g COD})(12.5\text{ g COD/g VSS·d}) - (0.10\text{ g VSS/g VSS·d})] - 1}$$

$$= 0.56\text{ g bsCOD/m}^3$$

2. Determine τ for 2500 g/m^3 MLVSS concentration.

Solve for τ in Eq. (7–53).

$$X_T = Y(S_o - S)\text{SRT}/[1 + b(\text{SRT})](\tau) + (f_d)(b)(X)\text{SRT} + (X_{o,i})\text{SRT}/\tau$$

$$\begin{aligned}2500\text{ g VSS/m}^3 = {} & (0.40\text{ g VSS/g COD})[(192 - 0.56)\text{ g COD/m}^3](6\text{ d})/\\ & [(1 + 0.10\text{ g VSS/g VSS·d}(6\text{ d})(\tau)]\\ & +(0.15\text{ g VSS/g VSS})(0.10\text{ g VSS/g VSS·d})(X)(6\text{ d})\\ & +30\text{ g bsCOD/m}^3(6\text{ d}/\tau)\end{aligned}$$

$$2500 = 287.2/\tau + 0.09(X) + 180/\tau$$

The biomass concentration X is determined using Eq. (7–42).

$$\begin{aligned} X &= [Y(S_o - S)]\text{SRT}/[1 + b(\text{SRT})](\tau) \\ &= \frac{(0.40\text{ g VSS/gCOD})[(192 - 0.56)\text{ g COD/m}^3](6\text{ d})}{[1 + (0.10\text{ g VSS/g COD})(6\text{ d})](\tau)} \\ &= (287.2\text{ g/m}^3\cdot\text{d})/\tau \end{aligned}$$

Substituting for X in the above expression yields:

$$2500 = 287.2/\tau + 180/\tau + 25.8/\tau = 493/\tau$$

and solving the above expression for τ yields

$$\tau = 0.197\text{ d}$$

Aeration tank volume $= \tau(Q) = 0.197\text{ d }(1000\text{ m}^3/\text{d}) = 197\text{ m}^3$

3. Determine the total sludge production as kg VSS/d using Eq. (7–48).

$$\begin{aligned} P_{X_T,\text{VSS}} &= X_T(V)/(\text{SRT}) \\ &= (2500\text{ g VSS/m}^3)(197\text{ m}^3)(1\text{ kg}/10^3\text{g})/6\text{d} = 82.1\text{ kg VSS/d} \end{aligned}$$

4. Determine the total sludge production as kg TSS/d using Eq. (7–55) and the assumed coefficients.

$$P_{X_T,\text{TSS}} = \frac{QY(S_o - S)}{1 + (b)\text{SRT}}\left(\frac{1}{0.85}\right) + \frac{(f_d)(b)YQ(S_o - S)\text{SRT}}{1 + (b)\text{SRT}}\left(\frac{1}{0.85}\right) + QX_{o,i} + Q(\text{TSS}_\text{o} - \text{VSS}_\text{o})$$

$$= \frac{(1000\text{ m}^3/\text{d})(0.40\text{ g VSS/g COD})[(192 - 0.56)\text{ g COD/m}^3]}{[1 + (0.10\text{ g VSS/g VSS}\cdot\text{d})(6\text{ d})](0.85)}$$

$$+ \frac{(0.15)(0.10)(1000\text{ m}^3/\text{d})(0.40)[(192 - 0.56)\text{ g COD/m}^3](6\text{ d})}{[1 + (0.10\text{ g VSS/g VSS}\cdot\text{d})(6\text{ d})](0.85)}$$

$$+ (1000\text{ m}^3/\text{d})(30\text{ g/m}^3) + (1000\text{ m}^3/\text{d})(10\text{ g/m}^3)$$

$$= (56.3 + 5.1 + 30 + 10)(10^3\text{ g/d}) = 101.4 \times 10^3\text{ g/d} = 101.4\text{ kg/d}$$

5. Determine the biomass fraction from the values for X and X_T.

$$X = (287.2\text{ g/m}^3\cdot\text{d})/\tau = (287.2\text{ g/m}^3\cdot\text{d})/0.197\text{ d} = 1458\text{ g VSS/m}^3$$

Biomass fraction $= X/X_T = 1458/2500 = 0.58$

6. Calculate the observed solids yield, g VSS/g bsCOD removed and g TSS/g bsCOD removed.

Solids wasted/d $= P_{X_T} = 82.1$ kg VSS/d and 101.4 kg TSS/d

$$\begin{aligned} \text{bsCOD removed/d} &= Q(S_o - S) \\ &= (1000\text{ m}^3/\text{d})[(192 - 0.56)\text{ g COD/m}^3](1\text{ kg}/10^3\text{ g}) \\ &= 191{,}440\text{ g COD/d} = 191.4\text{ kg/d} \end{aligned}$$

As VSS, $Y_\text{obs} = 82.1/191.4 = 0.43$ g VSS/g bsCOD

As TSS, $Y_\text{obs} = 101.4/191.4 = 0.53$ g TSS/g bsCOD

7. Determine the oxygen required using Eq. (7–61).

$$R_o = Q(S_o - S) - 1.42\, P_{X,\text{bio}}$$

$$\begin{aligned} P_{X,\text{bio}} &= P_{X_T,\text{VSS}} - P_{\text{nbVSS}} \\ &= 82.1\,\text{kg/d} - (1000\,\text{m}^3/\text{d})(30\,\text{g VSS/m}^3)(1\,\text{kg}/10^3\,\text{g}) = 52.2\,\text{kg/d} \end{aligned}$$

$$\begin{aligned} R_o &= (1000\,\text{m}^3/\text{d})[(192 - 0.56)\text{g COD/m}^3](1\,\text{kg}/10^3\,\text{g}) - 1.42(52.2\,\text{kg VSS/d}) \\ &= 117.7\,\text{kg O}_2/\text{d} \end{aligned}$$

Comment The same approach can be used to treat wastewater with particulate biodegradable COD by assuming it is equal to bsCOD. For complete-mix suspended growth designs if the SRT is 3 d or more, essentially all of the degradable particulate COD will be converted to bsCOD.

Design and Operating Parameters

In the mass balance for the complete mix reactor presented above, the SRT was introduced as the fundamental process parameter that affects the treatment efficiency and general performance for the activated sludge process. Two other activated sludge process parameters used for the design and operation of the activated sludge process, the food to microorganism ratio and the volumetric loading rate, are introduced below.

Food to Microorganism (F/M) Ratio. The F/M ratio is defined as the rate of BOD or COD applied per unit volume of mixed liquor:

$$\text{F/M} = \frac{\text{total applied substrate rate}}{\text{total microbial biomass}} = \frac{QS_o}{VX} \tag{7–62}$$

and

$$\text{F/M} = \frac{S_o}{\tau X} \tag{7–63}$$

where F/M = food to biomass ratio, g BOD or bsCOD/g VSS·d
Q = influent wastewater flowrate, m^3/d
S_o = influent BOD or bsCOD concentration, g/m^3
V = aeration tank volume, m^3
X = mixed liquor biomass concentration in the aeration tank, g/m^3
τ = hydraulic retention time of aeration tank, V/Q, d

The F/M ratio is useful for understanding the effect of transient loads on a system. The higher the specific BOD loading rate (g BOD/g VSS·d), the faster is the substrate utilization rate and thus the reactor would have a higher substrate concentration.

F/M ratio and SRT. The F/M ratio can be related to the system SRT by noting that there is a given substrate removal efficiency at a given F/M. The process removal efficiency E as percent BOD or bsCOD removed across the activated sludge system is defined as

$$E = \frac{S_o - S}{S_o}(100) \tag{7–64}$$

Thus E/100 times F/M equals

$$\frac{E}{100}\left(\frac{\mathrm{F}}{\mathrm{M}}\right) = \frac{QS_o(S_o - S)}{VX(S_o)} = \frac{Q(S_o - S)}{VX} \tag{7–65}$$

Substituting Eq. (7–40) in Eq. (7–65) yields

$$\frac{E}{100}\left(\frac{\mathrm{F}}{\mathrm{M}}\right) = \frac{r_{su}}{X} \tag{7–66}$$

In Eq. (7–66), the term (r_{su}/X) is known as the *specific substrate utilization rate, U*. Rearranging Eq. (7–39) it can be shown that U is related to the SRT and the bacteria growth and decay coefficients.

$$U = \frac{r_{su}}{X} = \frac{\left(\dfrac{1}{\mathrm{SRT}} + b\right)}{Y} \tag{7–67}$$

where terms are as defined earlier.

Substituting Eq. (7–67) into Eq. (7–66) yields

$$\frac{1}{\mathrm{SRT}} = Y(F/M)\frac{E}{100} - b \tag{7–68}$$

From Eq. (7–68) it can be seen that systems operated with a higher F/M ratio result in a lower steady-state SRT value. For systems designed for the treatment of municipal wastewater with activated sludge SRT values in the 20- to 30-d range, the corresponding F/M values may range from 0.10 to 0.05 g BOD/g VSS·d, respectively. At SRTs in the range of 5 to 7 d, the F/M values may range from 0.3 to 0.5 g BOD/g VSS·d, respectively.

Organic Volumetric Loading Rate. The organic volumetric loading rate, defined as the amount of BOD or COD applied to the aeration tank volume per day, is

$$L_{\mathrm{org}} = \frac{(Q)(S_o)}{(V)(10^3\ \mathrm{g/1\ kg})} \tag{7–69}$$

where L_{org} = volumetric organic loading rate, kg BOD/m^3·d
Q = influent wastewater flowrate, m^3/d
S_o = influent BOD concentration, g/m^3
V = aeration tank volume, m^3

Process Performance and Stability

The effects of the kinetics considered above on the performance and stability of the system shown on Fig. 7–14 will now be examined further. It was shown previously that 1/SRT, the net microorganism specific growth rate, and U, the specific substrate utilization rate, are related directly [see Eqs. (7–67) and (7–39)]. For a specified waste, a given biological community, and a particular set of environmental conditions, the kinetic coefficients Y, k, K_s, and b are fixed. It is important to note that domestic wastewater may have significant variability in its composition and may not always be treated as a single waste type in evaluating the kinetic coefficients. For given values of the coefficients, the steady state effluent substrate concentration from the reactor is a direct function of the SRT, as given by Eq. (7–46). Setting the SRT value fixes the values of U and m and also defines the efficiency of biological waste stabilization. Equation (7–46) for substrate is plotted on Fig. 7–14(a) for a growth-specified complete-mix system with recycle. As shown, the

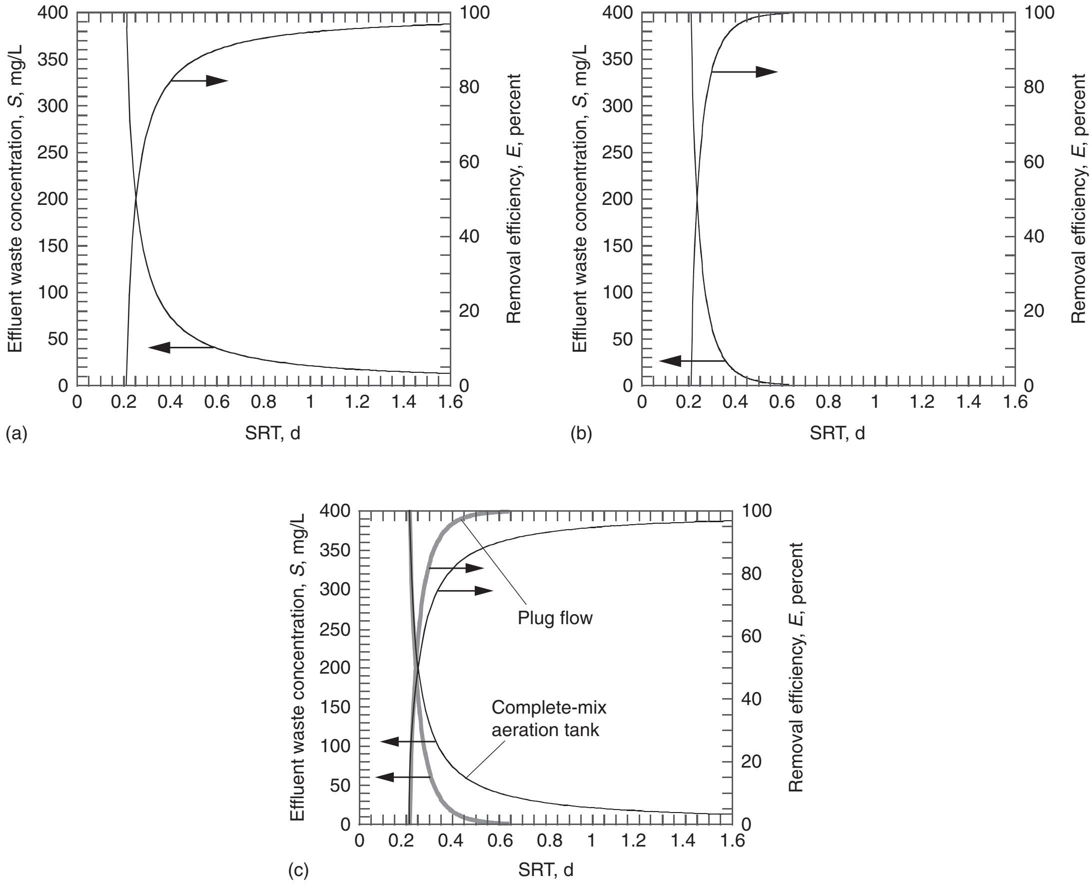


Figure 7–14

Effluent substrate concentration and removal efficiency versus SRT for: (a) complete-mix reactors with recycle, (b) plug flow reactor with recycle, and (c) plug flow and complete-mix plotted on the same graph for comparison.

treatment efficiency and the substrate concentration are related directly to the SRT, and the reactor hydraulics (i.e., complete-mix or plug-flow).

It can also be seen from Fig. 7–14(a) that there is a certain value of SRT below which waste stabilization does not occur. The critical SRT value is called the minimum solids retention residence time $\mathrm{SRT}_{\min}$. Physically, $\mathrm{SRT}_{\min}$ is the residence time at which the cells are washed out or wasted from the system faster than they can reproduce. The minimum SRT can be calculated using Eq. (7–23), in which $S = S_o$. When washout occurs, the influent concentration S_o is equal to the effluent waste concentration S.

$$\frac{1}{\mathrm{SRT}_{\min}} = \frac{YkS_o}{K_s + S_o} - b \tag{7–70}$$

In many situations encountered in waste treatment, S_o is much greater than K_s so that Eq. (7–70) can be rewritten to yield

$$\frac{1}{\mathrm{SRT}_{\min}} \approx Yk - b \tag{7–71}$$

or

$$\frac{1}{\text{SRT}_{\text{min}}} \approx \mu_m - b \tag{7–72}$$

Equations (7–71) and (7–72) can be used to determine the SRT_{min}. Typical kinetic coefficients that can be used to solve for SRT_{min} for BOD removal systems are given in Table 7–8. Biological treatment processes should not be designed with SRT values equal to SRT_{min}. To ensure adequate waste treatment, biological treatment processes are usually designed and operated with a design SRT value from 2 to 20 times SRT_{min}. In effect, the ratio of the design SRT (SRT_{des}) to SRT_{min} can be considered to be a process safety factor, SF, against system failure (Lawrence and McCarty, 1970).

$$\text{SF} = \frac{\text{SRT}_{\text{des}}}{\text{SRT}_{\text{min}}} \tag{7–73}$$

Modeling Plug-Flow Reactors

The plug-flow system with biomass recycle can be used to model certain forms of the activated sludge process. The distinguishing feature of this recycle system is that the hydraulic regime of the reactor is of a plug-flow nature. In a true plug-flow model, all the particles entering the reactor stay in the reactor an equal amount of time. Some particles may make more passes through the reactor because of recycle, but while they are in the tank, all pass through in the same amount of time.

A kinetic model of the plug-flow system is mathematically complex, but Lawrence and McCarty (1970) have made two simplifying assumptions that lead to a useful kinetic model of the plug-flow reactor:

1. The concentration of microorganisms in the influent to the reactor is approximately the same as that in the effluent from the reactor. This assumption applies only if $\text{SRT}/\tau > 5$. The resulting average concentration of microorganisms in the reactor is symbolized as $\overline{X}$.
2. The rate of change of substrate concentration as the waste passes through the reactor is given by the following expression:

$$\frac{dS}{dt} = -\frac{kS\overline{X}}{K_s + S} \tag{7–74}$$

Integrating Eq. (7–74) over the retention time of the wastewater in the aeration tank, substituting Eq. (7–42) for $\overline{X}$, and simplifying, the following expression is obtained:

$$\frac{1}{\text{SRT}} = \frac{Yk(S_o - S)}{(S_o - S) + (1 + R)K_s \ln(S_i/S)} - b \tag{7–75}$$

where S_o = influent concentration
S = effluent concentration
S_i = influent concentration to reactor after dilution with recycle flow

$$= \frac{S_o + RS}{1 + R}$$

R = clarifier return sludge recycle ratio (return flowrate divided by the influent wastewater flowrate)

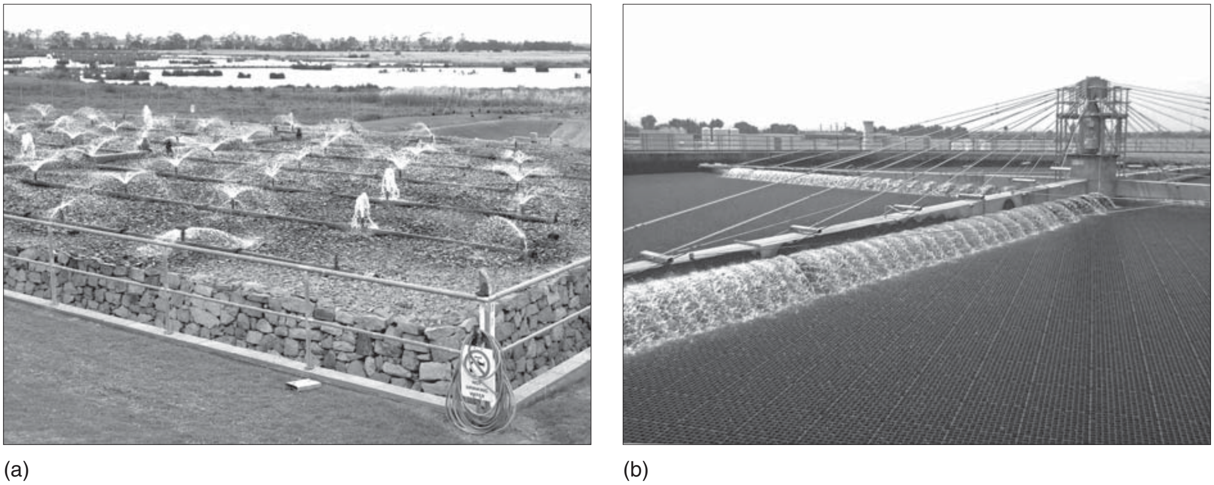
Other terms are as defined previously.

The effluent substrate concentration in Eq. (7–75) is a function of both the influent concentration and SRT, whereas for a complete-mix system [see Eq. (7–46)], the effluent substrate concentration was only a function of the SRT. A version of Eq. (7–75) in which Eq. (7–42) is not substituted for $\overline{X}$ is shown in Chap. 8 in the design of sequencing batch reactors.

The true plug-flow recycle system is theoretically more efficient in the stabilization of most soluble wastes than in the continuous-flow stirred-tank recycle system. A graphical representation is shown on Fig. 7–14(b). In actual practice, a true plug-flow regime is essentially impossible to obtain because of longitudinal dispersion caused by aeration and mixing. By dividing the aeration tank into a series of reactors, the process approaches plug-flow kinetics with improved treatment efficiency compared to a complete-mix process. Because of the greater dilution with the influent wastewater, the complete-mix system can handle shock loads better than staged reactors in series. Reactor selection is discussed further in Chap. 8.

7–7 SUBSTRATE REMOVAL IN ATTACHED GROWTH TREATMENT PROCESS

In an attached growth treatment process, a biofilm consisting of microorganisms, particulate material, and extracellular polymers is attached and covers the support packing material, which may be plastic, rock, or other material (see Fig. 7–15). The growth and substrate utilization kinetics described for the suspended growth process were related to the dissolved substrate concentration in the bulk liquid. For attached growth processes, substrate is consumed within a biofilm.



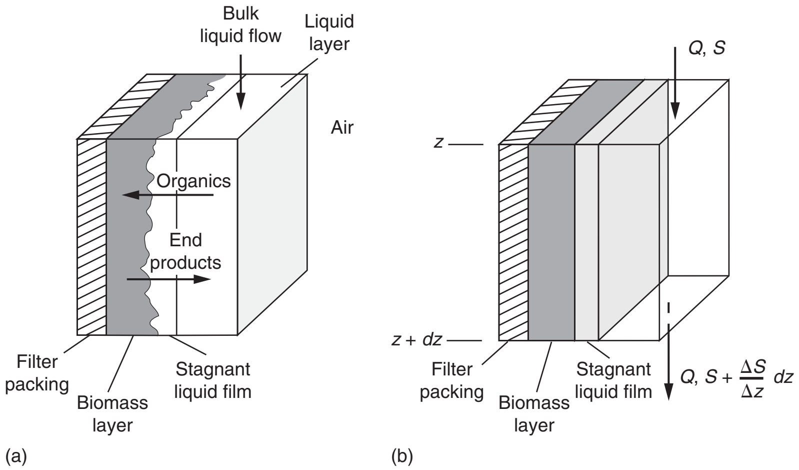
(a) (b)

Figure 7–15

Typical packing for trickling filters: (a) rock with fixed spray nozzles and (b) plastic media in tower trickling filter.

Figure 7–16

Schematic representation of the cross section of a biological slime layer in a tricling filter: (a) pictorial and (b) idealized.



Biofilm Characteristics

Depending on the growth conditions and the hydrodynamics of the system, the biofilm thickness may range from 100 μm to 10 mm (WEF, 2000). A stagnant liquid layer (diffusion layer) separates the biofilm from the bulk liquid that is flowing over the surface of the biofilm or is mixed outside of the fixed film [see Fig. 7–16(a)]. Substrates, oxygen, and nutrients diffuse across the stagnant liquid layer to the biofilm, and products of biodegradation from the biofilm enter the bulk liquid after diffusion across the stagnant film.

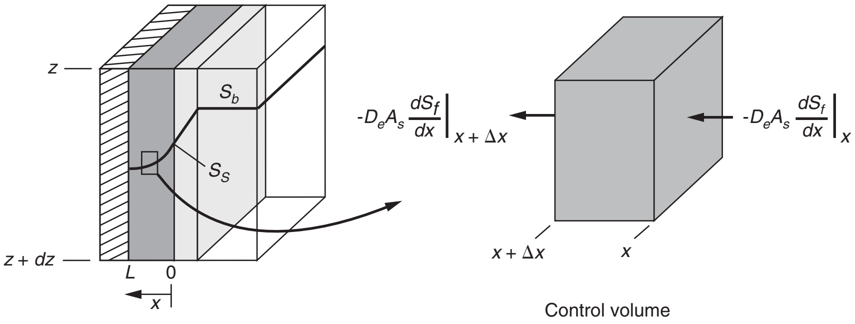
The substrate concentration at the surface of the biofilm, S_s as shown on Fig. 7–17, decreases with biofilm depth as the substrate is consumed and diffuses into the biofilm layers. As a result, the process is said to be *diffusion limited*. The substrate and oxygen concentrations within the film are lower than the bulk liquid concentration and change with biofilm depth and the substrate utilization rate. The overall substrate utilization rate is less than would be predicted based on the bulk liquid substrate concentration.

Biomass Characterization

The total amount of substrate used per unit of biofilm cross-sectional area must diffuse across the stagnant layer. This rate of mass transfer is termed the surface flux and is expressed as mass per unit area per unit time (g/m^2·d). The biofilm layer is not simply a planar surface as depicted on Fig. 7–16(b) (Costerton et al., 1995). The biofilm layers are in fact very complex nonuniform structures with uneven protrusions much like peaks and

Figure 7–17

Definition sketch for the analysis of substrate concentration in the biofilm.



valleys, and are believed to have vertical and horizontal pores through which liquid flows. The biomass can be very dense in biofilms and may also vary in density and depth. Biofilm VSS concentrations may range from 40 to 100 g/L. Uniform growth across the support packing also does not occur because of periodic sloughing, as well as the hydrodynamics and media configuration (Hinton and Stensel, 1991).

Mechanistic Models

Mechanistic models have been developed by a number of investigators to describe mass transfer and biological substrate utilization kinetics in biofilms (Williamson and McCarty, 1976; Rittman and McCarty, 1980; Kissel et al., 1984; Saez and Rittman, 1992; Suidan and Wang, 1985; Wanner and Gujer, 1986; and Rittman and McCarty, 2001) and provide useful tools for the evaluation of biofilm processes. However, because of the complexity of attached growth reactors and the inability to define accurately the physical parameters and model coefficients, empirical relationships, based on observed performance, are used for design. The empirical relationships used for design are presented and illustrated in Chap. 9. Fundamental concepts of mass transfer and substrate utilization that can be used to model the behavior of substrate removal in attached growth processes are introduced here.

Substrate Flux in Biofilms

The substrate flux across the stagnant layer to the biofilm, a function of the substrate diffusion coefficient and concentration, is given by Eq. (7–76). The negative sign is used because the substrate concentration is decreasing along the stagnant layer and substrate is removed from the bulk liquid.

$$r_{sf} = -D_w \frac{dS}{dx} = -D_w \frac{(S_b - S_s)}{L} \tag{7–76}$$

where r_{sf} = rate of substrate surface flux, g/m^2·d
D_w = diffusion coefficient of substrate in water, m^2/d
dS/dx = substrate concentration gradient, g/m^3·m
S_b = bulk liquid substrate concentration, g/m^3
S_s = substrate concentration at outer layer of biofilm, g/m^3
L = effective thickness of stagnant film, m

The thickness of the stagnant layer will vary with the fluid properties and fluid velocity. Higher velocities result in thinner films with greater substrate flux rates (Grady et al., 1999).

Mass transfer within the biofilm is described by Fick's law for diffusion (see Sec. 1–9 in Chap. 1) in an aqueous solution, with a modification to the diffusivity constant to account for the effect of the biofilm structure on the effective diffusion.

$$r_{bf} = -D_e \frac{dS_f}{dx} \tag{7–77}$$

where r_{bf} = rate of substrate flux in biofilm due to mass transfer, g/m^2·d
D_e = effective diffusivity coefficient in biofilm, m^2/d
dS_f/dx = substrate concentration gradient, g/m^3·m

The substrate utilization rate within the biofilm at any point can be defined as a saturation-type reaction (Eq. 7–12) for the substrate concentration (S_f) at that location:

$$r_{su} = \frac{kS_fX}{K_s + S_f} \tag{7–78}$$

where r_{su} = rate of substrate utilization in biofilm, g/m^2·d
S_f = substrate concentration at a point in the biofilm, g/m^3

Substrate Mass Balance for Biofilm

A substrate mass balance around a differential element (dx) shown on Fig. 7–17 within the biofilm yields

$$\begin{array}{c} \text{Rate of substrate} \\ \text{accumulation within} \\ \text{differential element} \end{array} = \begin{array}{c} \text{rate of substrate} \\ \text{flow into} \\ \text{differential element} \end{array} - \begin{array}{c} \text{rate of substrate} \\ \text{flow out of} \\ \text{differential element} \end{array} - \begin{array}{c} \text{rate of substrate} \\ \text{utilization in} \\ \text{differential element} \end{array} \tag{7–79}$$

For steady-state conditions, the mass balance is

Accumulation = inflow – outflow + generation − utilization

$$0 = -D_e A_s \frac{dS_f}{dx}\bigg|_{x} + D_e A_s \frac{dS_f}{dx}\bigg|_{x+\Delta x} - \Delta x A_s\left(\frac{kS_fX}{K_s + S_f}\right) \tag{7–80}$$

where A_s = biofilm area normal to the substrate flux, m^2

Δx = width of differential section, m

Dividing both sides by A_s and dx, and taking the limit as Δx approaches zero yields the following general equation for the change in substrate concentration within the biofilm:

$$D\frac{d^2S_f}{dx^2} - X\left(\frac{kS_f}{K_s + S_f}\right) = 0 \tag{7–81}$$

Solutions to the above equation require two boundary conditions. The first boundary condition is that the substrate flux at the biofilm surface equals the substrate flux through the stagnant liquid film, as given by Eq. (7–76). The second boundary condition is that there is no flux at the packing surface.

$$\frac{dS_f}{dx}\bigg|_{x=L} = 0 \tag{7–82}$$

Solutions for Eq. (7–81) vary, depending on (1) whether a deep biofilm exists such that the biofilm substrate concentration approaches zero toward the support surface, (2) whether a shallow film exists such that S_f is a finite value throughout the film, and (3) the relative concentration of S_f compared to K_s. Solution approaches are provided in a number of references, including Williamson and McCarty (1976), Grady et al. (1999), and Rittman and McCarty (2001).

Substrate Flux Limitations

An important implication of diffusion-limited processes is the relationship between the bulk liquid electron donor and electron acceptor concentrations. An assumption in the mechanistic models used is that either the electron donor or electron acceptor (i.e., oxygen or nitrate) is limiting. The substrate limitation may be due to reaction rates within the biofilm or to bulk liquid concentrations and diffusion rates across the stagnant layer. These are referred to by Williamson and McCarty (1976) as substrate and surface flux limitations, respectively. There are situations where the substrate limitation may switch between electron donor and electron acceptor with depth in the biofilm. For the situation where the substrate limitation can switch, numerical analysis techniques must be used to evaluate the biofilm behavior. A simple method that can be used to evaluate whether a surface flux limitation exists has been proposed by Williamson and McCarty (1976). The proposed method can also be used to assess the relative electron acceptor bulk liquid substrate concentrations needed to sustain electron donor utilization within the biofilm.

The effect of surface flux substrate limitation described by Williamson and McCarty (1976) is summarized in the following two equations:

$$\nu_d + \nu_a + \text{growth requirements} \rightarrow \text{end products} + \text{cells} \tag{7–83}$$

$$S_{ba} < \frac{D_{wd}\nu_a mw_a}{D_{wa}\nu_d mw_d} S_{bd} \tag{7–84}$$

where ν_d = molar stoichiometric reaction coefficient for electron donor, mole
ν_a = molar stoichiometric reaction coefficient for electron acceptor, mole
S_{ba} = bulk liquid electron acceptor substrate concentration, mg/L
S_{bd} = bulk liquid electron donor substrate concentration, mg/L
D_{wd} = diffusivity coefficient of electron donor in water, cm^2/d
D_{wa} = diffusivity coefficient of electron acceptor in water, cm^2/d
mw_a = molecular weight of electron acceptor, g
mw_d = molecular weight of electron donor, g

Nitrification rates in fixed-film systems are often limited by the bulk liquid DO concentration. In the following example, Eqs. (7–83) and (7–84) are used to illustrate this important issue regarding fixed-film process applications.

EXAMPLE 7–7 **Oxygen Limitation for Nitrification in a Biofilm** For bulk liquid NH_4-N concentrations of 1.0, 2.0, and 3.0 mg/L, respectively, what bulk liquid DO concentration must be present so that the nitrification rate in the biofilm is not limited due to the surface flux rate of oxygen? Assume the following conditions apply:

Electron donor = NH_4-N, $mw_d = 14$

Electron acceptor = oxygen, $mw_a = 32$

NH_4-N diffusivity coefficient at 20°C = $D_{wd} = 1.6\ \text{cm}^2/\text{d}$

Oxygen diffusivity coefficient at 20°C = $D_{wa} = 2.6\ \text{cm}^2/\text{d}$

Solution

1. Determine the stoichiometric coefficients from the reaction stoichiometry.

$$NH_4^+ + 2O_2 \rightarrow NO_3^- + 2H^+ + H_2O$$

$$\nu_d = 1.0$$

$$\nu_a = 2.0$$

2. Determine the DO concentration where oxygen is flux-limited using Eq. (7–84).

$$S_{ba} < \frac{D_{wd}\nu_a mw_a}{D_{wa}\nu_d mw_d} S_{bd} < \frac{(1.6\ \text{m}^2/\text{d})(2.0)(32\ \text{g/mole})}{(2.6\ \text{m}^2/\text{d})(1.0)(14\ \text{g/mole})} S_{bd} = 2.8\ S_{bd}$$

Thus, if S_{ba} is equal to 2.8 (S_{bd}), the nitrification rate is not hindered by the oxygen flux rate through the stagnant layer. Bulk liquid DO concentrations necessary to prevent an oxygen flux limitation for nitrification are summarized in the following table.

Bulk liquid NH_4-N concentration, g/m^3	Bulk liquid DO concentration, g/m^3
1.0	2.8
2.0	5.6
3.0	8.4

Comment For low bulk liquid NH_4-N concentrations, which result in lower nitrification rates in the biofilm, lower DO concentrations can be tolerated.

7–8 AEROBIC OXIDATION

Dating back to the early 1900s, the primary purpose of biological wastewater treatment has been to (1) remove organic constituents and compounds to prevent excessive DO depletion in receiving waters from municipal or industrial point discharges, (2) remove colloidal and suspended solids to avoid the accumulation of solids and the creation of nuisance conditions in receiving waters, and (3) reduce the concentration of pathogenic organisms released to receiving waters. The U.S. EPA secondary treatment regulatory standards, set in 1972 and still in effect, were focused mainly on the removal of BOD and TSS, and require 85 percent removal of each (see Table 1–2 in Chap. 1). Most treatment applications involve the removal of organic constituents and compounds. Because a wide range of constituents and compounds exist in wastewater, the organic content is quantified in terms of biodegradable soluble COD (bsCOD) or BOD. Additional information on the characterization of the organic constituents in wastewater is presented in Sec. 8–2 in Chap. 8.

Process Description

The removal of BOD can be accomplished in a number of aerobic suspended growth or attached (fixed film) growth treatment processes as illustrated on Figs. 7–3 and 7–4, respectively, and described in detail in Chaps. 8 and 9. Both require sufficient contact time between the wastewater and heterotrophic microorganisms and sufficient oxygen and nutrients. During the initial biological uptake of the organic material, more than half of it is oxidized, and the remainder is assimilated as new biomass, which may be further oxidized by endogenous respiration. For both suspended and attached growth processes, the excess biomass produced each day is removed and processed to maintain proper operation and performance. The biomass is separated from the treated effluent by gravity separation, and more recent designs using membrane separation are finding applications.

Microbiology

A wide variety of microorganisms are found in aerobic suspended and attached growth treatment processes used for the removal of organic material. Aerobic heterotrophic bacteria found in these processes are able to produce extracellular biopolymers that result in the formation of biological flocs (or biofilms for attached growth processes) that can be separated from the treated liquid by gravity settling with relatively low concentrations of free bacteria and suspended solids.

Protozoa also play an important role in aerobic biological treatment processes. By consuming free bacteria and colloidal particulates, protozoa aid effluent clarification. Protozoa require a longer SRT than aerobic heterotrophic bacteria, prefer dissolved oxygen concentrations above 1.0 mg/L, and are sensitive to toxic materials. Thus, their presence is a good indicator of a trouble-free stable process operation. Because of their size, protozoa can easily be observed with a light microscope at a magnification factor of 100 to 200. Rotifers can also be found in activated sludge and in biofilms, as well as nematodes and other multicellular microorganisms. These organisms occur at longer biomass retention times, and their importance has not been well defined.

Aerobic attached growth processes, depending on the biofilm thickness, generally have a much more complex microbial ecology than activated sludge. Biofilms contain bacteria, fungi, protozoan, rotifers, and possibly annelid worms, flatworms, and nematodes (WEF, 2000). The nature of biofilms and their microbial composition is discussed in more detail in Chap. 9.

Process Operation Issues

Aerobic suspended growth processes are not without operational issues. Two important operational issues are sludge bulking and foaming as discussed below.

Sludge Bulking. A principal concern in activated sludge processes with clarifiers for liquid-solids separation is to maintain a good settling sludge. However, depending on the activated sludge tank configuration, environmental factors, and operating conditions, a poor settling sludge or *bulking sludge* can develop. The term bulking is derived from the observation that the volume of a given mass of sludge increases when poor settling occurs. For this reason, the sludge volume index (SVI) is used as an indicator of sludge settling properties. The SVI is defined as the volume (mL) occupied per g of settled sludge after 30 min of settling in a 1 to 2 liter graduated container. The onset of a bulking condition and potential settling problems in gravity solids separation correlates with SVI values greater than 150 mL/g. Other forms of the SVI tests are discussed in Chap. 8. In the extreme, bulking sludge can result in high effluent suspended solids concentrations and poor treatment performance. Many bulking conditions have been associated with a wide range of filamentous type bacteria, which grow as a string of attached single cells to great lengths outside the activated sludge floc (Jenkins et al., 2004).

Foaming. Another nuisance condition in the activated sludge system is foaming, which has been related to the development of bacteria with hydrophobic cell surfaces that attach to air bubbles (see Fig. 7–18). One type results in a thick brown viscous foam layer on the activated sludge surface with bubbles that collapse inward and has been referred to as *Nocardia* foaming because of the name given to the type of bacteria observed under the microscope. However, most of the foam-causing organisms observed in activated sludge

Figure 7–18

Examples of foam caused by *Gordonia amarae* accumulated on the surface of activated sludge aeration tanks.

(a) (b)

are contained in the phylum *Actinobacteria* and include the nocardia type or *Gordonia amarae* under the Mycolata morphytes and *Candidatus Microthrix parvicella* (Seviour et al., 2008). The organisms can be found at high concentrations in the foam above the activated sludge liquid. The above types of nuisance organisms along with others are considered in Chap. 8.

Stoichiometry of Aerobic Biological Oxidation

The stoichiometry for aerobic oxidation was discussed previously but is repeated here for completeness. In aerobic oxidation, the conversion of organic matter is carried out by mixed bacterial cultures in general accordance with the stoichiometry shown below.

$$\underset{\substack{\text{Organic}\\\text{matter}}}{\text{COHNS}} + O_2 + \text{nutrients} \xrightarrow{\text{bacteria}} CO_2 + NH_3 + \underset{\text{new cells}}{C_5H_7NO_2} + \begin{matrix}\text{other}\\\text{end}\\\text{products}\end{matrix} \tag{7–85}$$

Endogenous respiration:

$$C_5H_7NO_2 + O_2 \xrightarrow{\text{bacteria}} 5CO_2 + 2H_2O + NH_3 + \text{energy} \tag{7–86}$$

In Eq. (7–85), COHNS is used to represent the organic matter in wastewater, which serves as the electron donor while the oxygen serves as the electron acceptor. Although the endogenous respiration reaction [Eq. (7–86)] is shown as resulting in relatively simple end products and energy, stable organic end products are also formed. If all of the cells (i.e., the electron donor) were oxidized completely, the UBOD or COD of the cells is equal to 1.42 times the concentration of cells as VSS [see Eq. (7–5)]. At longer SRT values, a greater portion of the cells will be oxidized.

Using the half reactions given in Table 7–6, the stoichiometry for the aerobic oxidation of acetate (the electron donor) can be represented as given below, assuming ammonia will serve as the nitrogen source for cell tissue, oxygen is the electron acceptor, and f_s for the reaction is 0.59 (see Example 7–4).

$$\begin{aligned}0.125CH_3COO^- + 0.0295NH_4^+ + 0.103O_2 \rightarrow\ & 0.0295C_5H_7O_2N + 0.0955H_2O\\ & + 0.0955HCO_3^- + 0.007CO_2\end{aligned} \tag{7–87}$$

Growth Kinetics

The form of the rate expressions for substrate utilization and biomass growth for the heterotrophic oxidation of organic substrates, based on the stoichiometry given above, were presented previously but are repeated below for ease of reference.

$$r_{su} = \frac{kXS}{K_s + S} \tag{7–12}$$

$$r_x = Yr_{su} - bX \tag{7–21}$$

$$= Y\frac{kXS}{K_s + S} - bX \tag{7–22}$$

These expressions, as noted previously, are similar to the saturation equation proposed by Monod (1942) for growth and the Michaelis-Menten equation for substrate utilization (Bailey and Ollis, 1986). Typical k and K_s values at 20°C vary from 8 to 12.0 g COD/g VSS·d and 10 to 40 g bsCOD/m^3, respectively. As noted in Sec. 7–3, the K_s value can vary depending on the nature and complexity of the bsCOD components. For easily biodegradable single substrates, K_s values of less than 1.0 mg bsCOD/L have been measured (Bielefeldt and Stensel, 1999).

Applying the above expressions for substrate utilization and biomass growth leads to the development of a series of design parameters including the solids retention time (SRT), the *food to microorganism ratio* (F/M), and the *specific utilization rate* (U). These design parameters are applied to the design of a variety of activated sludge processes in Chap. 8. With the exception of some difficult-to-degrade constituents in industrial wastewaters, the kinetics for aerobic oxidation of organic substrates seldom control the SRT design value for the activated sludge process. For good floc formation, sufficient time is needed for the biomass in the activated sludge aeration tank to develop extracellular polymers and a floc structure. More optimal flocculation and TSS removal in clarification occur typically at SRT values greater than 2.5 to 3.0 d at 20°C and 3 to 5 d at 10°C. However, some wastewater-treatment plants in warmer climates operate at SRT values varying from less than 1 to 1.5 d. High purity oxygen systems routinely operate at low SRT values. Excessively long SRTs (>20 d) may lead to floc deterioration with the development of small pinpoint floc particles that produce a more turbid effluent. However, even with pinpoint floc, effluent suspended solids concentrations of less than 30 mg/L are generally achieved. The SRT may be varied in treatment plant operations to find the most optimal settling condition.

Environmental Factors

For carbonaceous removal, pH in the range of 6.0 to 9.0 is tolerable, while optimal performance occurs near a neutral pH. A reactor DO concentration of 2.0 mg/L is used commonly, and at concentrations above 0.50 mg/L there is little effect of the DO concentration on the degradation rate. Where industrial wastewaters are discharged to municipal collection systems, care must be taken to assure that sufficient nutrients (N and P) are available for the amount of bsCOD to be treated. Heterotrophic bacteria responsible for BOD removal can tolerate higher concentrations of toxic substances as compared to the bacteria and archaea responsible for ammonia oxidation or the production of methane.

7–9 BIOLOGICAL OXIDATION OF INORGANIC NITROGEN

The need to oxidize ammonia (NH_4-N) and nitrite (NO_2-N) in wastewater treatment arises from water quality concerns over (1) the effect of ammonia on receiving water with respect to DO concentrations and fish toxicity, (2) the need to provide nitrogen removal to control eutrophication, and (3) the need to provide nitrogen control for water-reuse applications including groundwater recharge. For reference, the current (2001) drinking water maximum contaminant level (MCL) for nitrate is 45 mg/L as nitrate or 10 mg/L as nitrogen. The total concentration of organic and ammonia nitrogen in municipal wastewaters is typically in the range from 25 to 45 mg/L as nitrogen based on a flowrate of 380 L/capita·d (100 gal/capita·d). In many parts of the world with limited water supplies, total nitrogen concentrations in excess of 200 mg/L as N have been measured in domestic wastewater.

Nitrification is the term used to describe the two-step biological process in which one type of autotrophic bacteria oxidize ammonia to nitrite (NO_2-N) and a second type of autotrophic bacteria oxidize nitrite to nitrate (NO_3-N). Nitritation is the term used to describe a biological process with oxidation of NH_4-N to only NO_2-N. Nitification occurs in most aerobic suspended growth and fixed film biological process designs used to accomplish ammonia or nitrogen removal, but nitritation processes are also used in which the growth of autotrophic bacteria that oxidize nitrite to nitrate is prevented or inhibited.

Nitritation is a key factor in processes that reduce or eliminate carbon requirements for nitrogen removal. These include the SHARON Process (Single Reactor System for High Activity Ammonia Removal Over Nitrite) (Hellinga et al., 1998) and the ANAMMOX Process (Anaerobic Ammonia Oxidation) (Mulder et al., 1995), which are introduced and discussed in detail in Chap. 15 under sidestream treatment technologies. Nitritation may also occur in activated sludge "simultaneous nitrification-denitrification" (SNdN) systems or biological fixed film systems treating influent wastewater under limited dissolved oxygen conditions.

For many decades since Winogradsky's (1890) isolation of *Nitrosomonas*, the common believe was that autotrophic aerobic bacteria are responsible for ammonia and nitrite oxidation. However, Strous et al. (1999a) reported a novel bacteria capable of oxidizing ammonia with nitrite under anaerobic conditions (Anammox Process), and Konneke et al. (2005) showed that ammonia oxidation is not limited to that by bacteria and can be done by organisms of the domain Archaea. The first *ammonia-oxidizing archaea* (AOA) isolate was obtained from a marine aquarium tank and named *Candidatus Nitrosopumilus maritimus* (Konneke et al., 2005). Since then, the presence of AOA in activated sludge wastewater treatment systems has been identified by Park et al. (2006), Wells et al. (2009), Zhang et al. (2011), and Limpiyakorn et al. (2011). It has been reported that AOA were dominant over AOB in a membrane bioreactor system (MBR) at high mixed liquor concentrations (>8,000 mg/L) and low DO concentration (<0.20 mg/L), but that this dominance decreased following operation during months with colder temperatures Giraldo et al. (2011a, 2011b).

Process Description

As with BOD removal, nitrification can be accomplished in both suspended growth and attached growth biological processes. For suspended growth processes, a more common approach is to achieve nitrification along with BOD removal in the same single-sludge process, consisting of an aeration tank, clarifier, and sludge recycle system [see Fig. 7–19(a)]. In cases where there is a significant potential that the wastewater may contain toxic and inhibitory substances, a two-sludge suspended growth system may be considered [see Fig. 7–19(b)]. The two-sludge system consists of two aeration tanks and two clarifiers in series with the first aeration tank/clarifier unit operated at a short SRT for BOD removal. The BOD and toxic substances are removed in the first unit, so that nitrification can proceed unhindered in the second. A portion of influent wastewater usually has to be bypassed to the second sludge system to provide a sufficient amount of solids for efficient solids flocculation and clarification. A two-sludge suspended growth system has also been used in biological nitrogen removal systems (Boehnke et al., 1997, WERF, 2010) as an approach to sustainable environmental engineering by reducing aeration energy needs and increasing sludge wasting to anaerobic digesters to enhance biomethane production [see Fig. 7–19(c)]. The first sludge system is operated with a short SRT and high BOD loading rate. The second sludge system is operated at a longer SRT to promote ammonia oxidation. The bacteria responsible for nitrification grow much more slowly than heterotrophic bacteria, so that systems designed for nitrification generally have much longer hydraulic and solids retention times than those for systems designed only for BOD removal.

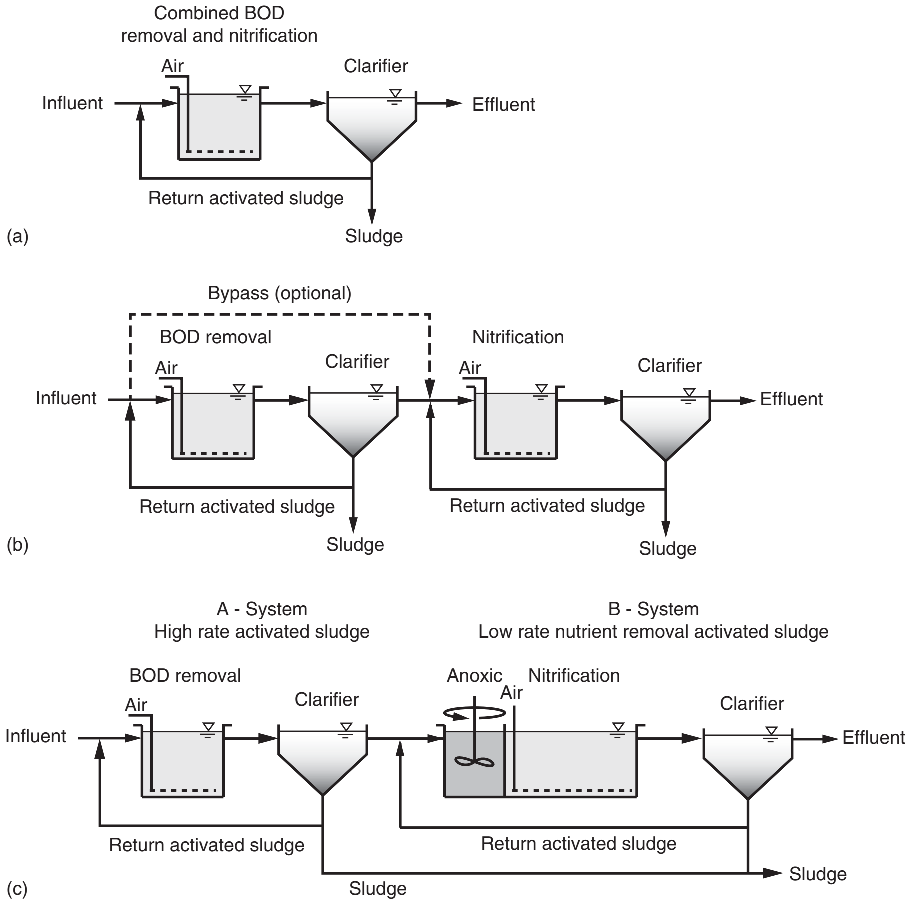
In attached growth systems used for nitrification, most of the BOD must be removed before nitrifying organisms can be established. The heterotrophic bacteria have a higher biomass yield and thus can dominate the surface area of fixed-film systems over nitrifying bacteria. Nitrification is accomplished in an attached growth reactor after BOD removal or in a separate attached growth system designed specifically for nitrification. The design of attached growth biological systems is described in Chap. 9.

Microbiology

Ammonia-oxidizing bacteria (AOB) and *nitrite-oxidizing bacteria* (NOB) are aerobic chemoautotrophs because they use CO_2 for their carbon source and require dissolved oxygen to oxidize an inorganic compound (NH_4-N or NO_2-N) to obtain cell energy. The

Figure 7–19

Process configuration used for biological nitrification: (a) single-sludge suspended growth system, (b) two-sludge suspended growth system, and (c) AB Process (A-system with high rate activated sludge, B-system with low rate nutrient removal activated sludge) (Boehnke et al., 1997).



phylogenetic distribution of AOB and NOB is based on differences in 16S ribosomal RNA (rRNA) sequences (Rowan et al., 2003) and are classified under the *α-Proteobacteria* and *β-Proteobacteria*. The AOB under the *α-Proteobacteria* are found in marine environments and thus not important for wastewater treatment applications. The AOB in the *β-Proteobacteria* are divided into two genera: the *Nitrosomonas* and the *Nitrosospira* (Purkhold et al., 2000 and Koops and Pommerening-Roser, 2001).

Distribution of AOB and NOB. The phylogenetic distribution of AOB within these genera is summarized in Table 7–9. There are five sub clusters under *Nitrosomonas* and two of these, *N. marina* and *N. cryotolerans*, are obligate halophilic bacteria and thus of less importance in wastewater treatment. The remaining three are *europaea/eutropha*, *N. communis*, *N. oligotropha*.

The NOB phylogeny, summarized in Table 7–10, has more diversity with four genera in three Proteobacteria groups. *Nitrobacter* are within *α-Proteobacteria, Nitrococcus* within *γ-Proteobacteria*, and *Nitrospina* and *Nitrospira* within the *δ-Proteobacteria*. Of these, the *Nitrospira marina,* the *Nitrospina gracilis,* and *Nitrococcus mobilis* are obligate halophilic bacteria and are less important to wastewater treatment. While *Nitrobacter* generally occur as free cells, *Nitrospira* are more commonly observed attached to flocs or biofilms in their natural environments.

Table 7–9

Phylogeny of Ammonia-Oxidizing Bacteria [Adapted from Koops and Pommerening-Roser (2001) and Ward et al. (2011)]

Subclass of Proteobacteria	Genus	Sub Clusters	Species
β-Proteobacteria	*Nitrosomonas*	*europaea-mobilis*	*Nitrosomonas europea*
			Nitrosomonas eutropha
			Nitrosomonas halophilar
			Nitrosococcus mobilis
		communis	*Nitrosomonas communis*
			Nitrosomonas sp. I
			Nitrosomonas sp. II
			Nitrosomonas nitrosa
		oligotrophia	*Nitrosomonas ureae*
			Nitrosomonas oligotropha
		marina	*Nitrosomonas marina*
			Nitrosomonas sp.III
			Nitrosomonas aestuarii
			Nitrosomonas cryotolerans
	Nitrosospira	*nitrosospira*	*Nitrosolobus multiformis*
			Nitrosovibrio tenuis
			Nitrosospira sp. I

Molecular Tools. Molecular tools have been helpful for the evaluation of nitrifying cultures in suspended growth and fixed film nitrification systems. Using oligonucleotide probes for ammonia-oxidizing bacteria, Wagner et al. (1995) showed that *Nitrosomonas* was common in activated sludge systems. A review by Geets et al. (2006) of molecular biology studies of nitrifying populations in wastewater treatment facilities found that the genus *Nitrosomonas* often dominates the AOB population with a few studies showing domination by the Nitrosospira-related strains. A review of population studies of NOB in

Table 7–10

Phylogeny of Nitrite-Oxidizing Bacteria [Adapted from Koops and Pommerening-Roser (2001)]

Subclass of Proteobacteria	Genus	Species
α-Proteobacteria	Nitrobacter	*Nitrobacter alkalicus*
		Nitrobacter winogradskyi
		Nitrobacter vulgaris
		Nitrobacter hamburgenis
γ-Proteobacteria	Nitrococcus	*Nitrococcus mobilis*
	Nitrospina	*Nitrospina gracilis*
δ-Proteobacteria	Nitrospira	*Nitrospira moscoviensis*
		Nitrospira marina

wastewater facilities (Kim et al., 2006) found that, contrary to the commonly accepted idea that Nitrobacter were the major nitrite-oxidizers, the genus Nitrospira was the more common dominant population. Teske et al. (1994) also found that *Nitrococcus* was quite prevalent in fixed film nitrification systems.

Diverse populations are also found for activated sludge and fixed film systems. Siripong and Rittman (2007) found that coexistence of AOB *Nitrosomonas* and *Nitrosospira* genera and NOB *Nitrobacter* and *Nitrospira* genera was found in studies of seven activated sludge facilities in the Metropolitan Water Reclamation District of Greater Chicago (MWRDGC). Diversity of AOB in an aerated-anoxic process was also noted by Park et al., (2002) in which they observed both *Nitrosomonas* and *Nitrosospira*. Varying growth conditions in a nitrification system may encourage the development of diverse populations as reported for NOB by Daims et al. (2001) for a sequencing batch reactor (SBR) operation. Higher nitrite concentrations during the initial aerobic cycle were thought to favor *Nitrobacter* growth but later at lower nitrite concentrations *Nitrospira* growth was favored. Coskuner and Curtis (2002) also reported on the co-existence of *Nitrospira* and *Nitrobacter* in a full scale activated sludge plant. Dytczak et al. (2008) suggested that different growth conditions in an aerobic-only SBR versus an anoxic-aerobic SBR selected for different AOB populations with different nitrification kinetics with higher rates seen for the anoxic-aerobic system.

Dominant Nitrifying Bacteria. The nitrifying bacteria that dominate a biological suspended growth or fixed film process are assumed to be the result of selective pressures, such as NH_4-N or NO_2-N concentration, DO concentration, pH, salinity, and temperature in the bioreactor. In terms of the nitrogen and DO concentration, the bacteria are divided into r-and K-strategists (Andrews and Harris, 1986). The r-strategists grow slower than the K-strategists at low substrate concentration, but grow faster than the K-strategists at higher substrate concentration. The nitrifying bacteria with high substrate affinity at low concentration (K-strategists) are *Nitrosospira* and *Nitrospira* for AOB and NOB, respectively (Schramm et al., 1999), while the AOB *Nitrosomonas Europea* and NOB *Nitrobacter* spp. grow faster at high concentration (r-strategists). Kim et al. (2006) found that low NO_2-N concentrations favored growth of *Nitrospira* and high NO_2-N concentrations favored *Nitrobacter*, which had a specific NO_2-N utilization rate five times greater than that for *Nitrospira*. Park and Noguera (2004) showed a population shift for AOB growing at high DO concentration (8.5 mg/L) versus growth at low DO concentration (0.12 to 0.24 mg/L) in laboratory reactors seeded with a wastewater facility activated sludge. However, the population change was not to a genera associated with low DO growth, but to bacteria under a *Nitrosomonas Europea* linkage.

Stoichiometry of Biological Nitrification

The energy-yielding two-step oxidation of ammonia to nitrate is as follows:
Nitroso-bacteria (Nitritation):

$$2NH_4^+ + 3O_2 \rightarrow 2NO_2^- + 4H^+ + 2H_2O \tag{7–88}$$

Nitro-bacteria:

$$2NO_2^- + O_2 \rightarrow 2NO_3^- \tag{7–89}$$

Total oxidation reaction:

$$NH_4^+ + 2O_2 \rightarrow NO_3^- + 2H^+ + H_2O \tag{7–90}$$

Based on the above total oxidation reaction, the oxygen required for the complete oxidation of ammonia is comprised of 4.57 g O_2/g NH_4-N oxidized, 3.43 g O_2/g NH_4-N for oxidation of NH_4-N to NO_2-N, and 1.14 g O_2/g NO_2-N for NO_2-N oxidation to NO_3-N. Neglecting cell tissue, the amount of alkalinity required to carry out the reaction given in Eq. (7–88) can be estimated by writing Eq. (7–90) as follows:

$$NH_4^+ + 2HCO_3^- + 2O_2 \rightarrow NO_3^- + 2CO_2 + 3H_2O \tag{7–91}$$

In the above equation, 2 moles of alkalinity are consumed per mole of NH_4-N oxidized, which is equal to 7.14 g of alkalinity as $CaCO_3$ consumed per g of NH_4-N oxidized [2 × (50 g $CaCO_3$/eq)/14]. The actual amount of oxygen and alkalinity consumed per unit of ammonia removed in nitrification systems is less than that predicted by the above stoichiometric equations because some of the ammonia removed is incorporated into the biomass produced during nitrification.

The estimated cell yields from nitrification vary widely. Biomass growth yields for AOB are 0.33 g VSS/g NH_4-N based on energetics calculations (Rittman and McCarty, 2001) and from 0.10 to 0.15 from experimental results (U.S. EPA, 1993, Haug and McCarty, 1972 and Fang et al., 2009). Biomass growth yields for NOB are 0.08 g VSS/g NH_4-N based on energetics calculations (Rittman and McCarty, 2001) and from 0.04 to 0.07 from experimental results (U.S. EPA, 1993, Haug and McCarty, 1972 and Fang et al., 2009).

Assuming a synthesis yield value of 0.12 g VSS per g NH_4-N oxidized to NO_2-N and the addition of alkalinity for NH_4-N oxidation, the following stoichiometric equation can be written for nitritation.

$$\begin{aligned} &NH_4(HCO_3) + 0.9852Na\,(HCO_3) + 0.07425CO_2 + 1.4035O_2 \rightarrow \\ &\qquad 0.01485C_5H_7NO_2 + 0.9852NaNO_2 + 2.9406H_2O + 1.9852CO_2 \end{aligned} \tag{7–92}$$

The amount of oxygen needed for the nitritation reaction shown in Eq (7–92) is 3.21 g O_2 per g NH_4-N oxidized to NO_2-N, which can be compared to a value of 3.43 [Eq. (7–88)] for nitritation without considering nitrogen used for cell synthesis.

To complete nitrification and assuming a synthesis yield coefficient of 0.04 g VSS/g NO_2-N the overall nitrification reaction can be written as follows:

$$\begin{aligned} &NH_4(HCO_3) + 0.9852Na\,(HCO_3) + 0.0991CO_2 + 1.8675O_2 \rightarrow \\ &\qquad 0.01982C_5H_7NO_2 + 0.9852NaNO_3 + 2.9232H_2O + 1.9852CO_2 \end{aligned} \tag{7–93}$$

From the above equation, for each g of NH_4-N converted to NO_3-N, 4.25 g of O_2 are utilized, 0.16 g of biomass is formed, and 7.09 g of alkalinity as $CaCO_3$ is consumed. The oxygen required to oxidize 1.0 g of NH_4-N to NO_3-N (4.27 g) is less than the theoretical value of 4.57 g computed using Eq. (7–88), which did not consider the portion of ammonia used for cell synthesis. Similarly, the alkalinity required for nitrification in Eq. (7–93) (7.09 g/g) is less than the value of 7.14 g/g. It should be recognized that the coefficient values in Eq. (7–93) are dependent upon the assumed biomass yield values. A lower net nitrifier biomass yield would have resulted in a value higher than 4.25 g O_2 per g of NH_4-N converted to NO_3-N. Werzernak and Gannon (1967) found a total oxygen consumption for nitrification of 4.33 g O_2/g N with 3.22 g O_2/g N used for NH_4-N oxidation and 1.11 g O_2/g N used for NO_2-N oxidation. These values compare to 3.21 g O_2/g N used for NH_4-N oxidation and 1.06 g O_2/g N used for NO_2-N oxidation for the above biomass synthesis assumptions and stoichiometric equations shown.

The wastewater nitrogen concentration, BOD concentration, alkalinity, temperature, and potential for toxic compounds are major issues in the design of biological nitrification processes. Nitrifying bacteria need CO_2 and phosphorus for cell growth, as well as trace elements. With such a low cell yield, the CO_2 in air is adequate, and phosphorus is seldom a concern unless metal salts are added to primary treatment or other upstream processes for phosphorus removal. Trace element concentrations that have been found to stimulate the growth of nitrifying bacteria in pure culture work are: Ca = 0.50, Cu = 0.01, Mg = 0.03, Mo = 0.001, Ni = 0.10, and Zn = 1.0 mg/L (Poduska, 1973).

Nitification Kinetics

The Monod growth kinetics model is commonly used to describe NH_4-N and NO_2-N oxidation kinetics. The specific growth rate of AOB and NOB is a function of the concentration of the respective nitrogen species being oxidized, DO concentration, and endogenous decay rate as shown in Eqs. (7–94) and (7–95). For completely mixed activated sludge systems at temperatures below 25°C, the process has normally been modeled by considering only the AOB, as the NOB are able to use nitrite much faster and therefore minimal NO_2-N is present. However, at temperatures above 28°C or at low DO concentrations (below 0.50 mg/L), the kinetics of both groups must be considered as the effect of higher temperature and low DO favors AOB over NOB such that the NH_4-N concentration may be lower than the NO_2-N concentration. The difference between AOB and NOB kinetics at high temperatures is an underlying principle of the SHARON® process for nitrogen removal, which is described in Sec. 15–9 in Chap. 15. Concentrations of NO_2-N may also be significant in batch fed systems or for aerobic reactors in series, and thus it is appropriate to model both AOB and NOB activity (Chandran and Smets, 2000 and Wett et al., 2011).

Modeling both species is also useful for predicting transient operating conditions. During the initiation of nitrification, NO_2-N concentrations will be greater than NH_4-N concentrations, as the growth of NOB cannot occur until the AOB generate nitrite. Under transient conditions, NO_2-N concentrations of 5 to 20 mg/L are possible.

The Monod models given below account for the effects of the reactor nitrogen and DO concentrations and endogenous decay on the specific growth rate of AOB or NOB.

$$\mu_{\mathrm{AOB}} = \mu_{\mathrm{max,AOB}}\left(\frac{S_{\mathrm{NH}}}{S_{\mathrm{NH}} + K_{\mathrm{NH}}}\right)\left(\frac{S_o}{S_o + K_{\mathrm{o,AOB}}}\right) - b_{\mathrm{AOB}} \tag{7–94}$$

$$\mu_{\mathrm{NOB}} = \mu_{\mathrm{max,NOB}}\left(\frac{S_{\mathrm{NO}}}{S_{\mathrm{NO}} + K_{\mathrm{NO}}}\right)\left(\frac{S_o}{S_o + K_{\mathrm{o,NOB}}}\right) - b_{\mathrm{NOB}} \tag{7–95}$$

Where μ_{AOB} = specific growth rate of ammonia-oxidizing bacteria, g VSS/g VSS·d
μ_{NOB} = specific growth rate of nitrite-oxidizing bacteria, g VSS/g VSS·d
$\mu_{\mathrm{max,AOB}}$ = maximum specific growth rate of ammonia-oxidizing bacteria, g VSS/g VSS·d
$\mu_{\mathrm{max,AOB}}$ = maximum specific growth rate of nitrite-oxidizing bacteria, g VSS/g VSS·d
b_{AOB} = specific endogenous decay rate of ammonia-oxidizing bacteria, g VSS lost/g VSS·d
b_{NOB} = specific endogenous decay rate of nitrite-oxidizing bacteria, g VSS lost/g VSS·d
S_{NH} = NH_4-N concentration, mg/L
K_{NH} = half-velocity coefficient for NH_4-N, mg/L
S_o = DO concentration, mg/L
$K_{o,\mathrm{AOB}}$ = half-velocity coefficent for DO for AOB, mg/L
S_{NO} = NO_2-N concentration, mg/L
K_{NO} = half-velocity coefficient for NO_2-N, mg/L
$K_{o,\mathrm{NOB}}$ = half-velocity coefficent for DO for NOB, mg/L

The maximum specific growth rate and specific endogenous decay rate coefficients are known to be a function of temperature and are modeled according to Eq. (1–44) in which the value for any temperature is related to the value at 20ºC and the temperature correction coefficient, θ.

$$\mu_{\max,T} = \mu_{\max,20}(\theta^{T-20}) \tag{7–96}$$

$\mu_{\max,T}$ = maximum specific growth rate coefficient at temperature T, ºC
$\mu_{\max,20}$ = maximum specific growth rate coefficient at 20ºC
θ = temperature coefficient

$$b_T = b_{20}(\theta^{T-20}) \tag{7–97}$$

Where b_T = endogenous decay coefficient at temperature T, ºC
b_{20} = endogenous decay coefficient at 20ºC

For a completely mixed activated sludge system (CMAS) operated at steady state conditions, the specific growth rate is the inverse of the SRT.

$$\mu_{\text{AOB}} = \frac{1}{\text{SRT}} \tag{7–98}$$

By combining Eqs (7–46) and (7–98), the effluent NH_4-N concentration can be determined using Eqs (7–99) and (7–100) at steady state operation for a CMAS as a function of the SRT and DO concentration and kinetic coefficients.

$$S_{\text{NH}} = \frac{K_{\text{NH}}[1 + b_{\text{AOB}}(\text{SRT})]}{\text{SRT}(\mu_{\max,\text{AOB,DO}} - b_{\text{AOB}}) - 1.0} \tag{7–99}$$

Where SRT = solids retention time, d
$\mu_{\max,\text{AOB,DO}} = \mu_{\max,\text{AOB}}$ corrected for DO concentration, g/g·d

$$\mu_{\max,\text{AOB,DO}} = \frac{(\mu_{\max,\text{AOB}})(S_o)}{(S_o + K_{o,\text{AOB}})} \tag{7–100}$$

A similar set of equations can be used to describe the NO_2-N concentrations for a CMAS reactor at steady state conditions.

The ammonia oxidation rate (r_{NH}, g/m^3·d) is a function of nitrification kinetics and reactor NH_4-N, DO and AOB concentrations as described by the general expression in Eq. (7–101). For a steady state operating condition, AOB concentration (X_{AOB}) is determined by applying Eq. (7–42) for oxidation of substrate as NH_4-N.

$$r_{\text{NH}} = \left(\frac{\mu_{\max,\text{AOB}}}{Y_{\text{AOB}}}\right)\left(\frac{S_{\text{NH}}}{S_{\text{NH}} + K_{\text{NH}}}\right)\left(\frac{S_o}{S_o + K_{o,\text{AOB}}}\right)X_{\text{AOB}} \tag{7–101}$$

$$X_{\text{AOB}} = \frac{Q(Y_{\text{AOB}})(N_{OX})\text{SRT}}{V[1 + b_{\text{AOB}}(\text{SRT})]} \tag{7–102}$$

Where: X_{AOB} = AOB concentration, g/m^3
Q = average daily influent flowrate, m^3/d
N_{OX} = NH_4-N oxidized by AOB from influent, g/m^3
V = volume of reactor containing AOB, m^3

The NH_4-N oxidation rate for AOB as a function of the biomass growth conditions [system SRT, average amount of NH_4-N oxidized daily (QN_{Ox}), and reactor volume] and reactor NH_4-N and DO concentrations is obtained by combining Eqs. (7–101) and (7–102).

$$r_{\mathrm{NH}} = \mu_{\max,\mathrm{AOB}}\left(\frac{S_{\mathrm{NH}}}{S_{\mathrm{NH}} + K_{\mathrm{NH}}}\right)\left(\frac{S_o}{S_o + K_{o,\mathrm{AOB}}}\right)\left\{\frac{Q(N_{ox})\mathrm{SRT}}{V[1 + b_{\mathrm{AOB}}(\mathrm{SRT})]}\right\} \tag{7–103}$$

Equations (7–99) and (7–103) can be used for two different types of tests to obtain nitrification kinetics. In the first case, the effluent NH_4-N concentration is measured at different operating steady-state SRT values to fit Eq. (7–99) to obtain the maximum specific growth rate, $\mu_{\max,\mathrm{AOB}}$ at a given temperature. Equation (7–103) is used with batch test data to obtain kinetic parameter values. Sufficient operating data on feed flowrate and NH_4-N oxidized at a constant SRT are needed before collecting test data to quantify biomass growth conditions. During the batch tests r_{NH} versus S_{NH} is measured with time and used in model fitting to obtain $\mu_{\max,\mathrm{AOB},}$ K_{NH}, $K_{\mathrm{o,AOB}}$, or $\mathrm{b}_{\mathrm{AOB.}}$ It should be noted that in both cases the value used for the endogenous decay rate, $\mathrm{b}_{\mathrm{AOB}}$, affects the calculated $\mu_{\max,\mathrm{AOB}}$ value.

AOB Kinetics

Values reported for $\mu_{\max,\mathrm{AOB}}$ have varied widely, ranging from 0.33 to 1.0 g/g•d at 20ºC, (Sedlak, 1991 and Randall et al., 1992). The values used for the specific decay rate coefficient ($\mathrm{b}_{\mathrm{AOB}}$) in nitrification kinetic studies have a major affect on the $\mu_{\max,\mathrm{AOB}}$ value. The selection of lower specific decay rate coefficient values results in higher $\mu_{\max,\mathrm{AOB}}$ values and vice versa. Thus, it is difficult to compare nitrification kinetic values between studies without an accurate value for $\mathrm{b}_{\mathrm{AOB}}$ (Dold et al., 2005). In early work on nitrification kinetics, the specific endogenous decay rate was believed to be very low and generally ignored, with recommended 20ºC $\mu_{\max,\mathrm{AOB}}$ values of 0.65 g/g•d (U.S. EPA, 1993) and 0.76 g/g•d (Downing et al., 1964). When considering the 20ºC endogenous decay coefficient value of 0.17 g/d•d, determined in a separate test method, a $\mu_{\max,\mathrm{AOB}}$ value of 0.90 g/g•d was recommended in a Water Environment Research Foundation (WERF) study (Melcer et al., 2003). The values of the temperature coefficient, θ, for these findings were 1.072 and 1.029 for $\mu_{\max,\mathrm{AOB}}$ and b, respectively.

Effect of Operating Conditions. The activated sludge operating conditions may affect the type of AOB selected and observed nitrification kinetics. Wett et al. (2011) claimed that two types of AOB, the "*r*" (or *u*) strategist and "*K*" strategist, may be present in the same activated sludge system with different proportions depending on the operation conditions. The *r*-strategist have higher specific growth rates and are favored by growth with higher NH_4-N concentrations. The *K*-strategist are the opposite, being more competitive at growth at lower NH_4-N concentrations and have lower half-velocity values (K_{NH}) then the *r* strategist. The effect of an increasing recycle ratio on decreasing $\mu_{\max}$ in a full scale activated sludge system with recycle from the aerobic nitrification tank back to an upstream anoxic tank was accounted for by modeling with the two types of AOB populations. Based on the modeling results, the fraction of *K*-strategist AOBs increased as the internal recycle ratio increased. Values for $\mu_{\max}$ and K_{NH} at 20°C used in the modeling for *K*- and *r*-strategists were 0.75 g/g•d and 0.30 g/m^3 and 0.95 g/g•d and 0.70 g/m^3, respectively. Based on nitrification pilot plant results from treating municipal wastewater, Munz et al. (2010) claimed that initial growth with a 20-d SRT favored *K*-strategist AOB over *r*-strategists at growth at an 8-d SRT. The 20ºC $\mu_{\max}$ values were 0.49 and 0.72 g/g•d, respectively, and the specific endogenous decay coefficient value of 0.10 g/g•d was applied in both cases.

Half-Velocity Constant. The half-velocity coefficient, K_{NH}, is an important kinetic parameter in the application of the Monod model to nitrification reactor design. Lower K_{NH} values predict lower effluent NH_4-N concentrations for a given aerobic SRT. The K_{NH}

values are affected by the system growth conditions and nitrifying bacteria selection of *r* versus *K*-strategist. Examples of widely varying literature values are 0.14 to 5.0 g/m^3 (Sin et al., 2008a) and 0.60 to 3.6 g/m^3 (U.S. EPA, 1993). Based on full scale plant performance K_{NH} values between 0.30 and 0.70 g/m^3 may be expected. In more recent models, no effect of temperature is assumed on the K_{NH} value (Henze et al., 1998 and Henze et al., 2008).

Specific Endogenous Decay. The AOB 20ºC specific endogenous decay coefficient value in aerobic activated sludge of 0.17 g/g·d for AOB reported by Melcer et al. (2003) is in general agreement with 0.17 g/g·d by Copp and Murphy (1995) and 0.15 g/g·d reported by Manser et al. (2006). Salem et al. (2006) obtained a AOB decay coefficient of 0.20 g/g·d at 23.5ºC from studies at a full-scale activated sludge facility, which is in close agreement the specific endogenous decay coefficient value of 0.17 g/d·d and temperature θ value by Melcer et al. (2003). During the anoxic phase of anoxic-aerobic activated systems, specific endogenous decay coefficients for AOB have been reported to be about 50 percent of that in the aerobic zone (Salem et al., 2006; Lee and Oleszkiewicz, 2003; Nowak et al., 1994; and Siegrist et al., 1999).

NOB Kinetics

In many applications the nitrification process has been designed adequately considering only AOB kinetics. For fully acclimated complete-mix activated sludge nitrification systems, at temperatures below 25°C with sufficient DO present, the NO_2-N concentration may be less than 0.10 mg/L as compared to NH_4-N concentrations in the range of 0.50 to 1.0 mg/L. However, there are cases where it is important to apply a two-step kinetic model for NH_4-N oxidation to NO_2-N by AOB and NO_2-N oxidation to NO_3-N by NOB. During the initial start up of nitrification, NO_2-N concentrations will be greater than NH_4-N concentrations, as the NOB growth cannot occur until the AOB generate nitrite. Under transient conditions, NO_2-N concentrations of 5 to 20 mg/L are possible at low NH_4-N concentrations. Under low DO concentration operation applications NO_2-N concentrations can be higher than NH_4-N concentrations, which can only be predicted by the two-step kinetic model. NOB kinetics are also important in batch or staged activated sludge processes, in which NO_2-N concentrations can be elevated during the initial reaction time or initial stages. At temperatures above 27ºC the NOB kinetics become less favorable compared to AOB, and use of the two-step kinetic model has led to controlling nitritation in the SHARON® process used in sidestream treatment of anaerobic digestion centrate or filtrate, which is presented in Chap.15.

Effect of Operating Conditions. Compared to AOB there have been limited studies on NOB kinetics, and in most cases the kinetics have been developed from model fitting of pilot plant or bench-scale results. Nitrite oxidation kinetic coefficients summarized by Sin et al. (2008a) show a wide variation that is related to the systems tested, model structure, and model fitting methods. The maximum specific growth rates for NOB at 20ºC are frequently reported to be higher than that for AOB, with values of 1.33 g/d·d (Wett and Rauch, 2003), 1.8 g/g·d (Sin et al., 2008a), 1.0 g/g·d (Kaelin et al., 2009) and 0.70 g/g·d (Jones et al., 2007). The μ_{max} temperature correction θ value for NOB has been given as 1.06 (Wett and Rauch, 2003, and Jones et al., 2007). As noted above the NOB kinetics can vary depending on reactor operating conditions that favor *r*- or *K*-strategist NOBs (Kim et al., 2006).

Half-Velocity Constant. There is less work on half-velocity coefficients for nitrite oxidation by NOB. In a comparative study, investigators found that the NOB substrate half-velocity coefficient was slightly higher than that for AOB (Manser et al., 2005). However in a summary of half velocity coefficients for AOB and NOB prepared by Sin et al. (2008a), lower K_{NO} values were reported for NOB, ranging from 0.05 to 0.30 g/m^3 for four sources. Much lower half-velocity coefficient values for NOB versus that for AOB were also reported by Cuidad et al. (2006).

Specific Endogenous Decay. The specific endogenous decay coefficient value found for NOB has been reported to be the same as that for AOB (Copp and Murphy, 1995; Manser et al., 2006; and Salem et al., 2006). In addition, the same temperature correction as that used for AOB has been applied to NOB (Wett and Rauch, 2003; Kaelin et al., 2009).

Environmental Factors

Nitrification and nitritation rates are affected by a number of environmental factors including dissolved oxygen concentration, pH, toxicity, metals, and unionized ammonia.

Dissolved Oxygen Concentration. Nitrification rates are affected by the liquid DO concentration in activated sludge (attached growth effects are described in Chap. 9). In contrast to what has been observed for aerobic heterotrophic bacteria degradation of organic compounds, nitrification rates increase up to DO concentrations of 3 to 4 mg/L. To account for the effects of DO, the double Monod growth rate model as shown in Eqs. (7–94) and (7–95) includes the effect of both substrate and DO concentration, with values for the DO half-velocity constant, K_o, used to describe the impact of DO on the process kinetics. Substrate oxidation rates by heterotrophic bacteria are generally not affected until the liquid DO concentration is below 0.20 mg/L.

Dissolved Oxygen Inhibition. Observed NOB NO_2 oxidation rates are inhibited more at lower DO concentrations than that for AOB NH_4-N oxidation rates, with elevated NO_2-N concentrations found when DO concentrations are depressed (Picioreanu et al., 1997; Garrido et al., 1997; Peng and Zhu 2006; Contreras, et al. 2008). Values of K_o for AOB have been reported over a wide range, from 0.10 to 1.0 g/m^3 (Cuidad et al., 2006, and Sin et al., 2008a) but respective NOB K_o values are greater. The ratio of the NOB to the AOB DO half-velocity coefficient values for studies with both AOB and NOB were 2.36 (Guisasola et al., 2005) and 1.4 (Ciudad et al., 2006). Ratios of 2.5 (Wett and Rauch, 2003), 2.0 (Jones et al., 2007) and 3.0 (Sin et al., 2008b) were used in nitrification modeling applications. Absolute values of oxygen half-velocity coefficients depend on the operating and activated sludge floc conditions and possible diffusion limitations in addition to the bacterial affinity for DO.

Absolute values of oxygen half-velocity coefficients depend on more than just the affinity for DO by the AOB or NOB. Stenstrom and Song (1991) have shown experimentally that the effect of DO on nitrification is affected by the activated sludge floc size and density, and total oxygen demand of the mixed liquor. Nitrifying bacteria are distributed within a floc containing heterotrophic bacteria and other solids, with floc diameters ranging from 100 to 400 μm. Oxygen from the bulk liquid diffuses into floc particles, and bacteria deeper within the floc are exposed to lower DO concentrations. At higher organic loading rates, there is a greater substrate concentration in the mixed liquor, which causes a higher oxygen consumption rate within the floc. Therefore, a higher bulk liquid DO concentration is needed to maintain the same internal floc DO concentration and subsequent nitrification rate.

With regard to floc size, lower K_o values have been shown for membrane bioreactor (MBR) systems with smaller floc size versus activated sludge/clarifier systems with large floc sizes (Manser et al., 2005 and Daebel et al., 2007). Blackburne et al. (2007) varied the floc size of a *Nitrobacter* culture by sonication and found K_o values from approximately 0.4 g/m^3 for small and medium size flocs, to 1.7 g/m^3 for large flocs.

Hydrogen-Ion Concentration (pH). Optimal nitrification rates occur at pH values in the 7.5 to 8.0 range. Ammonia oxidation rates decline significantly at pH values below 7.0. The decrease in the ammonia oxidation rate at lower pH may be due to the reduction in free ammonia (NH_3) concentration, as it has been reported that NH_3-N may be the true substrate for AOB (Suzuki et al., 1974). At pH values near 5.8 to 6.0, the ammonia oxidation rates may be 10 to 20 percent of the rate at pH 7.0 (U.S. EPA, 1993). Using the data from this source, the following relationship can be used to describe the relative nitrification rate at a given pH below 7.0 to that at pH 7.2.

$$\text{Relative nitrification rate} = \frac{NR_{pH}}{NR_{7.2}} = (0.0004017)e^{1.0946pH} \tag{7–104}$$

where: NR_{pH} = nitrification rate at pH
$NR_{7.2}$ = nitrification rate at pH = 7.2

Most observed pH effects on nitrification rates have been under transient conditions with cultures starting near a neutral pH. Long term acclimation at a lower pH could result in the selection of a different AOB species with much different rates at lower pH than the initial culture. Nitrification activity in a suspended growth reactor at pH values as low as 4.3 has been reported (Ward et al., 2011). The AOB community was dominated by *Nitrosomonas oligotropha* instead of *Nitrosomonas europaea* or *Nitrosomonas communis*, more common in activated sludge reactors.

To minimize possible inhibitory effects of low pH on nitrification rates, it is common to try to maintain an operational alkalinity value of 50–60 mg/L as $CaCO_3$, with a corresponding pH of 6.8 or greater. Alkalinity addition may be required for nitrification activated sludge treatment systems receiving wastewaters with low alkalinity or high ammonia concentrations. Alkalinity may be added in the form of lime, soda ash, sodium bicarbonate, or magnesium hydroxide depending on costs and chemical handling issues.

Toxicity. The AOB are the most sensitive nitrifying bacteria and their activity can be affected by a wide range of organic and inorganic compounds at concentrations well below those concentrations that would affect aerobic heterotrophic bacteria. In many cases, ammonia oxidation rates are inhibited, even though bacteria continue to grow and oxidize ammonia, but at significantly reduced rates. In some cases, toxicity may be sufficient to kill the nitrifying bacteria.

The AOB have been shown to be good indicators of the presence of organic toxic compounds at low concentrations (Blum and Speece, 1991). A comprehensive list of organic compounds that cause nitrification toxicity can be found in the Nutrient Control Design Manual (U.S. EPA, 2010). Compounds that are toxic include solvent organic chemicals, amines, proteins, tannins, phenolic compounds, alcohols, cyanates, ethers, carbamates, and benzene. Because of the numerous compounds that can inhibit nitrification, it is difficult to pinpoint the source of nitrification toxicity for wastewater plants with inhibition, and extensive sampling of the collection system is normally needed to find the source.

Metals. Metals are also of concern for nitrifiers. Skinner and Walker (1961) have shown complete inhibition of ammonia oxidation at 0.25 mg/L nickel, 0.25 mg/L chromium, and 0.10 mg/L copper.

Free Ammonia and Nitrous Acid Inhibition. Both AOB and NOB activity can be inhibited in systems that have high ammonia or nitrite concentrations, which can occur in aerobic digesters and in the treatment of high ammonia strength wastewaters, such as from anaerobic digester centrate return and animal feedlots. The compounds causing inhibition are un-ionized ammonia (NH_3-N) or free ammonia, and unionized nitrous acid (HNO_2). Their concentrations are a function of the reactor pH, temperature, and for NH_3-N, the total ammonia concentration or TAN (NH_3-N + NH_4-N), and for HNO_2, the NO_2-N concentration. The NH_3-N and HNO_2 concentrations can be estimated according the following equations (Anthonisen et al., 1976):

$$NH_3\text{-N} = \frac{\text{TAN}(10^{\text{pH}})}{(1/K_a) + 10^{\text{pH}}} \tag{7–105}$$

and

$$\frac{1}{K_a} = \exp[6334/(273 + T)] \tag{7–106}$$

where TAN = total NH_3-N + NH_4-N concentration, g/m^3
T = temperature, °C
K_a = ionization constant for ammonium

$$HNO_2\text{-N} = \frac{NO_2\text{-N}}{(K_n)(10^{\text{pH}})} \tag{7–107}$$

and

$$K_n = \exp[-2300/(273 + T)] \tag{7–108}$$

where HNO_2-N = free nitrous acid concentration as N, g/m^3
K_n = ionization constant for nitrous acid

At higher pH and temperature values, a greater fraction of the NH_3-N plus NH_4-N shifts to NH_3-N; at lower pH and temperature values a greater fraction of NO_2-N shifts to HNO_2-N.

Inhibition to AOB by NH_3-N was reported at 7.0 g/m^3 by Anthonisen et al. (1976). Complete loss of AOB activity at a 20 g/m^3 NH_3-N was found by Abeling and Seyfried (1992), but Wong-Chong and Loehr (1975) reported stable AOB activity at 50 g/m^3 NH_3-N following long term acclimation. Effects of AOB inhibition can occur in aerobic digestion of waste activated sludge due to NH_4-N accumulation under conditions of high intermittent feeding or limited DO concentrations. During solids digestion, protein from the activated sludge biomass is released and deamination produces NH_4-N and alkalinity. If the ammonia oxidation rate is not adequate relative to the NH_4-N production rate, the pH and NH_4-N increase and the NH_3-N concentration may increase to levels that inhibit AOB activity and cause further NH_4-N accumulation and inhibition. Possible TAN concentrations (NH_4 + NH_3) that may inhibit AOB at pH values from 7.0 to 8.5 and at temperatures from 20°C to 35°C are summarized in Table 7–11.

Inhibition to AOB by HNO_2, associated with high NO_2-N concentration, was reported at 0.065 to 0.83 g/m^3 by Anthonisen et al. (1976). For example at 20°C, the respective inhibitory NO_2-N concentration is estimated at 80 to 990 mg/L at pH 6.5. At a pH of 6.8, temperature of 30°C, and NO_2-N concentration of 200 g/m^3 (free nitrous acid equals 0.063 g/m^3), Silva et al. (2011) found a 37 percent reduction in AOB activity and 67 percent reduction in NOB activity showing that inhibition of NOB can also occur at high NO_2-N concentrations.

Table 7–11

Total ammonia-N (TAN) concentrations corresponding to AOB inhibition by 7.0 g/m^3 free ammonia-N at various pH and temperature conditions

	Temperature, °C			
pH	20	25	30	35
7.0	1712	1198	846	597
7.5	541	384	272	189
8.0	171	126	91	60
8.5	54	45	34	19

The NOB are more sensitive to NH_3-N inhibition than HNO_2. Inhibitory NH_3-N concentrations have been reported at 0.10 to 1.0 g/m^3 by Turk and Mavinic (1986), at 6.6 to 8.9 g/m^3 by Mauret et al. (1996), and at 3.5 g/m^3 by Wong-Chong and Loehr (1975) for unacclimated bacteria and 40 g/m^3 after an acclimation phase. Assuming NH_3-N inhibition at 8.9 g/m^3, NOB would be inhibited at a NH_4-N concentration of 488 g/m^3 at a pH of 7.5 and temperature of 25°C, which compares to 384 g/m^3 in Table 7–11 for AOB.

Ammonia Oxidizing Archaea. Limited information is available on the kinetics of ammonia oxidizing archaea (AOA), as most of the current focus has been to detect their occurrence in activated sludge treatment facilities. The only isolated ammonia-oxidizing archaea is *Nitrosopumilus maritimus* (Konneke et al., 2005). Originally classified under the Crenarchaeota phylum in the domain Archaea, *N. maritimus* has been reclassified under a new phylum named Thaumarchaeota. *N. maritimus* only grow within a narrow temperature range of 20 to 30°C and at pH between 7.0 and 7.8 (Ward et al., 2011). Unidentified AOA have been found in many activated sludge facilities used to treat domestic wastewater using specific polymerase chain reaction (PCR) primers that target the archaeal *amo*A gene (Park et al., 2006, Wells et al., 2009, Zhang et al., 2009, Limpiyakorn et al., 2011, and Giraldo et al., 2011a).

The maximum specific growth rate of *N. maritimus* at 28ºC was found to be 0.78 g/g·d by Konneke et al. (2005), but no such kinetic rates are currently found for AOA in WWTP activated sludge processes. A distinguishing characteristic with regard to kinetics of AOA is a very low half-velocity coefficient for both DO and ammonia. *N. maritimus* appears to be a *K*-strategist organism with a reported NH_4-N half-velocity coefficient (K_{NH}) of only 0.002 g/m^3 (Ward et al., 2011). Similarly with regard to DO, Giraldo et al. (2011a) found a DO half-velocity coefficient (K_o) of 0.01 g/m^3 for a mixed liquor from an MBR process operated at low DO with AOA accounting for 85 percent of the ammonia-oxidizing microorganisms based on *q*PCR measurements. Under winter temperature operation the population shifted to more AOB and the observed K_o increased to 0.25 g/m^3 (Giraldo et al., 2011b). Sonthiphand et al. (2011) also observed the advantages given to AOA at low NH_4-N concentrations. In enrichment reactors seeded with WWTP activated sludge the AOA population was abundant when the reactor NH_4-N concentration was in the range of 0.06 g/m^3, but it decreased by over 50 percent when the reactor NH_4-N concentration was 0.25 to 0.55 g/m^3.

7–10 DENITRIFICATION

The biological reduction of nitrate or nitrite to nitrogen gas is termed *denitrification*. Biological denitrification is an integral part of nitrification and denitrification processes for biological nitrogen removal, which with few exceptions is the method of choice for nitrogen removal for domestic and industrial wastewater treatment. Biological nitrogen removal is important in wastewater treatment where there are concerns for eutrophication and where groundwater must be protected against elevated NO_3-N concentrations when wastewater-treatment plant effluent is used for groundwater recharge and other reclaimed water applications. Without biological denitrification, 10 to 30 percent nitrogen removal may be found in domestic wastewater treatment due to biomass synthesis from BOD removal. The amount is a function of the influent BOD:N ratio, SRT, and the amount of nitrogen in recycle streams from solids dewatering after anaerobic or aerobic digestion.

Two modes of nitrate removal can occur in biological processes, and these are termed assimilatory or dissimilatory nitrate reduction (see Fig. 7–20). Dissimilatory denitrification is responsible for biological denitrification for enhanced nitrogen removal and involves nitrate/nitrite serving as the ultimate electron acceptor in lieu of oxygen in the bacteria cell respiratory electron transport chain for the oxidation of a variety of organic and inorganic substrates. Assimilatory nitrate reduction is independent of DO concentration and involves the reduction of nitrate to NH_4-N for use in cell synthesis when NH_4-N is not available.

In dissimilatory biological denitrification by heterotrophic bacteria, nitrate reduction proceeds through a series of intermediate products, nitrite (NO_2^-), nitric oxide (NO), and nitrous oxide (N_2O) to nitrogen gas (N_2) as shown in Eq. (7–109). NO and N_2O are nitrogen gases and the emission of N_2O is of greatest concern because it is one of the most potent greenhouse gases (see Sec. 7–12).

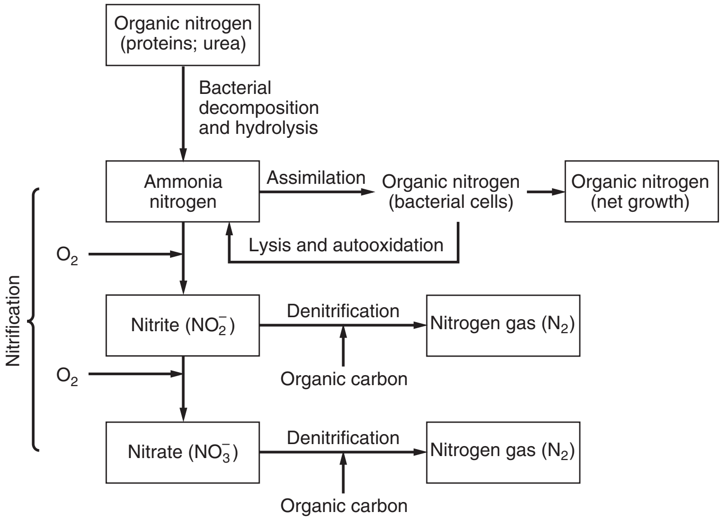
$$NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2 \qquad (7\text{–}109)$$

Process Description

Two basic flow diagrams for activated sludge denitrification and the conditions that drive the denitrification reaction rates are illustrated on Fig. 7–21. The first flow diagram [see Fig. 7–21(a)] is for the Modified Ludzak-Ettinger (MLE) process (U.S. EPA, 1993), the most common process used for biological nitrogen removal in municipal wastewater treatment. The process consists of an anoxic tank followed by the aeration tank where nitrification occurs. Nitrate produced in the aeration tank is recycled back to the anoxic tank.

Figure 7–20

Nitrogen transformations in biological treatment process. (Adapted from Sedlak, 1991.)



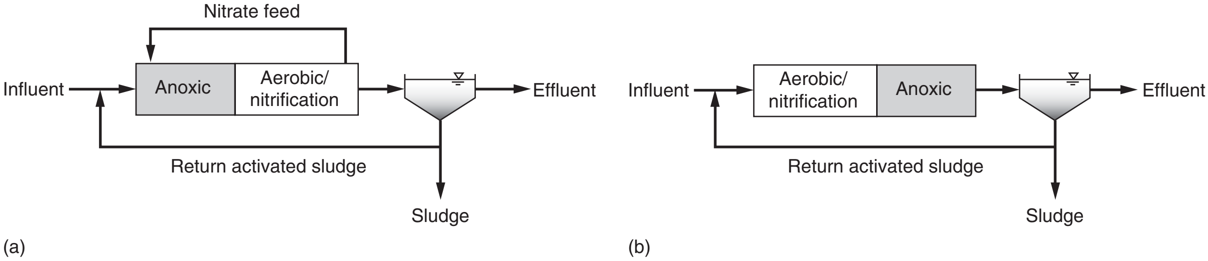


Figure 7–21

Types of denitrification processes and the reactors used for their implementation: (a) substrate driven (preanoxic denitrification) and (b) endogenous driven (postanoxic denitrification).

Because the organic substrate in the influent wastewater provides the electron donor for oxidation-reduction reactions using nitrate, the process is termed *substrate denitrification*. Further, because the anoxic process precedes the aeration tank, the process is known as *preanoxic denitrification*.

In the second process shown on Fig. 7–21(b), denitrification occurs after nitrification and the electron donor source is from endogenous decay. The process illustrated on Fig. 7–21(b) is generally termed *postanoxic denitrification* as wastewater influent BOD removal has occurred first and is not available to drive the nitrate reduction reaction. When a postanoxic denitrification process depends solely on endogenous respiration for energy, it has a much slower rate of reaction than for the preanoxic processes using wastewater BOD. Often an exogenous carbon source such as methanol or acetate is added to postanoxic processes to provide sufficient BOD for nitrate reduction and to increase the denitrification rate. Postanoxic processes include both suspended and attached growth systems. In one attached growth granular-medium filtration process, both nitrate reduction and effluent suspended solids removal occur in the same reactor.

The denitrification preanoxic and postanoxic processes described employ heterotrophic bacteria for nitrate reduction, but other pathways for biological nitrogen removal exist. Denitrification can also be accomplished by heterotrophic and autotrophic nitrifying bacteria. Autotrophic bacteria can also accomplish denitrification under anaerobic conditions, including the autotrophic AOB and the "Anammox" bacteria, which are described in the following section. Denitrifying bacteria in wastewater treatment are presented in the Microbiology section below with the exception of the anammox bacteria.

Microbiology

Bacteria capable of denitrification are both heterotrophic and autotrophic. Denitrification can be done by a wider range of heterotrophic organisms including the following genera: *Achromobacter*, *Acinetobacter*, *Agrobacterium*, *Alcaligenes*, *Arthrobacter*, *Bacillus*, *Chromobacterium*, *Corynebacterium*, *Flavobacterium*, *Halobacterium, Hypomicrobium*, *Methanomonas, Moraxella*, *Neisseria*, *Paracoccus*, *Propionibacterium*, *Pseudomonas*, *Rhizobium*, *Rhodopseudomonas*, *Spirillum*, and *Vibrio* (Payne, 1981 and Gayle, 1989). Most of these bacteria are facultative aerobic organisms with the ability to use oxygen as well as nitrate or nitrite, and some can also carry out fermentation in the absence of nitrate or oxygen.

Use of Supplemental Carbon. Methanol (CH_3OH) and other compounds such as waste glycerin and other commercially available supplemental carbon products have been added to many denitrification systems as a supplemental carbon to increase the amount of nitrate plus nitrite (NO_x) removed and/or to accelerate denitrification rates. As a single carbon compound, methanol degradation is done by more specialized bacteria, which are not the same as those growing on the influent wastewater organic substrates. The most commonly found methanol-utilizing bacteria are of the genus *Hyphomicrobium* (Timmermans and Van Haute, 1983; Sperl and Hoare, 1971) and possibly *Paracoccus denitrificans* (Van Verseveld and Stouthamer, 1978). In population characterization studies of a methanol-fed nitrification-denitrification system by stable isotope probing, Baytshtok et al. (2008) identified a *Methyloversatilis universalis* strain in addition to *Hyphomicrobium zavarzinili*. A unique feature of the *Methyloversatilis universalis* strain was that it could also grow on ethanol, which is not possible for the *Hyphomicrobium zavarzinili*.

Denitrification by Heterotrophic Bacteria. Denitrification can occur under aerobic conditions by heterotrophic nitrifying bacteria (Robertson and Kuenen, 1990, and Patureau et al. 1994), so that simultaneous nitrification and denitrification exist with the conversion of ammonia to gaseous nitrogen products. The heterotrophic bacteria, *Paracoccus pantotropha*, have been studied extensively for simultaneous ammonia oxidation and nitrate reduction. The oxidation of ammonia by heterotrophic bacteria requires energy, which can be obtained by nitrate or nitrite reduction using acetate by *P. pantotropha* under aerobic conditions. The conditions required for this form of denitrification are not considered practical in biological nitrification systems (van Loosdrecht and Jetten, 1998), and their presence was not found by Littleton et al. (2003) under DO condition most favorable for them in a full-scale oxidation ditch system.

Autotrophic Denitrification. A number of autotrophic bacteria have found to be capable of nitrate or nitrite reduction and oxidize a variety of electron donors including zero valance iron and Fe(II) by *Paracoccus ferrooxidans*, *Paracoccus denitrificans*, *P. pantotrophus,* and *P. versutus* (Kumaraswamy et al., 2006 Kielemoes et al., 2000), reduced sulfur compounds by *Thiobacillus denitrificans* (Bock et al., 1995) and ammonia by *Nitrosomonas eutropha*, *Nitrosomonas europaea*, and *Nitrosolobus multiformis* (Poth and Focht 1985, Bock et al., 1995; Zart and Bock 1998; Schmidt et al., 2003). Ammonia oxidation by *Nitrosomonas* under anoxic conditions has been shown to be slow and of little practical significance in activated sludge treatment (Littleton et al., 2003).

Stoichiometry of Biological Denitrification and Denitritation

Biological denitrification involves the biological oxidation of soluble organic substrates in wastewater treatment using nitrate and/or nitrite as the electron acceptor instead of oxygen. In the absence of DO or under limited DO concentrations, the nitrite and nitrate reductase enzymes in the electron transport respiratory chain are induced, which results in the transfer of hydrogen and electrons to nitrite or nitrate as the terminal electron acceptors. Oxidation-reduction reaction stoichiometry for three different electron donors for nitrate reduction is shown as follows. The term $C_{10}H_{19}O_3N$ is often used to represent the biodegradable organic matter in wastewater (U.S. EPA, 1993).

Wastewater:

$$C_{10}H_{19}O_3N + 10NO_3^- \rightarrow 5N_2 + 10CO_2 + 3H_2O + NH_3 + 10OH^- \tag{7–110}$$

Methanol:

$$5CH_3OH + 6NO_3^- \rightarrow 3N_2 + 5CO_2 + 7H_2O + 6OH^- \tag{7–111}$$

Acetic acid:

$$5CH_3COOH + 8NO_3^- \rightarrow 4N_2 + 10CO_2 + 6H_2O + 8OH^- \tag{7–112}$$

It should be noted that acetic acid or acetate is not used commonly because of cost. In all the above heterotrophic denitrification reactions, one equivalent of alkalinity is produced per equivalent of NO_3-N reduced, which equates to 3.57 g of alkalinity (as $CaCO_3$) production per g of nitrate nitrogen reduced. The same amount of alkalinity is produced for NO_2-N reduction. Recall from nitrification that 7.14 g alkalinity (as $CaCO_3$) was consumed per g of NH_4-N oxidized, so that by denitrification about one-half of the amount destroyed by nitrification can be recovered.

Denitritation refers to biological nitrite reduction. Using acetic acid as an example, the oxidation-reduction reaction for nitrite as the electron acceptor is as follows:

$$3CH_3COOH + 8NO_2^- \rightarrow 4N_2 + 6CO_2 + 2H_2O + 8OH^- \tag{7–113}$$

Comparing Eq. (7–112) to Eq. (7–113), denitritation requires 60 percent of the acetate required for denitrification. However, when applying the bioenergetics analysis (Sec. 7–4) to account for COD used for biomass synthesis with the energy yielding oxidation reactions, the COD or acetate used with nitrite reduction is about 67 percent of that used with nitrate reduction, due to the fact that theoretically more energy is produced with nitrite versus nitrate reduction. The following stoichiometric equations developed from bioenergetics can be used to compare the effect of nitrate and nitrite electron acceptors along with ammonia as the nitrogen source on biomass growth:

Nitrate reduction with acetate:

$$\begin{aligned} NO_3^- + H^+ + 0.33\,NH_4^+ + 1.45\,CH_3COO^- \\ \rightarrow 0.5\,N_2 + 0.33\,C_5H_7O_2N + 1.60\,H_2O + 1.12\,HCO_3^- + 0.12\,CO_2 \end{aligned} \tag{7–114}$$

Nitrite reduction with acetate:

$$\begin{aligned} NO_2^- + H^+ + 0.24\,NH_4^+ + 0.98\,CH_3COO^- \\ \rightarrow 0.5\,N_2 + 0.24\,C_5H_7O_2N + 1.24\,H_2O + 0.74\,HCO_3^- + 0.008CO_2 \end{aligned} \tag{7–115}$$

Organic Substrate Requirements for Denitrification and Denitritation

A sufficient amount of organic substrate must be available for depletion of the nitrite/nitrate (NOx) fed to an anoxic zone by recycle and upstream flows. Thus, an important design parameter for nitrogen removal is the amount of bsCOD or BOD needed to provide a sufficient amount of electron donor for NOx reduction. In biological nitrogen removal processes, the electron donor is typically one or more of the following four sources: (1) the bsCOD in the influent wastewater, (2) the bsCOD produced during biological hydrolysis of particulates and colloids, (3) the bsCOD produced during endogenous decay, and (4) an exogenous source such as methanol or acetate. The latter has been added in separate treatment units, such as polishing filters, after nitrification where almost no bsCOD remains. As a general rule for domestic wastewater treatment in a preanoxic aerobic (MLE) process, Barth et al. (1968) estimated that 4 g of BOD is needed per g of NO_3-N reduced. However, the actual value will depend on the system operating conditions and the type of electron donor used for denitrification.

When using an exogenous carbon source it is important to estimate the substrate dose as a function of the NOx to be removed. The dose can be quantified in terms of the g COD added per g of NOx removed and is referred to as the COD/N ratio. The COD/N ratio is determined by a COD balance, similar to what was done to predict the amount of oxygen per unit of bsCOD removed in Example 7–1 (Sec. 7–3). The oxygen equivalent of nitrate and nitrite must be known to perform a COD balance for substrate and NOx removal in a denitrification reactor.

From oxidation-reduction half reactions, the oxygen equivalent of using nitrate or nitrite as electron acceptors can be determined. The half reactions per mole e-transferred from Table 7–6 are as follows:

For oxygen:

$$0.25O_2 + H^+ + e^- \rightarrow 0.5H_2O \tag{7–116}$$

For nitrate:

$$0.20NO_3 + 1.2H^+ + e^- \rightarrow 0.1N_2 + 0.6H_2O \tag{7–117}$$

For nitrite:

$$0.333NO_2^- + 1.333H^+ + e^- \rightarrow 0.6667H_2O + 0.1667N_2 \tag{7–118}$$

Comparing the above half reactions for oxygen [Eq. (7–116)] and nitrate [Eq. (7–117)], 0.25 mole of oxygen is equivalent to 0.2 mole of nitrate for one electron transfer in oxidation-reduction. Thus, the oxygen equivalent of nitrate is (0.25 × 32 g O_2/mole) divided by the nitrate gram equivalent (0.20 × 14 g N/mole) and equals 2.86 g O_2/g NO_3-N. The oxygen equivalent is a useful design factor when calculating the total oxygen required for nitrification-denitrification biological treatment systems. Similarly, for nitrite as the electron acceptor, the oxygen equivalent of nitrite is 1.71 g O_2/g NO_2-N.

It has been shown in Example 7–1 and Eq. (7–6) that the COD removed is either oxidized or accounted for in cell growth. A similar expression can be applied to biological removal of soluble COD:

$$\text{bsCOD}_r = \text{bsCOD}_{\text{cell}} + \text{bsCOD}_{\text{ox}} \tag{7–119}$$

For cell synthesis, the $\text{bsCOD}_{\text{cell}}$ is calculated from the net biomass yield and the ratio of 1.42 g O_2/g VSS.

$$\text{bsCOD}_{\text{cell}} = 1.42Y_n\text{bsCOD}_r \tag{7–120}$$

where Y_n = net biomass yield, g VSS/g bsCOD_r

and

$$Y_n = \frac{Y}{1 + b(\text{SRT})} \tag{7–121}$$

Thus,

$$\text{bsCOD}_r = \text{bsCOD}_{\text{ox}} + 1.42Y_n\text{bsCOD}_r \tag{7–122}$$

Rearranging yields

$$\text{bsCOD}_{\text{ox}} = (1 - 1.42Y_n)\text{bsCOD}_r \tag{7–123}$$

In Eq. (7–123), bsCOD_{ox} is the COD oxidized and is equal to the oxygen equivalent of the NO_3-N used for bsCOD oxidation. Hence,

$$\text{bsCOD}_{ox} = 2.86\,NO_x \tag{7–124}$$

where 2.86 = O_2 equivalent of NO_3-N, g O_2/g NO_3-N
NO_x = NO_3-N reduced, g/d

Substituting Eq. (7–124) in Eq. (7–123) yields

$$2.86\ \mathrm{NO_3} = (1 - 1.42\ Y_n)\ \mathrm{bsCOD}_r \tag{7–125}$$

or

$$\frac{\mathrm{bsCOD}}{\mathrm{NO_3\text{-}N}} = \frac{2.86}{1 - 1.42Y_N} \tag{7–126}$$

$$\text{Thus, g COD/g NO}_3\text{-N} = \frac{2.86}{1 - 1.42Y_N} \tag{7–127}$$

$$\text{and the g COD/g NO}_2\text{-N} = \frac{1.71}{1 - 1.42Y_N} \tag{7–128}$$

If oxygen is entering an anoxic zone via recycle streams, electron donor would be used also for oxygen consumption with following ratio:

$$\text{g COD/g O}_2 = \frac{1.0}{1 - 1.42Y_N} \tag{7–129}$$

The g COD/g NO_3-N in Eq. (7–127) is the same as the substrate "consumptive ratio" defined by McCarty et al. (1969) for using exogenous carbon sources for denitrification. They showed that exogenous substrates with lower biomass synthesis yields had lower consumptive ratios and thus required less substrate addition for a given amount of NO_3-N to be removed. The consumptive ratio for methanol was about 70 percent of that for glucose, due to methanol having a lower synthesis yield, allowing a greater fraction of the COD added to be used for nitrate reduction. Required methanol consumptive ratios are 4.0 to 5.0 g COD/g NO_3-N, based on reported biomass yields ranging from 0.20 to 0.30 g VSS/g COD used (Stensel et al., 1973, Christensen et al., 1994, Purtschert and Gujer, 1999, Sobieszuk et al., 2006, Dold et al., 2008, and Baytshtok et al., 2008). Methanol has a COD of 1.5 g COD/g CH_3OH, so the requirement based on methanol is 2.7 to 3.3 g CH_3OH/g NO_3-N. Field applications in the range of 3.5 to 3.8 are common and account for the yield, DO entering the anoxic zone, and methanol in the anoxic zone effluent. The use of exogenous carbon sources is discussed further in denitrification system designs in Section 8–6.

Denitrification Kinetics

Denitrification rates have often been expressed in terms of a specific denitrification rate (SDNR) based on g NO_3-N/g MLVSS·d, which has been found to vary as a function of the type and amount of biodegradable COD available and the temperature in the anoxic reactor. For preanoxic zones treating domestic wastewater the SDNR may range from 0.04 to 0.25 g NO_3-N/g MLVSS·d. The SDNR in postanoxic tanks, where the substrate for denitrification is provided by endogenous decay, ranges from 0.01 to 0.03 g NO_3-N/g MLSS·d or it can be 5 to 10 times higher if a supplemental substrate is added to the postanoxic tank. Supplemental substrates used to enhance denitrification include methanol, acetate, ethanol, glycerin, corn syrup, and various brewery, distillery, and food processing wastes. For all these cases the soluble organic substrate utilization rate by denitrifying bacteria determines the nitrate and nitrite reduction rates.

Soluble Substrate Utilization Rate. Whether for preanoxic or postanoxic reactors, the soluble substrate utilization rate can be described by modifying Eq. (7–24) to account for the effect of having a zero DO concentration in the anoxic zone and the effect of the nitrate concentration on the substrate utilization kinetics. Note that the effect of the nitrate concentration on substrate utilization rates is only at concentrations below 0.10 to 0.20 g/m³.

$$r_{\text{su}} = \left[\frac{\mu_{H,\max} S_S}{Y_{\text{H}}(K_s + S_S)}\right]\left(\frac{S_{\text{NO}}}{K_{\text{NO}} + S_{\text{NO}}}\right)(\eta)X_H \tag{7–130}$$

Where r_{su} = substrate utilization rate in the reactor, g/m³·d
Y_{H} = heterotrophic bacteria synthesis yield, g VSS/g COD used
$\mu_{H,\max}$ = maximum specific growth rate of denitrifying heterotrophs, g VSS/g VSS·d
S_S = soluble degradable substrate concentration *in the reactor*, g COD/m³
K_S = substrate utilization half-velocity coefficient, g COD/m³
S_{NO} = NO_3-N concentration, g/m³
K_{NO} = nitrate half-velocity coefficient, g/m³
η = fraction of substrate utilization rate with nitrate as the electronic acceptor versus oxygen
X_H = heterotrophic bacteria concentration, g/m³

Additional equations and mass balances are required to determine the reactor soluble degradable COD concentration as a function of the soluble substrate in the reactor influent, the soluble substrate produced from hydrolysis of particulate and colloidal matter, and from endogenous decay.

Nitrate Consumption Rate. The reactor nitrate consumption rate (r_{NO}) can be determined as a function of the substrate utilization rate by applying Eq. (7–127).

$$\text{g COD/g NO}_3\text{-N} = \frac{r_{\text{su}}}{r_{\text{NO}}} = \frac{2.86}{1 - 1.42Y_N}$$

Substituting for r_{su} from Eq. (7–130) gives the reactor nitrate consumption rate:

$$r_{\text{NO}} = \left(\frac{1 - 1.42Y_{\text{H}}}{2.86}\right)\left[\frac{\mu_{\text{H,max}} S_S}{Y_{\text{H}}(K_s + S_S)}\right]\left(\frac{S_{\text{NO}}}{K_{\text{NO}} + S_{\text{NO}}}\right)(\eta)X_{\text{H}} \tag{7–131}$$

where:

r_{NO} = nitrate consumption rate, g/m³·d
Other terms as defined previously.

The term η in Eqs. (7–130) and (7–131) is applied to account for the fact that a lower equivalent oxygen consumption rate occurs when the electron acceptor is nitrate or nitrite instead of oxygen. The term is also used to account for possible changes in kinetic rates using NO_x electron acceptors and for the fact that not all of the heterotrophic bacteria can use nitrate/nitrite. The value for η has been found to vary from 0.20 to 0.80 for preanoxic denitrification reactors fed domestic wastewaters (Stensel and Horne, 2000). The activated sludge configuration, the system SRT, and the fraction of influent BOD removed with nitrate appear to affect the η value. For anoxic/aerobic processes with substantial substrate and nitrate utilization in the preanoxic zone an η value of 0.80 is often appropriate.

The nitrate consumption rate in Eq. (7–131) can be applied to anoxic reactor applications in which the substrate used is derived from the influent wastewater, endogenous decay, or from supplemental carbon addition. When supplemental carbon addition is used, the heterotrophic bacteria concentration (X_H) may have to be based on growth using only the supplemental substrate, and not from growth on the supplemental substrate and the BOD removed from the influent wastewater. This growth situation occurs when methanol is added as the supplemental carbon, which results in the growth of only specialized methylotrophic bacteria from methanol utilization. Also when applying the substrate utilization kinetic model to a system with both influent and supplemental carbon, Eq. (7–131) has to be applied separately and cumulatively to account for both substrate types. Appropriate coefficients must be used for $\mu_{H,\max}$, Y_{H}, K_S, and η for the different substrates and bacteria populations.

For separate postanoxic suspended growth or attached growth processes after the activated sludge BOD removal and nitrification process, the biomass is developed under mainly anoxic conditions and with a selected single organic substrate. In this case, the η term in Eq. (7–130) is not necessary because the biomass consists of mainly denitrifying bacteria. The biokinetic equations presented previously can then be used with the appropriate kinetic coefficient values to design a postanoxic complete-mix suspended growth process. The kinetic coefficient values for growth using methanol have been developed at 10 and 20°C in laboratory studies (Randall et al., 1992). The kinetics for methanol utilization are such that the SRT values required for a denitrification suspended growth process are in the same range as SRT values for aerobic systems designed for BOD utilization only, about 3 to 6 d.

Effect of Dissolved Oxygen Concentration. Dissolved oxygen can inhibit nitrate reduction by repressing the nitrate reduction enzyme. In activated sludge flocs and biofilms, denitrification can proceed in the presence of low bulk liquid DO concentrations. A dissolved oxygen concentration of 0.2 mg/L and above has been reported to inhibit denitrification for a *Pseudomonas* culture (Skerman and MacRae, 1957; Terai and Mori, 1975) and by Dawson and Murphy (1972) for activated sludge treating domestic wastewater. Nelson and Knowles (1978) reported that denitrification ceased in a highly dispersed growth at a DO concentration of 0.13 mg/L. The effect of DO concentration on nitrate utilization rates is accounted for by adding a correction factor to Eq. (7–131) to account for DO inhibition as follows:

$$r_{\mathrm{NO}} = \left(\frac{1 - 1.42Y_{\mathrm{H}}}{2.86}\right)\left[\frac{\mu_{H,\max}S_S}{Y_{\mathrm{H}}(K_s + S_S)}\right]\left(\frac{S_{\mathrm{NO}}}{K_{\mathrm{NO}} + S_{\mathrm{NO}}}\right)\left(\frac{S_o}{K_o' + S_o}\right)(\eta)X_H \tag{7–133}$$

where K_o' = DO inhibition coefficient for nitrate reduction, g/m^3

Other terms are as defined previously.

The value of K_o' is system-specific. Values in the range from 0.1 to 0.2 mg/L have been proposed for K_o' (Barker and Dold, 1997). Assuming a K_o value of 0.1 mg/L the rate of substrate utilization with nitrate as the electron acceptor at DO concentrations of 0.10, 0.20, and 0.50 mg/L would be at 50, 33, and 17 percent of the maximum rate, respectively.

Effect of Simultaneous Nitrification-Denitrification. In activated sludge systems, the issue of DO concentration is confounded by the fact that the measured bulk liquid DO concentration does not represent the actual DO concentration within the activated sludge floc. Under low DO concentration conditions, denitrification can occur in the floc interior, while nitrification is occurring at the floc exterior. Also in activated sludge tanks operated at low DO concentrations, both aerobic and anaerobic zones exist depending on mixing conditions and distance from the aeration point, so that nitrification and denitrification occur in the same tank. Under these conditions, nitrogen utilization that occurs in a single aeration tank is referred to as *simultaneous nitrification and denitrification*. Although both nitrification and denitrification are occurring at reduced rates as indicated by the DO effects described for both processes, if a sufficient SRT and τ exist, the overall nitrogen removal can be significant. Rittman and Langeland (1985) reported greater than

90 percent nitrogen removal by nitrification and denitrification in an activated sludge system used to treat municipal wastewater at DO concentrations below 0.50 mg/L and with values of τ greater than 25.

Environmental Factors

Alkalinity is produced in denitrification reactions and the pH is generally elevated instead of being depressed, as in nitrification reactions. In contrast to nitrifying organisms, there has been less concern about pH influences on denitrification rates. No significant effect on the denitrification rate has been reported for pH between 7.0 and 8.0, while Dawson and Murphy (1972) reported a decrease in the denitrification rate as the pH was decreased from 7.0 to 6.0 in batch unacclimated tests. Biomass acclimation to external carbon sources must also be considered.

7–11 ANAEROBIC AMMONIUM OXIDATION

The oxidation of ammonia by lithotrophic bacteria using nitrate or nitrite as an electron acceptor was proposed as being thermodynamically possible in a 1977 paper by E. Broda, which claimed "two kinds of lithotrophs missing in nature" (Kuenen, 2008). At the same time, based on the analysis of nitrogen balances in a highly stratified anoxic fjord, an unexplained ammonia loss was found (Ward et al., 2011). From the summary of the Gibbs free energy for ammonia oxidation by various electron acceptors given in Table 7–12, bacterial growth with nitrate or nitrite as electron acceptors should be comparable to that with oxygen. Finally in 1995, Mulder et al. (1995) observed anaerobic ammonia oxidation with nitrogen gas production in a laboratory fluidized-sand bed reactor and assigned the name Anammox (anaerobic ammonium oxidation) to the biological process. Tests by Van de *Graaf* et al. (1995) with ^{15}N labeled ammonium and biological inhibitors confirmed that the ammonia oxidation was accomplished with nitrite under anaerobic conditions and was biologically mediated. Strous et al. (1999a) were able to identify the responsible organisms as an autotrophic bacterium under the order Planctomycetales through density gradient centrifugation of an anammox enrichment to characterize its 16S rRNA gene phylogeny. Researchers have since found numerous occurrences of the anammox bacteria in wastewater treatment and in marine and fresh water sediments (Kuenen, 2008, Van Hulle et al., 2010).

Process Description

Anammox has been defined as a "deammonification" process involving two steps: the partial nitritation of ammonia and subsequently the anaerobic oxidation of ammonia and nitrite to nitrogen gas. The anammox process requires that aerobic nitritation to NO_2-N be accomplished for about 55 percent of the NH_4-N in the waste stream before the anaerobic oxidation

Table 7–12

Comparison of Gibbs Energy for inorganic nitrogen oxidation

Inorganic *N* Oxidation Reaction	ΔG°, kJ/mole
$NH_4^+ + 1.5O_2 \rightarrow NO_2^- + 2H^+$	−275
$NO_2^- + 0.5O_2 \rightarrow NO_3^-$	−74
$NH_4^+ + NO_2^- \rightarrow N_2 + H_2O$	−375
$5NH_4^+ + 3NO_3^- \rightarrow 4N_2 + 9H_2O + 2H^+$	−297

Adapted from Schmidt et al. (2003) and Jetten et al. (1999).

of NH_4-N with NO_2-N as the electron acceptor and N_2 production. The process provides a means for biological nitrogen removal without any organic carbon consumption, in contrast to the classic biological aerobic nitrification/anoxic denitrification process. In addition, because it is an autotrophic bacteria, no organic carbon is needed for cell growth. Because only a portion of the ammonia in the deammonification process feed stream is oxidized to nitrite, much less aeration energy is needed compared to the conventional biological nitrogen removal process in which most of the available ammonia is oxidized to nitrate.

The deammonification process has been demonstrated successfully for high temperature (30–35ºC) and high ammonia waste streams in both fixed film and suspended growth biological reactors (Schmidt et al., 2003). A unique feature of the anammox bacteria that has been used to an advantage in suspended growth anammox processes is that they are able to form a compact granular, rapid settling biomass (Innerebner et al., 2007). The anammox process technology has not yet been developed for the reliable removal of nitrogen in low or ambient temperature and dilute ammonia concentrations in wastewater treatment, but the technology has been applied full-scale for nitrogen removal from anaerobic digester dewatering recycle streams. Anammox process designs for side stream treatment are presented in Chap. 15

Microbiology

Investigations on anammox bacteria have resulted in identifying nine species within five genera as members of the bacteria order Planctomycetales (Ward et al., 2011). They are preceded by the name Candidatus, which is used when a species or genus is well characterized but has not been studied in pure culture. These are "Candidatus *Kuenenia*," "*Candidatus Brocadia*," "*Candidatus Scalindua*," "*Candidatus Jettenia*," and "*Candidatus Anammoxogloubus.*" The species found in wastewater are *Kuenenia stuttgartiensis*, *Anammoxoblobus propionicus*, *Jettenia asiatica, Brocadia anammoxidans, Brocadia fulgida, Scalindua wagneri,* and *Scalindua brodae. Scalindua sorokinii* and *Scalindua arabica* were found in marine environments (Van Hulle et al., 2010). *"*Candidatus *Kuenenia"* and "*Candidatus Brocadia"* are the most commonly found organisms in enrichments from WWTPs (Kuenen, 2008). None of these bacteria have been identified in pure cultures but have been characterized by molecular methods (Strous et al., 2002). In contrast to other prokaryotes, the Planctomcyetes typically contain membrane-bound sub-cellular compartments. Jetten et al. (2001) identified such an organelle in *B. anammoxidans*, which contained hydroxylamine oxidoreductase and named it anammoxosome. Anammox bacteria enrichments develop a deep red color, which is thought to be related to hemes present in the hydroxylamine oxidoreductase enzyme, which was referred to as cytochrome P460 (Jetten et al., 1999).

Anammox bacteria are found in dense granular flocs in stable operating systems. Strous et al. (1999b) reported the need to have 10^{10} to 10^{11} cells/mL for an active anammox system. A possible explanation for this is that hydrazine produced in the anammox reaction may be lost by diffusion to the bulk liquid in smaller flocs and thus limit anammox activity and growth. The addition of hydroxylamine or hydrazine can stimulate anammox bacteria activity (Van Hulle et al., 2010). Seeding from a previous anammox system is necessary to avoid an extensive time period for the start of a new anammox systems.

Anammox Stoichiometry

The energy yielding reaction in the anammox process is the oxidation of NH_4-N by NO_2-N:

$$NH_4^+ + NO_2^- \rightarrow N_2 + H_2O \tag{7–134}$$

A proposed metabolic model by Van de Graaf et al. (1997) consists of (1) the reduction of nitrite to hydroxylamine (NH_2OH), (2) the condensation of hydroxylamine with ammonium to hydrazine (N_2H_4), and (3) the oxidation of hydrazine to nitrogen gas. During the conversion of ammonia some nitrate is formed from nitrite, which may provide the reducing power for fixation of carbon dioxide (Schmidt et al., 2002). The anabolic reaction is as follows (van Niftrik et al., 2004):

$$CO_2 + 2NO_2^- + H_2O \rightarrow CH_2O + 2NO_3^- \tag{7–135}$$

The following overall reaction, accounting for cell synthesis, has been suggested by Strous et al. (1999b).

$$\begin{aligned} &1.0NH_4^+ + 1.32NO_2^- + 0.066HCO_3^- + 0.13H^+ \\ &\quad \rightarrow 1.02N_2 + 0.26NO_3^- + 0.066CH_2O_{0.5}N_{0.021} + 2.03H_2O \end{aligned} \tag{7–136}$$

The amount of NO_3-N produced accounts for 11.2 percent of the NH_4-N and NO_2-N metabolized. Acid is decreased in the biological reactor due to the anammox reactions as shown by the 0.13 moles of H^+ consumed and the removal of nitrous acid (HNO_2^-) with a smaller molar amount of nitric acid (HNO_3^-) production. As demonstrated in Example 7–8, the amount of alkalinity consumed for the anammox process is less than that for a nitritation and heterotrophic denitritation process.

EXAMPLE 7–8 **Alkalinity Consumption in the Anammox Process** Compare the net amount of alkalinity consumed by the anammox process from the biological conversion of 200 g NH_4-N/m^3 to that for the same amount of NH_4-N conversion to nitrogen gas via biological aerobic nitritation and heterotrophic denitritation with carbon addition.

1. Alkalinity consumed by aerobic NH_4-N oxidation to NO_2-N = 7.14 g as $CaCO_3$/g NH_4-N
2. Alkalinity produced by heterotrophic denitritation = 3.57 g as $CaCO_3$/g NO_x reduced to N_2.
3. Use Eq. (7–136) to determine the amount of NO_2-N produced by nitritation and the alkalinity changes caused by acid consumption in the anammox process

Solution

1. Determine the net alkalinity consumption by nitritation and heterotrophic denitritation for processing 200 g/m^3 NH_4-N.

   Net alkalinity consumed =

   Alkalinity consumed for nitritation – alkalinity produced by denitritation

   $= [(7.14-3.57) \text{ g as } CaCO_3/\text{g N}](200 \text{ g/m}^3) = 714.0 \text{ g/m}^3 \text{ as } CaCO_3$

2. Determine the net alkalinity change by the anammox process.
   a. Determine the alkalinity consumed by NO_2-N production by nitritation.
      Determine the fraction of NH_4-N processed via NO_2-N production using Eq. (7–136)

$$\text{Fraction } NO_2\text{-N} = \frac{1.32 \text{ mole } NO_2}{1.0 \text{ mole } NH_4 + 1.32 \text{ mole } NO_2} = 0.57$$

NO_2-N produced = $0.57(200 \text{ g/m}^3) = 113.8 \text{ g/m}^3$

Alkalinity used for NO_2-N production:

$= (7.14 \text{ g as } CaCO_3/\text{g N})(113.8 \text{ g/m}^3) = 812.5 \text{ g/m}^3 \text{ as } CaCO_3$

b. Determine the net acid consumed in eq/mole N processed in the anammox reaction in Eq. (7–136). Note the computed value is equivalent to alkalinity production

i. Net mole H^+ consumed/mole N processed =

$$\frac{0.13 \text{ mole } H^+ - 0.066 \text{ mole } HCO_3^-}{2.32 \text{ mole N}} = 0.0276 \text{ mole H consumed/mole N}$$

Equivalent of H/mole H = 1.0

ii. Net change in acid due to nitrous acid depletion and nitric acid production in mole/mole N processed

$$= \frac{1.32 \text{ mole } HNO_2 - 0.26 \text{ mole } HNO_3}{2.32 \text{ mole N}} = 0.457 \text{ mole acid/mole N}$$

Equivalent of acid/mole acid = 1.0

iii. Total acid consumption in eq/mole N processed =

$$= [0.0276 \text{ mole H/mole N} + 0.457 \text{ mole acid/mole N}](1.0 \text{ eq/mole})$$

$$= 0.4844 \text{ eq alkalinity production/mole N processed}$$

Alkalinity produced/g N =

$$\left(\frac{0.4846 \text{ eq}}{\text{mole N}}\right)\left(\frac{50 \text{ g as } CaCO_3}{\text{eq}}\right) = \frac{24.23 \text{ g as } CaCO_3}{\text{mole N}}$$

$$\text{mole N processed} = \frac{200 \text{ g N/m}^3}{14 \text{ g N/mole N}} = 14.29 \text{ mole N/m}^3$$

Alkalinity produced in g/m^3 =

$$= \left(\frac{24.23 \text{ g as } CaCO_3}{\text{mole N}}\right)\left(\frac{14.29 \text{ mole N}}{\text{m}^3}\right) = 346.2 \text{ g as } CaCO_3$$

Net alkalinity consumed = (812.5 − 346.2) g/m^3 = 466.3 g/m^3 as $CaCO_3$

This compares to 714.0 g/m^3 as $CaCO_3$ for the nitritation and heterotrophic denitritation process.

Anammox Seeding. Anammox bacteria are relatively slow-growing bacteria, and an initial seed source with the typical dense granular anammox floc greatly accelerates the start up of a new anammox process application (Strous et al., 1999a). Strous et al. (1999a) found that a critical bacteria concentration of 10^{10} to 10^{11} cells/mL was necessary to realize good anammox activity. A possible reason is that for small aggregates the hydrazine produced diffuses quickly to the bulk liquid. The addition of hydroxylamine or hydrazine was found to accelerate anammox bacteria activity (Van Hulle et al., 2010).

Alternative Anammox Substrates. Anammox bacteria are capable of nitrate reduction with the oxidation of formate, acetate, and propionate as electron donors (Guven et al., 1995; Kartal et al., 2007a). These organic acids are not used in cell growth. The ability to reduce nitrate was found with five anammox species: *B. anammoxidans*, *B. fulgida,* *A. propionicus*, *K. stuttgartiensis*, and *Scalindua sp*. (Ward et al., 2011). Whereas heterotrophic denitrification bacteria reduce nitrate to nitrogen gas via nitrite, nitric oxide, and nitrous oxide as shown in Sec. 7–10, through ^{15}N labeling studies, it has been found that the anammox bacteria reduce nitrate to nitrite and then to ammonia (Kartal et al., 2007a). Both ammonia and nitrite serve as substrates for the anammox reaction in the reduction of nitrate to nitrogen gas. With propionate addition, it has been found that *A. propionicus* can outcompete the growth of other anammox bacteria and heterotrophic denitrifiers (Kartal et al., 2007b). It also appears the nitrate reduction with propionate occurs simultaneously with the anammox reaction. Of the anammox species listed above, *B. fulgida* is more competitive for acetate. The long-term growth of *B. fulgida* in a granular sludge reactor at a lower temperature than most previous anammox applications (18°C) and the ability to remove acetate and nitrate at a COD/N ratio of 0.50 have been demonstrated (Winkler et al., 2012). Higher ratios may encourage the growth of heterotrophic denitrifiers.

Growth Kinetics

Most of the information on anammox bacteria kinetics has been obtained from studies and reactor operations at 30 to 35°C. At this temperature, favorable growth rates have been observed, which also coincides with the temperatures in the treatment of anaerobic digester reject water with the anammox process for biological nitrogen removal. Anammox growth between 4 and 43°C has been claimed by Ward at al. (2011), with lower temperature growth based on observations of anammox activity in Arctic environments. Sustained growth at 15°C (Ward et al., 2011) and 18°C (Winkler et al., 2012) has been demonstrated in laboratory reactors. In batch tests using anammox bacteria from a 30°C reactor, Strous at al. (1997a) found maximum ammonium oxidation rates between 30 and 35°C, but the rates were less than 5.0 percent of that at temperatures below 20°C. Rates would be higher with temperature acclimation.

The biokinetics of anammox bacteria are compared to that for ammonia oxidation by AOB in Table 7–13. At 30°C the anammox bacteria maximum specific growth rate is less than 10 percent of that for AOB. Because of the reduced growth rate the SRT for ammonia oxidation by anammox must be about 10 times longer than that for aerobic ammonium oxidation. However, a maximum specific growth rate that is almost twice as high as that shown in Table 7–13 for anammox bacteria has been reported by van der Star et al. (2008). The ability to achieve a long SRT for the anammox process can be aided by the dense granular floc that is developed. The anammox bacteria have a very high affinity for ammonia and nitrite as indicated by their very low half-velocity coefficients in the table. The biomass yield for anammox bacteria is in the same range as that for AOB and much lower

Table 7–13

Comparison of biokinetics of ammonia oxidizing bacteria (AOB) and anammox bacteria

Parameter	Units	AOB[a] at 20°C	Anammox at 30–35°C	Anammox references

than for heterotrophic bacteria, as is typical for autotrophic bacteria with their energy needs for CO_2 fixation.

Environmental Factors

Important environmental factors affecting anammox bacteria activity are pH, and nitrite and DO concentration. Growth at pH 6.7 to 8.3 is feasible, with pH 8.0 reported to be optimal (Strous et al., 1999a).

Nitrite Inhibition. Nitrite, a key substrate in the anammox process, inhibits anammox bacteria activity at elevated concentrations. The inhibitory nitrite concentrations are affected by the reactor operational mode. Nitrite-N concentrations at 60 g/m^3 were not inhibitory in an anammox SBR operation with ammonium and nitrite in the feed stream (Strous et al., 1999) and van der Star et al. (2007) indicated stable growth at nitrite-N concentrations fed from 40 to 80 g/m^3 in a full-scale anammox reactor. However, in an intermittently aerated reactor in which nitrite was produced in the aerobic period, Wett et al., (2007) found inhibition at nitrite-N concentrations as low as 5.0 g/m^3 and an irreversible inhibition at 50 g/m^3. Sustained nitrite-N concentrations above 5.0 g/m^3 resulted in loss of anammox activity and were considered a long term toxic concentration (Wett et al., 2010). The addition of hydrazine at 3.0 g/m^3 was able to restore anammox activity in a previously inhibited reactor (Strous et al., 1999a).

Dissolved Oxygen Inhibition. Anammox bacteria are inhibitated by DO at very low concentrations as they are strict anaerobic bacteria. The effective inhibitory DO concentration is a function of the granular anammox floc thickness or fixed film thickness as AOB can consume oxygen in the outer floc or biofilm. Strous et al. (1997b) found that DO inhibition was reversible and thus suggested that an intermittently aerated reactor for nitritation and deammonification was possible.

7–12 GREENHOUSE GAS FROM BIOLOGICAL NITROGEN TRANSFORMATIONS

Certain biological nitrogen transformation processes produce nitric oxide (NO) and nitrous oxide (N_2O). The impact of nitrous oxide, one of the most potent greenhouse gases, is estimated to be 300 times that of carbon dioxide. It also has the greatest impact on ozone depletion, which is expected to continue as such through the 21st century (Ravishankara et al., 2009). Nitric oxide is not considered a greenhouse gas but can be oxidized rapidly in air to nitrogen dioxide ($NO_{2,g}$), which is a toxic air pollutant and a contributor to smog.

Source of Nitrous Oxide Emissions

Agriculture is the major source of nitrous oxide emissions, and wastewater treatment sources have been estimated as the sixth largest contributor, accounting for about three percent of the total global emissions in 2006. The wastewater contribution is expected to rise between now and 2020 (Law et al., 2012). Based on the results of monitoring studies at twelve WWTPs in the United States, it was found that nitrous oxide emissions varied from 0.01 to 1.8 percent of the influent nitrogen, but other investigators have found emissions as high as 15 percent (Ahn et al., 2010a). Nitrous oxide emissions were higher in the aerated zones than the anoxic zones of anoxic/aerobic biological nitrogen removal processes, and it varied with diurnal nitrogen loading rates (Ahn et al., 2010b). Higher gas stripping from aeration versus the nonaerated mixed anoxic zones must also be considered in comparing nitrous oxide emissions in biological nitrogen removal processes.

Nitrous Oxide Production Pathways

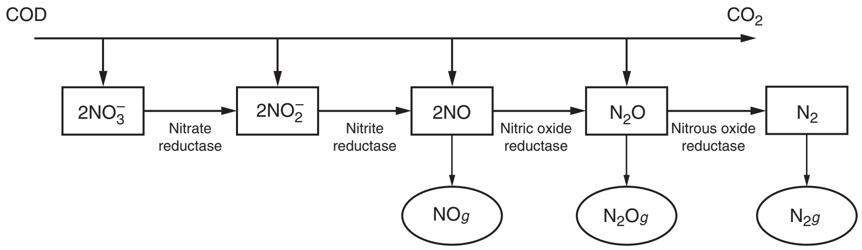
Nitrous oxide is produced during biological nitritation by AOB oxidation of ammonia to nitrite and during biological denitrification by heterotrophic bacteria oxidizing organic substrates with nitrate or nitrite as the initial electron acceptor. There is no evidence for direct nitrous oxide production by NOB. The anammox bacteria and AOB capable of deammonification are also not expected to produce nitrous oxide, as their degradation pathway under anaerobic conditions involves a direct reaction between ammonia and nitrite to produce dinitrogen gas. Presently, there is insufficient information to determine if the AOA have the necessary genes and pathways for nitrous oxide production (Ward et al., 2011).

Nitrous Oxide Production from Heterotrophic Denitrification. The pathways for nitrous oxide production during heterotrophic denitrification and aerobic ammonia oxidation are summarized on Fig. 7–22. The heterotrophic denitrification pathway is the same as that given in Eq. (7–109). The COD is oxidized under anoxic conditions with electron transfer to nitrate, nitrite, nitric oxide, and finally nitrous oxide to produce dinitrogen gas. Under steady operating conditions, the nitrous oxide reduction rate is almost four times faster than the nitrate and nitrite reduction rates, and thus, little if any nitrous oxide would be present (Wicht, 1996). But under transient conditions nitrous oxide can accumulate because the induction of nitrous oxide reductase is slower than that for the upstream reductase enzymes (Holtan-Hartwig et al., 2000).

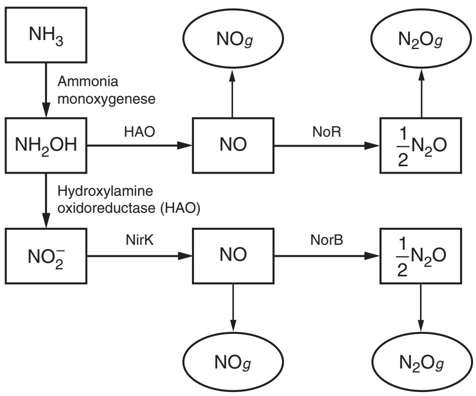
Dissolved oxygen affects nitrous oxide production by inhibiting the synthesis and activity of nitrous oxide reductase, and its activity has been found to stop immediately when the denitrifying bacteria moved from an anaerobic to aerobic environment. Nitrite reductase activity continues at a lower rate under the same transition, so that nitrous oxide emissions will occur (Law et al., 2012). The effect of DO is not the same for all denitrifying bacteria.

Figure 7–22

Pathways for nitrus oxide (N_2O) production in biological nitrogen transformation.



(a) Heterotrophic denitrification



(b) Ammonia oxidation

Lu and Chandran (2010) found that bacteria grown with methanol substrate were much less sensitive to transient DO changes than bacteria grown with ethanol. Insufficient carbon for complete denitrification can also cause more nitrous oxide production (Rassamee et al., 2011).

Nitrous Oxide Production from Ammonia Oxidation. Biological ammonia oxidation to nitrite plays a major role in nitrous oxide production. As illustrated on Fig. 7–22(b), two pathways have been proposed for the production of nitrous oxide by AOB: (1) hydroxylamine (NH_2OH) oxidation and (2) denitrification of nitrite (Ward et al., 2011 and Law et al., 2012).

In the upper pathway, aerobic oxidation of ammonia is started with the membrane bound ammonia mono-oxygenase enzyme (AMO) to produce NH_2OH. The subsequent step of converting NH_2OH to NO_2^- is catalyzed by hydroxylamine oxidoreductase (HAO), which involves a nitroxyl radical (NOH) and conversion of NOH to NO_2^-. Nitric oxide can be formed from HAO activity and the NOH intermediate as shown on Fig. 7–22. The NO thus formed can then be reduced to N_2O. There are also other enzymes, especially in AOB, which can convert NO to N_2O, which for the sake of brevity could be collectively termed NO reductases.

In the second pathway involving nitrite reduction, the AOB contain gene homologues that encode for the production of nitrite reductase (NirK) and nitric oxide reductase (NorB), respectively. There is no gene to express nitrous oxide reductase, and thus nitrous oxide is the end product of nitrite reduction by AOB (Yu et al., 2010). AOB can use hydroxylamine, hydrogen, and ammonia as electron acceptors for nitrite and nitric oxide reduction (Poth and Focht, 1985, Bock et al., 1995, and Ritchie and Nicholas, 1972). Nitrous oxide production by AOB can occur at both low DO (Poth and Focht, 1985) and high DO concentrations (Beaumont et al., 2004), depending on the level of gene expression for *nirK* and *norB*. A key factor to inducing enzymes for more nitrous oxide production is higher specific AOB ammonium oxidation rates, which occurs with an increase in the reactor ammonium concentration and DO concentration (Yu et al., 2010).

An exponential increase in nitrous oxide production with increasing specific ammonium oxidation rates has been shown by Law et al. (2012). Such conditions can occur in biological nutrient removal processes, with a preanoxic contact tank before aerobic nitrification or transient operating conditions that caused spikes in ammonium concentration (Yu et al., 2010; Kampschreur et al., 2008). Higher nitrite concentrations during nitrification can also cause more nitrous oxide emission (Kim et al., 2010; Yang et al., 2009; Gustavsson and Jansen, 2011; Ahn et al., 2011). Nitrification processes that have less variable conditions in ammonia and DO concentration and low nitrite concentration are more favorable for minimizing nitrous oxide emissions. In anoxic/aerobic activated sludge systems for biological nitrogen removal, the nitrous oxide emissions are greater from the nitrification step than from the preanoxic zone due to conditions that increase the ammonia concentrations (Chandran et al., 2011).

Nitrous Oxide Production from Anammox Deammonification. Nitrous oxide emissions have been observed in applications of the anammox deammonification process. Although anammox bacteria by themselves cannot produce N_2O, they can produce NO, which might be reduced to N_2O by other bacteria in the mixed population, including AOB and heterotrophic denitrifying bacteria. Nitrous oxide production has been related to a carbon limitation by having only endogenous respiration to provide carbon for heterotrophic denitrification (Schneider et al., 2011). In another study, a recommendation to avoid excessive nitrous oxide emissions was to operate the anammox process with a minimal reactor nitrite concentration (Weissenbacher et al., 2010).

7–13 ENHANCED BIOLOGICAL PHOSPHORUS REMOVAL

Phosphorus removal from wastewater treated effluent is done to control eutrophication because phosphorus is a limiting nutrient in most freshwater systems. Treatment plant effluent discharge permit limits for phosphorus removal have ranged from 0.10 to 1.0 mg/L of phosphorus, and in some locations as low as 0.05 mg/L, depending on plant location and potential impact on receiving waters. Phosphorus can be removed by chemical treatment, biological phosphorus removal, or a combination of both. Chemical treatment using alum or iron salts, followed by tertiary filtration or membrane separation, is the technology used most commonly for achieving low effluent phosphorus concentrations (see Sec. 6–4 in Chap. 6).

Enhanced biological phosphorus removal involves the incorporation of phosphorus in the biomass produced in the treatment system and subsequently the removal of the biomass in sludge wasting. Biomass produced by cell growth by ordinary heterotrophic bacteria from BOD removal may contain about 0.015 g P/g VSS, such that only 10 to 20 percent phosphorus removal can be expected by this pathway in domestic wastewater treatment. However, since the late 1970s full-scale plant design configurations that select for phosphorus storing bacteria commonly called *phosphorus accumulating organisms* (PAOs) have been used to provide over 80 percent biological phosphorus removal. These processes have been referred to as *enhanced biological phosphorus removal* (EBPR). The principal advantages of enhanced biological phosphorus removal are reduced chemical costs and less sludge production as compared to chemical precipitation. A review of the discovery and implementation of EBPR processes is provided by Barnard (1998). In addition EBPR captures influent phosphorus in a form that is suitable for phosphorus recovery in wastewater treatment.

Process Description

Phosphorus accumulating organisms (PAOs) are encouraged to grow and consume phosphorus in systems that use a reactor configuration that provides PAOs with a competitive advantage over other bacteria. The reactor configuration utilized for phosphorus removal is comprised of an anaerobic tank having a hydraulic retention time, τ, of 0.50 to 1.0 h that is placed ahead of the activated sludge aeration tank (see Fig. 7–23). The contents of the anaerobic tank are mixed to provide contact with the return activated sludge and influent wastewater. Anaerobic contact tanks have been placed in front of many different types of suspended growth processes (see detailed discussion in Sec. 8–6 in Chap. 8), with aerobic SRT values ranging from 3 to 40 d.

The key to the PAO competitive advantage in the anaerobic contact zone is that they are able to transport and consume influent readily biodegradable COD (rbCOD) in the form of volatile fatty acids (e.g., acetic acid and propionic acid) by using energy made available from their stored phosphorus as polyphosphates. They are also able to use that energy along with cellular glycogen to direct the substrate uptake to internal carbohydrate storage products for oxidation later in the aerobic zone. The other heterotrophic bacteria in the anaerobic zone are not able to consume the rbCOD because they need an electron acceptor, such as oxygen, nitrate, or nitrite, for oxidation-reduction reactions to provide energy for substrate utilization.

The anaerobic zone in the anaerobic/aerobic treatment process is termed a “selector,” because it provides conditions that favor the uptake of rbCOD and proliferation of the PAOs over other heterotrophic bacteria. Because the PAOs prefer low-molecular-weight fermentation product substrates, the preferred food source would not be available without the anaerobic zone that provides for the fermentation of the influent rbCOD to acetate.

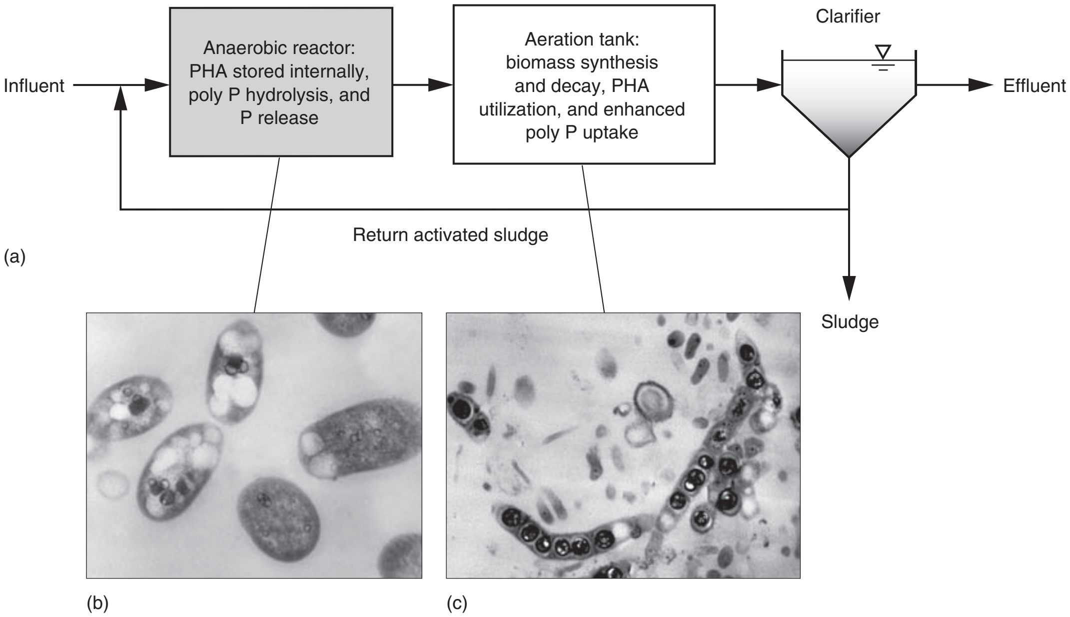


Figure 7–23

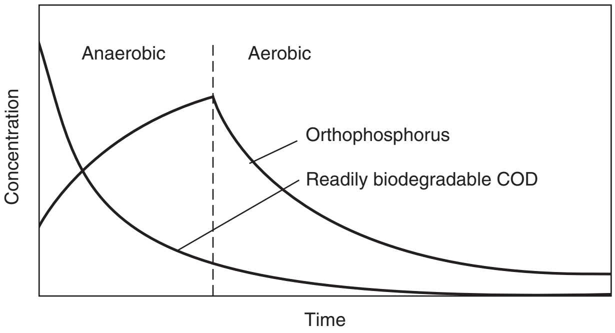
Enhanced biological phosphorus removal: (a) typical reactor configuration. Photos below flow diagram are of (b) transmission electron microscope image of polyhydroxybutyrate storage and (c) polyphosphate storage granules.

Other aerobic heterotrophic bacteria have no such mechanism for acetate uptake, and they are starved while the PAOs assimilate COD in the anaerobic zone. It should also be noted that the PAOs form very dense floc that settles well, which is an added benefit. In some facilities, the anaerobic/aerobic process sequence has been used as a "selector" to produce a sludge that settles well, even though EBPR was not required.

The biological process steps for EBPR are summarized below and indicated in the anaerobic and aerobic zones in Fig. 7–23. An example of the change in orthophosphorus and rbCOD concentrations in a batch anaerobic/aerobic operation after wastewater feeding is given on Fig. 7–24. The anaerobic zone soluble orthophosphorus concentration is often two to three times higher than the influent soluble orthophosphorus concentration and is a good indicator of an active EBPR system. The phosphorus release rate is normally faster than the subsequent phosphorus uptake rate.

Figure 7–24

Fate of rbCOD and phosphorus in enhanced biological phosphorus removal reactor. (Adapted from Sedlak, 1991.)



Processes Occurring in the Anaerobic Zone

Acetic and propionic acid are consumed by PAOs in the anaerobic zone. These VFAs may enter the anaerobic zone in the influent wastewater and are also produced by other facultative bacteria through fermentation of influent rbCOD, which, as defined earlier, is dissolved degradable organic material that can be assimilated easily by the biomass. Most of the volatile fatty acids available are in the form of acetate. Depending on the anaerobic zone hydraulic retention time, some colloidal and particulate COD is also hydrolyzed and converted to acetic acid/propionic acid, but the amount is generally much less than that from the rbCOD.

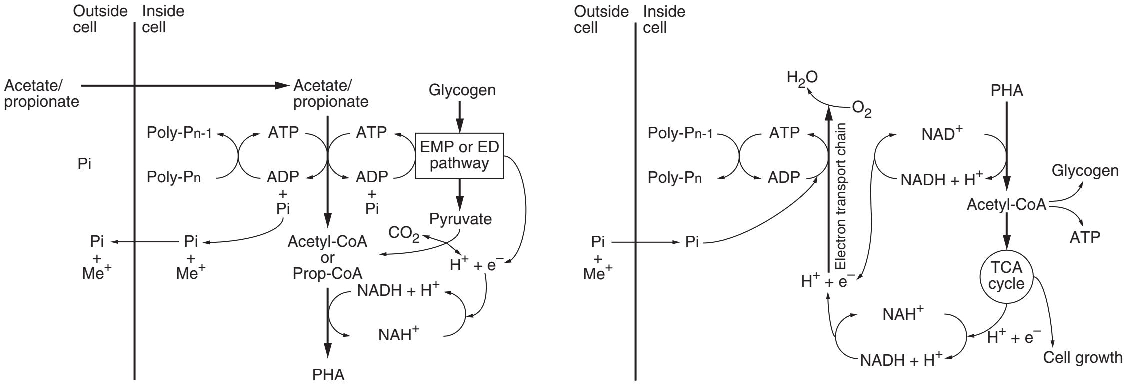
Using energy available from stored polyphosphates, the PAOs assimilate acetate and produce intracellular poly-β-hydroxyalkanoate (PHA) storage products. The typical PHAs are poly-β-hydroxybutyrate (PHB) and polyhydroxyvalerate (PHV). Some glycogen contained in the cell is also used for PHA storage. Concurrent with the acetic acid/propionic acid uptake is the release of orthophosphate (O-PO_4), as well as magnesium, potassium, and calcium cations. The PHA content in the PAOs increases while their polyphosphate content decreases.

Processes Occurring in a Downstream Aerobic or Anoxic Zone

The principal processes occurring downstream are

1. Stored PHA is metabolized, providing energy from oxidation and carbon for new cell growth.
2. Some glycogen is produced from PHA metabolism.
3. The energy released from PHA oxidation is used to form polyphosphate bonds in cell storage so that soluble orthophosphate (O-PO_4) is removed from solution and incorporated into polyphosphates within the bacterial cell. Cell growth also occurs due to PHA utilization and the new biomass with high polyphosphate storage accounts for phosphorus removal.
4. As a portion of the biomass is wasted, stored phosphorus is removed from the biotreatment reactor for ultimate disposal with the waste sludge.
5. These processes can also occur in a downstream anoxic zone prior to anaerobic zone, as there are PAO species that can use nitrate and nitrite as the electron acceptor for substrate oxidation.

Biochemical models have been presented to describe the interactions between acetate uptake, polyphosphates, and PHA storage in the anaerobic and aerobic zones and a representation of these is given on Fig. 7–25 (Comeau et al., 1986, Wentzel et al., 1991, Smolders et al., 1995, and Mino et al., 1998). In the anaerobic zone, energy is required for transport of acetate across the cell and for conversion of it to acetyl coenzyme A (acetyl-CoA). As the cell uses energy, adenosine diphosphate (ATP) is converted to adenosine disphosphate (ADP). The ADP is regenerated to ATP from hydrolysis of the stored polyphosphates with release of phosphorus and a metal cation for charge balance, typically potassium or magnesium. The PHA is produced from the acetyl-CoA and the reducing power provided by degradation of glycogen through the Embden-Meyerhof or Entner-Doudoroff pathways. The glycolysis also provides some ATP for the production of acetyl-CoA. In the aerobic zone the PAOs use the stored PHA as an energy and carbon source for cell growth. Metabolism of the PHA results in cell growth, glycogen production by gluconeogenisis, and energy production through electron transport phosphorylation with



(a) Anaerobic

(b) Aerobic

Figure 7–25

Biochemical model for phosphorus release and removal by PAOs: (a) under anaerobic conditions and (b) under aerobic conditions.

oxygen or nitrate/nitrite as the final electron acceptor. With the energy produced, polyphosphate synthesis occurs with uptake of orthophosphate and the metal cations from solution.

Microbiology

Isolation of PAOs has not been successful, but through the use of molecular techniques Bond et al. (1995) identified PAOs in the *Rhodocyclus* group in the *Betaproteobacteria* named them "Candidatus *Accumulibacter Phosphatis*," which have subsequently been divided into Accumulibacter Type I and Type II (Oehmen et al., 2010). Type I can use nitrate or nitrite as electron acceptors and are referred to as denitrifying PAOs (DPAOs) (Nielsen et al., 2010). The complete genome of *A. Phosphatis* has been sequenced to provide valuable information about the gene makeup and metabolism (Martin et al., 2006). A *Tetrasphaera*-related PAO within the *Actinobacteria* has also been found in domestic WWTPs and with greater abundance in industrial WWTPs (Kong et al., 2005). *Tetrasphaera* do not store PHA, may prefer amino acids, and can use nitrate but not nitrite in addition to oxygen as an electron acceptor. However, information on their metabolism is limited.

A competitor to PAOs for volatile fatty acid (VFA) uptake under anaerobic conditions is referred to as a glycogen accumulating organism (GAO). This type of organism was originally observed as tetrad forming cells by Cech and Hartman (1990) and referred to as "*G*" bacteria because of their growth and glycogen storage with glucose feed. The term GAO is from Mino et al. (1995) based on the organism's storage of glycogen under aerobic conditions and consumption of glycogen under anaerobic conditions to provide energy for VFA uptake and production of PHA in the anaerobic zone of an EBPR system. The GAOs do not have stored polyphosphates for energy during VFA uptake and do not provide EBPR. One indicator of having a competitive GAO population in an EBPR system is a reduced phosphorus release to acetate uptake ratio in the anaerobic zone to well below the typical value of 0.50 g P/g acetate for PAOs (Gu et al., 2008).

The GAOs have been identified as a phenotype belonging to *Gammaproteobacteria* and were named "Candidatus *Competibacter Phosphatis*" by Crocetti et al. (2002). These and many GAOs form tetrads, which are large cells in groupings of four. *Defluviicoccus vanus* is another tetrad-forming GAO found within the *Alphaproteobacteria* (Wong et al., 2004), but these are not considered as common in EBPR WWTPs as the *Competibacter*. All of the GAOs identified so far have been shown capable of using nitrate as an electron acceptor in addition to oxygen, but only *Competibacter* Type I can use nitrite as well (Nielsen et al., 2010).

Factors that affect the competition between PAOs and GAOs include the feed acetate and propionate composition, pH, temperature, and SRT. *Accumulibacter* are able to use acetate and propionate at similar rates and outcompete *Competibacter* with only propionate present due to a greatly reduced uptake of propionate versus acetate by *Competibacter* (Oehmen et al., 2006). However, the *Alphaproteobacteria* GAOs consume propionate faster than acetate and thus can compete with the PAOs. A strategy of alternating VFA feed between acetate and propionate almost completely eliminated GAOs, as the *Accumulibacter* could compete against the *Competibacter* under propionate feed and against the *Alphaproteobacteria* under acetate feeding (Lu et al., 2006).

Higher pH values above 7.0 favor PAO growth over GAO, with a pH value above 7.5 being most favorable for PAOs (Lopez-Vazquez et al., 2009a). A critical pH of 7.25 was reported by Filipe et al. (2001), with GAO growth greatly favored below that value due to a faster anaerobic VFA consumption rate at lower pH. Zhang et al. (2005) found that EBPR performance was greatly decreased when the pH was reduced from 7.0 to 6.5.

Effective EBPR performance has been observed at temperatures as low as 5°C (Brdjanovic et al., 1998). At temperatures of 10°C and less, PAOs are greatly favored over GAOs, regardless of pH (Lopez-Vazquez et al., 2009a). Based on a metabolic model for PAOs and GAOs, Lopez-Vazquez et al. (2009b) found that at temperatures between 20 and 30°C, GAO tend to dominate over PAOs unless a high pH is present (≥7.5) or a favorable acetate to propionate feed ratio (75:25 or 50:50, respectively) is used. At temperatures below 15°C and above 30°C, the GAOs have much lower growth rates and require much higher aerobic tank SRTs than the PAOs (Lopez-Vazquez et al., 2009a). A dominant GAO population was changed to a dominant PAO population by Whang and Park (2006) at 30°C by reducing the aerobic SRT from 6 to 1.8 d.

Other Process Considerations for EBPR

If significant amounts of dissolved oxygen or nitrate enter the anaerobic zone, the VFAs can be depleted before it is taken up by the PAOs, and treatment performance will be hindered due to less growth of PAOs. Biological phosphorus removal is not used in systems that are designed with nitrification without including a means for denitrification to minimize the amount of nitrate in the return sludge flow to the anaerobic zone. These processes are described in Sec. 8–7 in Chap. 8.

Phosphorus release by PAOs in the EBPR system or in waste sludge handling can have a negative impact on the WWTP phosphorus removal efficiency. When the PAO-containing mixed liquor, whether in the EBPR process or in waste sludge processing, is held under anaerobic conditions, phosphorus release will occur. Release of ortho phosphate (O-PO_4) is possible even without acetate addition as the bacteria use the stored polyphosphate for an energy source. The release of O-PO_4 can also occur after extended contact time in the anaerobic or anoxic zones of an EBPR system in the absence of VFA. However, because the release was not associated with acetate or propionate uptake with PHA storage for later oxidation, phosphorus may not be taken up in the aerobic zone. The release of O-PO_4

under these conditions is termed secondary release (Barnard, 1984), which can lead to a lower phosphorus removal efficiency for the biological process. Recycle return flow from waste sludge handling processes used in EBPR systems may contain high levels of phosphorus if the waste sludge handling involves anaerobic holding times, such as that from gravity thickeners and dewatering following anaerobic digestion. In addition, phosphorus is released due to biomass destruction in aerobic digestion. Uncontrolled struvite precipitation in sidestream piping system is also a common problem at EBPR plants that use digesters. The chemistry of struvite formation is considered in Chap. 6. The management of these return streams, including phosphorus recovery processes, is addressed in Sec. 15–4. in Chap. 15.

Stoichiometry of Enhanced Biological Phosphorus Removal

Based on the description of the phosphorus removal mechanism, the PAOs remove two other components from the influent wastewater to support their growth and phosphorus removal via waste sludge from an EBPR system: (1) metal cations and (2) VFA as acetate or propionate. The recommended molar ratio of P/Mg/K has been given as 1.0/0.33/0.33 respectively, by Pattarkine and Randall (1999). With consideration for calcium uptake, the recommended molar ratio of P/Mg/K/Ca of 1/0.28/0.26/0.09, respectively, was given by Sedlak (1991). Based on the latter molar ratio, 0.63 g of other inorganics is added to the waste sludge weight per g of phosphorus as P removed by PAOs. An increase in sludge volume is minimally affected due to the dense floc formed by PAOs. The VSS/TSS ratio for an enriched PAO system can be as low as 60 to 65 percent compared to 85 percent for ordinary heterotrophs. Most municipal wastewaters have sufficient amounts of the metal cations needed by PAOs, but care must be taken to assure sufficient amounts in industrial applications or laboratory experiments.

Acetate or propionate uptake in the anaerobic zone is critical in determining the amount of PAOs that can be produced and, thus, the amount of phosphorus that can be removed by this pathway. The amount of phosphorus removed by biological storage can be estimated from the amount of bsCOD that is available in the wastewater influent by assuming an rbCOD fraction that can be converted to acetate in the short anaerobic hydraulic retention time τ. Methods for determining the amount of rbCOD in the influent will be described in Sec. 8–2 in Chap. 8, which deals with wastewater characterization.

The following assumptions are used to evaluate the stoichiometry of biological phosphorus removal: (1) approximately 1.0 g acetate COD/g rbCOD fermented will be produced as most of the COD fermented will be converted to VFAs due to the low cell yield of the fermentation process, (2) a cell yield of 0.45 g VSS/g acetate COD consumed by PAOs, and (3) a cell phosphorus content 0.20 to 0.30 g P/g VSS at 20°C (Panswad et al., 2003). Using these assumptions, about 7 to 11 g of rbCOD will be required to remove 1 g of phosphorus by the EBPR mechanism. Actual values in EBPR systems may range from 8 to 20 g P/g rbCOD, depending on the relative GAO and PAO populations and the fraction of acetate in the influent rbCOD. Other bCOD removal in the activated sludge system will result in additional phosphorus removal by normal cell synthesis.

Better performance for biological phosphorus removal systems is achieved when rbCOD or acetate is available at a steady pace. Periods of starvation or low rbCOD concentrations result in changes in the intracellular storage reserves of glycogen, PHA, and polyphosphates and rapidly lead to decreased phosphorus removal efficiency (Stephens and Stensel, 1998). The amount of phosphorus that can be removed from a wastewater is illustrated in Example 7–9.

EXAMPLE 7–9 **Estimating the Amount of Phosphorus Removal** Given the following influent wastewater characteristics and the corresponding biological process information, estimate the effluent phosphorus concentration. Assume that 90 percent of the rbCOD is fermented to acetate in the EBPR anaerobic contact zone. and that the PAO specific endogenous decay rate is 0.08 g/g-d. No nitrification has occurred in the system, and the amount of DO entering the anaerobic zone is negligible.

Influent	Concentration, g/m^3
COD	300
bCOD	200
rbCOD	50
Phosphorus, as P	6.0

1. Conversion of rbCOD to acetate in the anaerobic zone = 90 percent
2. Bacteria synthesis yield, $Y = 0.45$ g VSS/g COD
3. Endogenous decay coefficient, $b = 0.08$ g VSS/g VSS·d
4. SRT = 5 d
5. Phosphorus content of PAOs = 0.30 g P/g VSS
6. Phosphorus content of other bacteria = 0.02 g P/g VSS
7. Clarifier effluent VSS concentration = 8 g/m^3

Solution

1. Determine phosphorus removed by PAOs.
   a. Acetate COD production = 0.90(50 g/m^3 rbCOD) = 45 g/m^3 COD
   b. Determine PAO biomass produced, normalized to flow, using Eq. (7–54) and neglecting cell debris.

$$\text{PAO biomass produced} = \left[\frac{Y}{1 + b(\text{SRT})}\right]\text{bsCOD}$$

$$= \left\{\frac{(0.45\text{ g VSS/g COD})}{[1 + (0.08\text{ g/g·d})(5\text{d})]}\right\}(45\text{ g bsCOD/m}^3) = 14.5\text{ g VSS/m}^3$$

   c. Determine the phosphorus removed by PAO biomass.

   P removed = (0.30 g P/g VSS)(14.5 g VSS/m^3) = 4.4 g/m^3

2. Determine phosphorus removed by other heterotrophs for cell synthesis from the conversion of bCOD.
   a. Determine the bCOD removed by other heterotrophic bacteria.

   bCOD removed = 200 – 45 g/m^3 = 155 g/m^3

$$\text{Other biomass produced} = \left[\frac{Y}{1 + b(\text{SRT})}\right]\text{bCOD}$$

$$= \left\{\frac{(0.45\text{ g VSS/g COD})}{[1 + (0.08\text{ g/g·d})(5\text{d})]}\right\}155\text{ g bCOD/m}^3 = 49.8\text{ g VSS/m}^3$$

   b. Determine the phosphorus removed.

   P removed = 0.02 g P/g VSS = 0.02(49.8) = 1.0 g/m^3

3. Determine total phosphorus removed into biomass and effluent soluble phosphorus concentration.

   Total P removed = 4.4 + 1.0 = 5.4 g/m^3

   Effluent soluble concentration = 6.0 – 5.4 = 0.60 g/m^3

4. Estimate P content of effluent VSS.

Average P content of effluent VSS

$$= \frac{(0.30\,\text{g P/g VSS})(14.5\,\text{g/m}^3) + (0.02\,\text{g P/g VSS})(49.8\,\text{g/m}^3)}{[(14.5 + 49.8)\,\text{g/m}^3)]}$$

$$= 0.083\,\text{g P/g VSS}$$

Phosphorus in effluent VSS $= 0.083(8\ \text{g/m}^3) = 0.67\ \text{g/m}^3$

Total effluent P concentration $= 0.60 + 0.67 = 1.27\ \text{g/m}^3$

Growth Kinetics

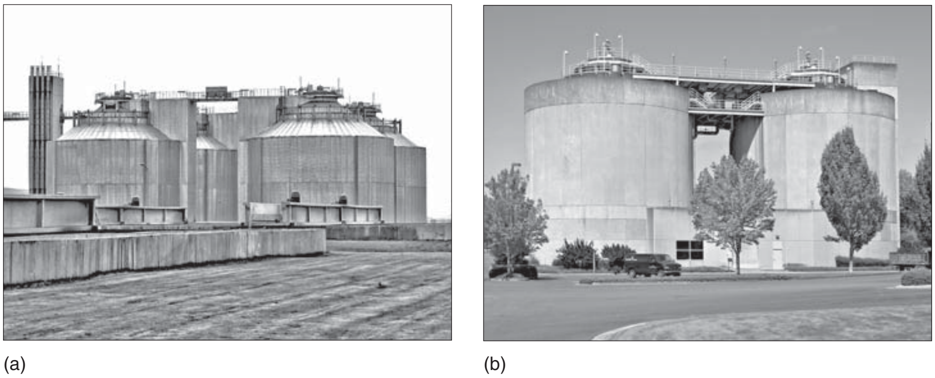
Biological phosphorus growth kinetics are within the same order of magnitude as other heterotrophic bacteria. Mamais and Jenkins (1992) showed that enhanced biological phosphorus removal could be maintained in anaerobic/aerobic systems at aerobic SRTs greater than 2.5 d at 20°C. A maximum specific growth rate at 20°C is given as 0.95 g/g•d (Barker and Dold, 1997).

Environmental Factors

System performance is not affected by DO as long as the aerobic zone DO concentration is above 1.0 mg/L. The effect of pH is primarily related to PAO versus GAO population distribution as given above. Denitrifying PAOs can use nitrite as an electron acceptor in addition to nitrate in the anoxic zone for oxidation of intracellular PHA. However, nitrite concentrations greater than 2.0 g/m^3 are inhibitory to phosphate uptake under both anoxic and aerobic conditions, with a greater effect under aerobic conditions. At 6.0 g/m^3, aerobic uptake of phosphate by PAOs is severely limited (Saito et al., 2004).

7–14 ANAEROBIC FERMENTATION AND OXIDATION

Anaerobic fermentation and oxidation processes are used primarily for the treatment of waste sludge (see Fig. 7–26) and high-strength organic wastes. In warm climates, anaerobic fermentation has been used as a pretreatment step for conventional biological treatment. Applications for dilute waste streams have also been demonstrated. A major



(a)

(b)

Figure 7–26

Views of anaerobic digesters: (a) Ankara, Turkey, and (b) Tigard, OR.

advantage of anaerobic fermentation and oxidation processes are lower biomass yields and energy production in the form of methane from the biological conversion of organic substrates. Although most fermentation processes are operated in the mesophilic temperature range (30 to 35°C), there is increased interest in thermophilic fermentation alone or before mesophilic fermentation for municipal sludge processing. The latter is termed temperature phased anaerobic digestion (TPAD) and is typically designed with a sludge SRT of 3 to 7 d in the first thermophilic phase at 50 to 60°C and 7 to 15 d in the final mesophilic phase (Han and Dague, 1997). Thermophilic anaerobic digestion processes, considered in Chap. 13, are used to accomplish high pathogen kill to produce *Class A biosolids* (defined in Chap. 14) that can be used in the United States for unrestricted reuse applications.

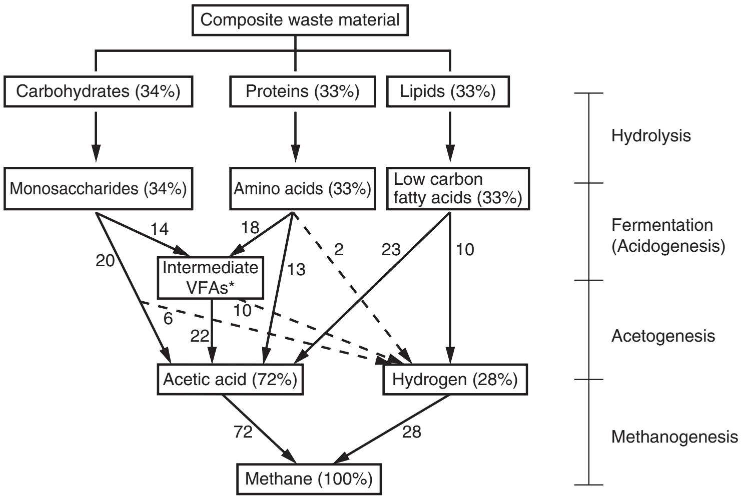
Anaerobic treatment for high-strength industrial wastewaters has been shown to provide a very cost-effective alternative to aerobic processes with savings in energy, nutrient addition, and reactor volume. Because the effluent quality is not as good as that obtained with aerobic treatment, anaerobic treatment is commonly used as a pretreatment step prior to discharge to a municipal collection system or is followed by an aerobic process. Suspended and attached growth anaerobic treatment process designs for liquid streams are presented in Chap. 10, and anaerobic digester designs for sludge treatment are presented in Chap. 13.

Process Description

Three basic steps are involved in the overall anaerobic oxidation of a waste: (1) hydrolysis, (2) acidogenesis (also known as fermentation or anaerobic oxidation), and (3) methanogenesis. The three steps are illustrated schematically on Fig. 7–27, which shows the fate of solids through hydrolysis, volatile fatty acids (VFAs) and hydrogen production to methane. An intermediate step, termed acetogenesis, occurs for some of the VFAs produced from acidogenesis. The starting point on the schematic for a particular application depends on the nature of the waste to be processed. Sometimes the process is intentionally stopped midway such as when primary solids are fermented in gravity thickeners, and the supernatant, which is rich in VFAs, is used for EBPR.

Figure 7–27

Fate of biodegradable COD in anaerobic processing of waste solids. (Adapted from Jerris and McCarty, 1963, 1981, and Batstone et al., 2006.)



* Propionate, butyrate, valerate

Hydrolysis. The first basic step, in which particulate material is converted to soluble compounds that can then be hydrolyzed further to simple monomers that are used by bacteria that perform fermentation, is termed *hydrolysis*. For some high strength soluble industrial wastewaters, fermentation may be the first step in the anaerobic process. Hydrolysis is carried out with extracellular enzymes produced by a variety of facultative and obligate anaerobes (Confer and Logan, 1998; Song et al., 2005). Lipids are broken down to long chain fatty acids (LCFAs) by lipases produced by bacteria that include *Butyrivibrio* sp., *Clostridium* sp., and *Anaerovibrio lipolytica.* Peptide and amino acid are due to bacteria exhibiting extracellular protease activity including *Clostridium proteolyticum*, *Eubacterium* sp., and *Peptococcus anaerobicus (*McInerney, 1988).

Acidogenesis. The second basic step, which is done by bacteria, is *acidogenesis* (also termed *fermentation*) and results in the production of VFAs, CO_2, and hydrogen as shown on Fig. 7–27. In the fermentation process, substrates serve as both the electron donors and acceptors. The principal fermentation products from the sugars and amino acids are acetate, propionate, butyrate, CO_2, and hydrogen. Fermentation of the LCFAs results in the production of acetate, CO_2, and hydrogen. A larger fraction of the LCFA COD is converted to hydrogen than that for the sugars and amino acids.

Acetogenesis. Acetogenesis refers to further fermentation by bacteria to convert intermediate products of acidogenesis (propionate and butyrate) to also produce acetate, CO_2, and hydrogen. Thus, the final products of fermentation are acetate, hydrogen, and CO_2, which are the precursors of methane formation. The free energy change associated with the conversion of propionate and butyrate to acetate and hydrogen requires that hydrogen be at low concentrations in the system ($H_2 < 10^{-4}$ atm), or the reaction will not proceed (McCarty and Smith, 1986). Most of the hydrogen produced comes from the oxidation of LCFAs and intermediate VFAs to acetic acid and is referred to as anaerobic oxidation.

Methanogenesis. The third basic step, *methanogenesis*, is carried out by a group of *Archaea* organisms known collectively as methanogens. Two groups of methanogenic organisms are involved in methane production. One group, termed *aceticlastic methanogens*, split acetate into methane and carbon dioxide. The second group, termed hydrogen-utilizing methanogens or *hydrogenotrophic methanogens*, use hydrogen as the electron donor and CO_2 as the electron acceptor to produce methane. Bacteria within anaerobic processes, termed *acetogens*, are also able to use CO_2 to oxidize hydrogen and form acetic acid. However, the acetic acid will be converted to methane, so the impact of this reaction is minor. As shown on Fig. 7–27, about 72 percent of the methane produced in anaerobic digestion is from acetate formation. The composition of the gas produced from a stable fermentation and methanogenesis operation typically contains about 65 percent methane and 35 percent CO_2. A higher lipid fraction in the waste results in a higher methane fraction in the digester gas (Li et al., 2002).

Microbiology

The group of nonmethanogenic microorganisms responsible for hydrolysis and fermentation consists of a diverse group of facultative and obligate anaerobic bacteria. Organisms isolated from anaerobic digesters include *Clostridium* spp., *Peptococcus anaerobus*, *Bifidobacterium* spp., *Desulphovibrio* spp., *Corynebacterium* spp., *Lactobacillus*, *Actinomyces*, *Staphylococcus*, and *Escherichia coli*. Other physiological groups present include those producing proteolytic, lipolytic, ureolytic, or cellulytic enzymes.

The microorganisms responsible for methane production, classified as archaea, are strict obligate anaerobes. Many of the methanogenic organisms identified in anaerobic digesters are similar to those found in the stomachs of ruminant animals and in organic sediments taken from lakes and rivers. The hydrogenotrophic methanogens are found within four orders of the Archaea: *Methanobacteriales*, *Methanococcales*, *Methanomicrobiales,* and *Methanopyrales* (Madigan et al., 2012). They obtain their energy from the oxidation of hydrogen and also use CO_2 for their carbon sources, resulting in low biomass synthesis yields.

$$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O \tag{7–137}$$

The archaea that produce methane from acetate are referred to as aceticlastic methanogens and are in the order *Methanosarcinales*. The acetate is cleaved, and the methyl carbon ends up in methane and the carboxyl carbon in CO_2.

$$CH_3COOH \rightarrow CH_4 + CO_2 \tag{7–138}$$

Only two genera within the order *Methanosarcinales* are able to use acetate to produce methane and carbon dioxide: *Methanosarcina* and *Methanosaeta* (formerly named *Methanothrix*) (Madigan et al., 2012). These organisms differ in both their morphology and kinetic characteristics. The *Methanosarcina* have a coccoid shape and appear in grape-like clumps, while the *Methanosaeta* have long rod to filament shapes (Lange and Ahring, 2001). The *Methanosarcina* have a high maximum specific growth rate ($\mu_{\max}$) and high half-saturation coefficient (K_S) and the *Methanosaeta* have a low $\mu_{\max}$ and low $K_{S\text{ values.}}$ The *Methanosaeta* are dominant in anaerobic digesters due to the long SRT and low acetate concentration. However, *Methanosarcina* handles increases in acetate more efficiently and thus promotes more stable digestion. Laboratory anaerobic digester investigations and digester modeling studies showed that a *Methanosarcina* population could be established with daily batch feeding versus frequent feeding intervals (Conklin et al., 2006 and Straub et al., 2006). Values for K_s for acetate utilization by enrichments of *Methanosaeta* and *Methanosarcina* are 90 g/m^3 and 320 g/m^3, respectively. Representative $\mu_{\max}$ values at 35°C are 0.16 g/g·d and 0.80 g/g·d for *Methanosaeta* and *Methanosarcina*, respectively (Conklin et al., 2006).

The acetate-utilizing methanogens were also observed in thermophilic reactors (van Lier, 1996; Zinder and Koch, 1984; and Ahring, 1994). Some species of *Methanosarcina* were inhibited by temperature at 65°C, while others were not, but no inhibition of *Methanosaeta* was shown. For hydrogen-utilizing methanogens at temperatures above 60°C, *Methanobacterium* was found to be very abundant.

Other anaerobic reactions by methanogenic archaea are formate degradation (Eq. 7–139) by organisms in the orders *Methanobacteriales*, *Methanomicrobiales*, and *Methanococcales*, methanol degradation Eq. (7–140) by organisms in the orders *Methanobacteriales* and *Methanosarcinales*, and methylamines degradation (Eq. 7–141) by organisms in the order *Methanosarcinales* (Madigan et al., 2012).

$$4HCOO^- + 4H^+ \rightarrow CH_4 + 3CO_2 + 2H_2O \tag{7–139}$$

$$4CH_3OH \rightarrow 3CH_4 + CO_2 + 2H_2O \tag{7–140}$$

$$4(CH_3)_3N + H_2O \rightarrow 9CH_4 + 3CO_2 + 6H_2O + 4NH_3 \tag{7–141}$$

Syntrophic Relationships in Fermentation. The methanogens and the acidogens form a syntrophic (mutually beneficial) relationship in which the methanogens convert fermentation end products such as hydrogen, formate, and acetate to methane and carbon dioxide. Because the methanogens are able to maintain an extremely low partial pressure of H_2, the equilibrium of the fermentation reactions is shifted toward the formation of more oxidized end products (e.g., formate and acetate). The utilization of the hydrogen produced by the acidogens and other anaerobes by the methanogens is termed *interspecies hydrogen transfer*. In effect, the methanogenic organisms serve as a hydrogen sink that allows the fermentation reactions to proceed. If process upsets occur and the methanogenic organisms do not utilize the hydrogen produced fast enough, the propionate and butyrate fermentation will be slowed with the accumulation of volatile fatty acids in the anaerobic reactor and a possible reduction in pH.

Nuisance Organisms. Nuisance organisms in anaerobic operations are the sulfate-reducing bacteria, which can be a problem when the wastewater contains significant concentrations of sulfate. These organisms can reduce sulfate to sulfide, which can be toxic to methanogenic bacteria at high enough concentrations. Where high sulfide concentrations occur, one solution is to add iron at controlled amounts to form iron sulfide precipitate. Sulfate-reducing bacteria, obligate anaerobes of the domain Bacteria, are morphologically diverse but share the common characteristic of being able to use sulfate as an electron acceptor and are divided into one of two groups, depending on whether they produce fatty acids or use acetate. Group I sulfate reducers can use a diverse array of organic compounds as their electron donor, oxidizing them to acetate and reducing sulfate to sulfide. A common genus found in anaerobic biochemical operations is *Desulfovibrio*. Group II sulfate reducers oxidize fatty acids, particularly acetate, to carbon dioxide, while reducing sulfate to sulfide. A bacteria commonly found in this group is in the genus *Desulfobacter*.

Stoichiometry of Anaerobic Fermentation and Oxidation

A COD balance can be used to account for the changes in COD during fermentation and oxidation. Instead of oxygen accounting for the change in COD, the COD loss in the anaerobic reactor is accounted for by the methane production. By stoichiometry the COD equivalent of methane can be determined. The COD of methane is the amount of oxygen needed to oxidize methane to carbon dioxide and water.

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O \tag{7–142}$$

From the above, the COD per mole of methane is 2(32 g O_2/mole) = 64 g O_2/mole CH_4. The volume of methane per mole at standard conditions (0°C and 1 atm) is 22.414 L, so the CH_4 equivalent of COD converted under anaerobic conditions is 22.414/64 = 0.35 L CH_4/g COD.

EXAMPLE 7–10 **Prediction of Methane Gas Production** An anaerobic reactor, operated at 35°C, is used to process a wastewater stream with a flow of 3000 m^3/d and a bCOD concentration of 5000 g/m^3. At 95 percent bCOD removal and a net biomass synthesis yield of 0.04 g VSS/g COD used, what is the amount of methane produced in m^3/d?

Solution

1. Prepare a steady-state mass balance for COD to determine the amount of the influent COD converted to methane.
   a. The required steady-state mass balance is

$$0 = \begin{array}{c}\text{Influent}\\ \text{COD}\end{array} - \begin{array}{c}\text{portion of}\\ \text{influent COD}\\ \text{in effluent}\end{array} - \begin{array}{c}\text{influent COD}\\ \text{converted to}\\ \text{cell tissue}\end{array} - \begin{array}{c}\text{influent COD}\\ \text{converted to}\\ \text{methane}\end{array}$$

$$COD_{in} = COD_{eff} + COD_{VSS} + COD_{methane}$$

b. Determine the values of the individual mass balance terms

$$\text{COD}_{\text{in}} = (5000\ \text{g/m}^3)(3000\ \text{m}^3/\text{d}) = 15{,}000{,}000\ \text{g/d}$$

$$\text{COD}_{\text{eff}} = (1 - 0.95)(5000\ \text{g/m}^3)(3000\ \text{m}^3/\text{d}) = 750{,}000\ \text{g/d}$$

$$\begin{aligned}\text{COD}_{\text{VSS}} &= (1.42\ \text{g COD/g VSS})(0.04\ \text{g VSS/g COD})(0.95)(15{,}000{,}000\ \text{g/d})\\ &= 809{,}400\ \text{g/d}\end{aligned}$$

c. Solve for the COD converted to methane

$$\text{COD}_{\text{methane}} = 15{,}000{,}000 - 750{,}000 - 809{,}400 = 13{,}440{,}600\ \text{g/d}$$

2. Determine the amount of methane produced at 35°C.

a. Determine the volume of gas occupied by 1 mole of gas at 35°C

$$V = \frac{nRT}{P}$$

$$V = \frac{(1\ \text{mole})(0.082057\ \text{atm}\cdot\text{L/mole}\cdot\text{K})[(273.15)K]}{1.0\ \text{atm}}$$

$$= 25.29\text{L}$$

b. The CH_4 equivalent of COD converted under anaerobic conditions is

$$(25.29\ \text{L/mole})/(64\ \text{g COD/mole CH}_4) = 0.40\ \text{L CH}_4/\text{g COD}.$$

c. Methane production

$$\begin{aligned}\text{CH}_4\ \text{production} &= (13{,}440{,}600\ \text{g COD/d})(0.40\ \text{L CH}_4/\text{g COD})(1\ \text{m}^3/10^3\ \text{L})\\ &= 5376\ \text{m}^3/\text{d}\end{aligned}$$

$$\begin{aligned}\text{At 65 percent methane the total gas flowrate} &= (5376\ \text{m}^3/\text{d})/0.65\\ &= 8271\ \text{m}^3/\text{d}\end{aligned}$$

Comment It is important to determine the volume occupied by the gas at the actual operating temperature.

Process Kinetics

Because of the relatively low free energy change for anaerobic reactions, growth yield coefficients are considerably lower than the corresponding values for aerobic oxidation. Typical synthesis yield and endogenous decay coefficients for fermentation and methanogenic anaerobic reactions are $Y = 0.06$ and 0.03 g VSS/g COD and $b = 0.02$ and 0.008 g VSS/g VSS·d, respectively.

In anaerobic processes two rate-limiting concepts are important: (1) the hydrolysis conversion rate and (2) the soluble substrate utilization rate for fermentation and methanogenesis. The flow of COD through acidogenesis and to methane production starts with hydrolysis of colloidal and solid particles.

Hydrolysis Conversion Limitations. For anaerobic digestion processes used for municipal waste sludges solids, hydrolysis rates and the reactor SRT determine the total amount of solids converted. A first order hydrolysis rate of 0.33 d^{-1} may be applied to the biodegradable portion of combined waste primary and waste activated sludge from domestic wastewater treatment to estimate the solids destruction efficiency of a mesophilic digester (35°C) as a function of the SRT. About 25 percent of the waste primary solids and waste activated sludge solids for domestic wastewater treatment are estimated as nonbiodegradable (Moen et al., 2004). An SRT greater than 30 d is needed to approach full conversion of degradable solids. The soluble substrate utilization kinetics by the bacteria responsible for fermentation and methanogenesis are of great concern to maintain a stable anaerobic process.

Production Versus Utilization. Production kinetics for VFAs are faster than the corresponding utilization and methane production kinetics for methanogens, but at steady state operation a sufficient methanogenic population is established to maintain a stable digester operation with a low VFA concentration (<200 g/m^3) and pH ≥ 7.0. Unstable digester operation can develop under transient loading conditions in which the VFA production rate exceeds the methanogenic VFA utilization rate. Subsequently the VFA concentration (typically acetate and propionate) increases, which may cause the pH to drop, depending on the amount of alkalinity available to buffer the organic acid concentration increase.

Effects of pH. The methanogenic VFA utilization kinetics decrease at lower pH, so the effect of transient loads that cause a pH drop can be compounded to lead to further accumulation of VFA and further decline in methanogenic activity. If this reduced utilization continues butyric acid also accumulates and the reactor operation is greatly inhibited. Butyric acid accumulation causes a sour odor and has led to the term of a "sour" or stuck digester to describe this extreme digestion upset condition. Methanogenic inhibition can occur when acetate concentration has exceeded 3000 g/m^3, even though there was sufficient alkalinity to maintain pH above 7.0 (Stallman et al., 2012). Unstable conditions can also be caused by anaerobic reactor upset by transient temperature changes and sufficient concentration of inhibiting substances.

Transient Capacity. Anaerobic reactors have an inherent capacity for a finite transient increase in feed COD without succumbing to an unstable condition. The excess capacity is related to the maximum acetate utilization capacity ($V_{\max}$) for the acetoclastic methanogens (Conklin et al., 2008). The $V_{\max}$ value varies with systems and is a function of the SRT, average COD loading rate history, and methanogenic acetoclastic population selected. Batch biochemical methane production (BMP) tests are done to determine $V_{\max}$ for a given system. The test involves spiking acetate to the anaerobic reactor sludge in closed serum bottles, followed by incubation at the reactor temperature and measuring CH_4 production rates over time. An acetate capacity number (ACN) is then determined as the ratio of $V_{\max}$ to the average estimated acetate production rate based on the reactor operating history. About 70 percent of the COD removed in the system is assumed to be converted to acetate prior to methane production.

$$\text{ACN} = \frac{V_{\max}}{V_{\text{plt}}} \tag{7–143}$$

where ACN = acetate capacity number,
$V_{\max}$ = maximum acetate utilization rate for the anaerobic reactor solids, g acetate COD/m^3·d
V_{plt} = average daily acetate utilization rate for the anaerobic reactor, g acetate COD/m^3·d

The ACN concept can be applied to anaerobic reactor operations to determine acceptable transient loading rates that can be used without causing an unstable digester condition as shown in the following example. Details on the BMP test procedure can be found in Conklin et al. (2008). An application of the ACN concept to evaluate an acceptable transient loading in an anaerobic reactor is illustrated in Example 7–11.

EXAMPLE 7–11 **Estimating the Acceptable Transient Load for Codigestion** Given the following anaerobic sludge digestion operating information and results from a BMP test for a high strength food waste to be added to the digester for codigestion, determine what volume of food waste can be added as a transient load without causing digester instability.

Parameter	Unit	Value
Digester average feed rate	m^3/d	1000
Digester SRT	d	20
Digester average feed COD	g/m^3	85,000
Digester average CH_4 production rate	m^3/d	16,000
BMP average acetate V_{max} at standard conditions	mL CH_4/mL·d	0.5
Codigest COD concentration	g/m^3	800,000
Codigest biodegradability fraction	%	90

1. Portion of methane produced from acetate utilization for anaerobic digester and codigest waste = 70 percent
2. Gas production at standard conditions = 0.35 m^3 CH_4/kg COD

Solution

1. Determine the digester ACN.
   a. Digester average acetate COD utilization rate, V_{plt},

   V_{plt} = kg acetate COD used/m^3·d

   Acetate COD used per day =

$$0.70(16{,}000 \text{ m}^3/\text{d CH}_4)\left(\frac{273}{273 + 35}\right)\left[\frac{1}{(0.35 \text{ m}^3 \text{ CH}_4/\text{kg COD})}\right] = 28{,}363 \text{ kg COD/d}$$

   b. Digester volume = $Q(\tau)$, τ = SRT = 20 d

   Volume = (1000 m^3/d)(20 d) = 20,000 m^3

   V_{plt} = (28,363 kg COD/d)/(20,000 m^3) = 1.41 kg acetate COD/m^3·d

   c. BMP test digester sludge acetate utilization rate, V_{max}, g COD/L·d

$$V_{max} = \left(\frac{0.65 \text{ m}^3 \text{ CH}_4}{\text{m}^3 \cdot \text{d}}\right)\left[\frac{1}{(0.35 \text{ m}^3 \text{ CH}_4/\text{kg COD})}\right] = 1.86 \text{ kg acetate COD/m}^3\cdot\text{d}$$

   d. ACN = V_{max}/V_{plt} = 1.86/1.41 = 1.32

   Thus, the digester methanogens have capacity for 32% more acetate.

2. Determine the codigest volume that can be added.
   a. Additional acetate COD loading = 0.32(28,363 kg COD/d)

   = 11,954 kg acetate COD/d

   b. Acetate COD available in codigest feed

   = (800,000 g COD/m^3)(0.90 g degrad./g COD)(0.70 g acetate COD/g COD)

   = 504,000 g acetate COD/m^3

c. Codigest volume

$$= \frac{(11{,}954 \text{ kg acetate COD/d})(10^3 \text{ g/1 kg})}{(504{,}000 \text{ g acetate COD/m}^3)} = 23.72 \text{ m}^3\text{/d}$$

Comment For this high strength codigest feed, the feed volume to the digester is increased by only $(23.72 \text{ m}^3\text{/d})100/(1000 \text{ m}^3\text{/d}) = 2.4$ percent, which has a minimal impact on the digester SRT and methanogenic population. In this problem, it was also assumed that there is no acclimation time for degradation of codigest feed.

Soluble Substrate Utilization Limitations. For soluble feeds or after solids hydrolysis, the rate-limiting step is the conversion of VFAs by the methanogenic organisms and not the fermentation of soluble substrates by the fermenting bacteria. Thus, methanogenic growth kinetics are of most interest in anaerobic process designs. Appropriate system SRTs are selected based on kinetics and treatment goals. At 20, 25, and 35°C, the washout or SRT_{min} values for methanogenesis are 7.8, 5.9, and 3.2 d, respectively (Lawrence and McCarty, 1970). Thus, with a factor of safety of 5, design SRT values would be about 40, 30, and 15 d, respectively, for a suspended growth process. Safety factors higher than 5 have been used to provide a more stable process (Parker and Owen, 1986).

Environmental Factors

Anaerobic processes are sensitive to pH , nutrient limitations (especially industrial wastewaters) and inhibitory substances. A pH value near neutral is preferred, and below 6.8 the methanogenic activity is inhibited. Because of the high CO_2 content in the gases developed in anaerobic processes (30 to 35 percent CO_2), a high alkalinity is needed to assure pH near neutrality. An alkalinity concentration in the range of 3000 to 5000 mg/L as $CaCO_3$ is often found. For sludge digestion sufficient alkalinity is produced by the breakdown of protein and amino acids to produce NH_3, which combines with CO_2 and H_2O to form alkalinity as $NH_4(HCO_3)$. For industrial wastewater applications, especially for waste containing mainly carbohydrates, it is necessary to add alkalinity for pH control. Substances inhibitory to anaerobic processes (e.g., NH_3, H_2S, and various other inorganic and organic compounds) are considered in Chap. 10.

7–15 BIOLOGICAL REMOVAL OF TOXIC AND RECALCITRANT ORGANIC COMPOUNDS

Most of the organic compounds in domestic wastewater and some in industrial wastewaters are of natural origin and can be degraded by common bacteria in aerobic or anaerobic processes. However, currently there are over 70,000 synthetic organic chemicals, termed *xenobiotic compounds*, in general use (Schwarzenbach et al., 2003). Unfortunately, some of these organic compounds pose unique problems in wastewater treatment, due to their resistance to biodegradation and potential toxicity to the environment and human health. Organic compounds that are difficult to treat in conventional biological treatment processes are termed *refractory*. In addition, there are naturally occurring substances, such as those found in petroleum products that are of similar concern. Examples of petroleum compounds and synthetic organic compounds found in different types of wastewater are reported in Table 7–14.

Table 7–14

Examples of toxic and recalcitrant organic compounds found in wastewater[a]

Type of waste	Types of organic compounds
Petroleum	Alkanes, alkenes, polyaromatic hydrocarbons, monocyclic aromatics-benzene, toluene, ethylbenzene, xylenes, naphthenes
Non-halogenated solvents	Alcohols, ketones, esters, ethers, aromatic and aliphatic hydrocarbons, glycols, amines
Halogenated solvents	Chlorinated methanes-methylene chloride, chloroform, carbon tetrachloride, chlorinated ethenes-tetrachloroethene, trichloroethene, chlorinated ethanes-trichlorethane, chlorinated benzenes
Insecticides, herbicides, fungicides	Organochloride compounds, organophosphate cmpds, carbamate esters, phenyl ethers, creosotes, chlorinated phenols
Munitions and explosives	Nitroaromatics-trinitrotolune, nitramines, nitrate esters
Industrial intermediates	Phthalate esters, benzene, phenol, chlorobenzenes, chlorophenols, xylenes,
Transformer and hydraulic fluids	Polychlorinated biphenyls
Production products	Dioxin, furans

Development of Biological Treatment Methods

Since the early 1970s, information and knowledge related to the biodegradation of toxic and refractory compounds has increased significantly, based on work with specific industrial wastewaters (i.e., petrochemical, textile, pesticide, pulp and paper, and pharmaceutical industries). In addition, since the 1980s, significant progress has also been made on the biodegradation of organic substances found at hazardous waste sites. Work in both of these fields has expanded knowledge on the capabilities and limitations of biodegradation. With a few exceptions most organic compounds can be biodegraded eventually, but in some cases the rates may be slow, unique environmental conditions may be required (i.e., redox potential, pH, temperature), fungi may be needed instead of prokaryotes, or specific bacteria capable of degrading the xenobiotic compounds may be needed. For example, anaerobic degradation of polychlorinated biphenyls (PCB) occurred using bacteria seed from sediment in the Hudson River where PCB had accumulated over decades, but after 1.5 years of exposure in a laboratory anaerobic digester used to treat municipal wastewater plant sludge, bacteria could not be developed to degrade PCB (Ballapragada et al., 1998).

Importance of Specific Microorganisms. The ability to degrade toxic and recalcitrant compounds will depend primarily on the presence of appropriate microorganism(s) and acclimation time. In some cases, special seed sources are needed to provide the necessary microorganisms. Once the critical microorganism is present, long-term exposure to the organic compound may be needed to induce and sustain the enzymes and bacteria required for degradation. Acclimation times can vary from hours to weeks depending on the microorganism population and organic compound. Melcer et al. (1994) found that a period of 3 weeks was required before complete removal of dichlorobenzene (DCB) occurred in a municipal activated sludge plant, and that intermittent addition of DCB resulted in much lower treatment efficiencies. Without acclimation and no biodegradation, the DCB was removed from the activated sludge aeration tank by volatilization as described in Chap. 16. Strand et al. (1999) found that after 4 weeks of constant exposure to dinitrophenol in a laboratory activated sludge process, seeded from a municipal wastewater plant, dinitrophenol degradation increased from 0 to 98 percent. When dinitrophenol was not added to the process, the ability to degrade dinitrophenol was eventually lost. Thus, it appears that a relatively constant supply of toxic and recalcitrant organic compounds can lead to better biodegradation performance than intermittent additions.

Biodegradation Pathways. The three principal types of degradation pathways that have been observed are (1) the compound serves as a growth substrate; (2) the organic compound provides an electron acceptor; and (3) the organic compound is degraded by cometabolic degradation. In cometabolic degradation, the compound that is degraded is not part of the microorganism's metabolism. Degradation of the compound is brought about by a nonspecific enzyme and provides no benefit to the cell growth. Complete biodegradation of toxic and recalcitrant organic compounds to harmless end products such as CO_2 and H_2O or methane may not always occur, and instead biotransformation to a different organic compound is possible. Many toxic and recalcitrant organic compounds are degraded under anaerobic conditions, with the compound serving as a growth substrate with fermentation and ultimately methane production. Typical examples include nonhalogenated aromatic and aliphatic compounds such as phenol, toluene, alcohols, and ketones. However, most chlorinated organic compounds are not attacked easily under anaerobic conditions and do not serve as growth substrates. Fortuitously, many of these compounds also serve as electron acceptors in anaerobic oxidation-reduction reactions. Most of the work and application for anaerobic degradation of chlorinated organic compounds have been related to subsurface contamination of chlorinated solvents at hazardous waste sites (McCarty, 1999).

Examples of chlorinated compounds degraded under anaerobic conditions include tetrachloroethene (perchloroethylene, PCE), trichloroethene, carbon tetrachloride, trichlorobenzene, pentachlorophenol, chlorohydrocarbons, and PCBs. The chlorinated compound serves as the electron acceptor, and hydrogen produced from fermentation reactions provides the main electron donor. Hydrogen replaces chlorine in the molecule, and such reactions under anaerobic conditions have generally been referred to as *reductive dechlorination* or a *dehalorespiration process*. For example, dechlorination of tetrachloroethene proceeds sequentially with a loss of chlorine in each step via trichloroethene to dichloroethene to vinyl chloride and finally to ethene. A number of bacteria capable of anaerobic reductive dechlorination chlorinated ethenes have been isolated, but only the eubacterium, *Dehaloccoides ethenogenes*, has been able to dechlorinate tetrachloroethene to ethene completely. Hydrogen is the only electron donor used by *Dehaloccoides ethenogenes*, but some dehalorespiring bacteria have been able to use formate, pyruvate or acetate (Holliger et al., 1999).

As the number of chlorine molecules on the organic molecule decreases, the reactions tend to be slower and less complete. Dechlorination of tetrachloroethene, trichlorobenzene, and pentachlorophenol has been demonstrated in lab-scale anaerobic digesters (Ballapragada et al., 1998) treating municipal primary and secondary sludge. However, the reaction rates were slow with mono- and dichlorophenol and mono- I dichlorobenzenes remaining. Conversion of tetrachloroethene to vinyl chloride and ethene occurred in the digesters after one year of acclimatization and constant exposure of the chloroethenes.

Aerobic Biodegradation

With proper environmental conditions, seed source, and acclimation time, a wide range of toxic and recalcitrant organic compounds have been found to serve as growth substrates for heterotrophic bacteria. Such compounds include phenol, benzene, toluene, polyaromatic hydrocarbons, pesticides, gasoline, alcohols, ketones, methylene chloride, vinyl chloride, munitions compounds, and chlorinated phenols. However, many chlorinated organic compounds cannot be attacked readily by aerobic heterotrophic bacteria and, thus, do not serve as growth substrates. Some of the lesser chlorinated compounds, such as dichloromethane, 1,2-dichloroethane, and vinyl chloride can be used as growth substrates by aerobic bacteria. Fortunately, a number of chlorinated organic compounds are degradable by cometabolic degradation. It should be noted that organic compounds that are saturated fully with chlorine are degraded only by anaerobic dechlorination (Stensel and Bielefeldt, 1997).

Cometabolic Degredation. Chlorinated organic compounds that have been degraded by cometabolic degradation include trichloroethene, dichloroethene, vinyl chloride, chloroform, dichloromethane, and trichloroethane. Cometabolic degradation is possible by bacteria that produce nonspecific mono-oxygenase or dioxygenase enzymes. These enzymes mediate a reaction with oxygen and hydrogen and change the structure of the chlorinated compound. Bacteria that produce oxygenase enzymes oxidize certain substrates that induce the enzyme. Oxygenase-producing bacteria include methanotrophic bacteria that oxidize methane, a number of bacteria that can oxidize phenol or toluene, a number of bacteria that can oxidize propane, and nitrifying bacteria that oxidize ammonia to nitrite.

Nonspecific Oxygenase Enzyme. The reaction of the nonspecific oxygenase enzyme with the organic chlorinated compound typically produces an intermediate compound that is degraded by other aerobic heterotrophic bacteria in the biological consortia. Various reactor designs have been developed to apply this biological process for treatment of contaminated groundwater or vapor extraction gas streams (Lee et al., 2000). While such reactions are possible in municipal and industrial biological wastewater treatment processes, a large amount of the chlorinated organic compounds that may be present are more likely lost from the process by volatilization during aeration, because of their high volatility and the minimal potential for cometabolic bacteria to be present.

Abiotic Losses

Due to concerns about environmental and health effects of toxic and recalcitrant compounds, it is important to understand their fate and transport in biological treatment processes. For many toxic and recalcitrant organic compounds entering biological wastewater treatment processes, nonbiological or abiotic losses may be more significant than biodegradation. Abiotic losses include adsorption of the compound to the mixed-liquor solids in the reactor with subsequent transport out of the system by the waste sludge and volatilization with release of the compound to the surrounding atmosphere.

Losses Due to Adsorption. For certain compounds, removal by partitioning (i.e., adsorbing) onto the biomass can be more significant than biodegradation or volatilization. To describe solids partitioning, the Freundlich Isotherm model (see Sec. 11–7 in Chap. 11) is modified to a general linear equilibrium relationship ($n = 1$) for adsorption to solids at relatively low liquid organic concentrations:

$$q = K_p S \tag{7–144}$$

where q = g organic adsorbed/g adsorbent
K_p = partition coefficient, L/g
S = concentration of organic compound in liquid, g/L

Adsorption of organic compounds in biological treatment processes has been observed to be relatively fast (Melcer et al., 1994), so that Eq. (7–144) can be used to describe the distribution of the compound between the solid biomass and liquid phases as a function of the partition coefficient K_p for the compound. The value for K_p depends on the hydrophobic nature of the compound and the adsorption characteristics of the solids. Solids with high carbon content and greater surface area result in higher K_p values. It is common to consider the partition coefficient as a function of the carbon content of the solids instead of the solids weight. In this case the partition coefficient is given as K_{oc}:

$$K_{oc} = \frac{K_p}{f_{oc}} \tag{7–145}$$

where K_{oc} = partition coefficient relative to solids carbon concentration, L/kg
f_{oc} = fraction of carbon in solids, g carbon/g solids

More hydrophobic compounds are expected to partition more to the solid phase and thus there had been interest to relate the partition coefficient of a compound for solids in wastewater treatment to the octanol-water partition coefficient (Dobbs et al., 1989), which are available for many compounds.

$$\log K_{oc} = \text{A} \log K_{ow} + B \tag{7–146}$$

where K_{ow} = octanol/water partition coefficient, dimensionless
A, B = empirical coefficients, dimensionless

Values for coefficients in Eq. (146) can be found in Schwarzenbach et al. (2003) for many compounds found in wastewater treatment. Octanol-water partition coefficient values have been developed for many organic compounds (Schwarzenbach et al., 2003; LaGrega et al., 2001) and values for some selected compounds are given in Table 16–12 in Chap. 16. The test to determine K_{ow} involves measuring the concentration of the organic compound in an octanol/water mixture after quiescent separation of the octanol layer above the water layer. Greater amounts of more hydrophobic compounds will be found in the octanol layer, and these compounds will have greater K_p values in solids/water mixtures. Ranges of K_p values for various types of compounds are shown in Table 7–15. Based on the information given in Table 7–15, benzopyrene and PCBs are more likely to be found on solids than in the liquid than compounds like benzene and trichloroethene, as their K_p values are greater by a factor of about 150. Such high partition coefficients result in very low liquid concentrations, which minimize the amount of the organic compound lost by biodegradation and volatilization.

Table 7–15

Comparison of selected estimated partition coefficients (K_p) values for different types of organic compounds

Organic compound	K_p, (L/g)
Benzene	0.23
Dinitrotoluene	0.29
Dieldrin	0.81
Phenanthrene	5.33
Pentachlorophenol	10.96
Polychlorinated biphenyl	43.87
Benzopyrene	45.15

Using the equilibrium partition coefficient, the amount of organic compound removed by sludge wasting can be estimated from the ratio of the mass of organic compound adsorbed to the mass of solids wasted per day:

$$q = \frac{r_{ad}}{r_{X,w}} \tag{7–147}$$

where q = g organic compound adsorbed/g solids
r_{ad} = rate of organic compound absorbed daily, g/d
$r_{X,w}$ = rate of solids wasted daily, g/d

By substituting Eq. (7–144) for q and solving for r_{ad}, the amount of compound lost daily due to adsorption is

$$r_{ad} = r_{X,w}K_pS \tag{7–148}$$

At steady state, the amount of solids wasted daily is related to the average SRT value for the activated sludge system as given by Eq. (7–48):

$$r_{X,w} = \frac{X_TV}{\text{SRT}} \tag{7–149}$$

Substituting Eq. (7–149) into Eq. (7–148) yields the following expression for the mass loss rate due to adsorption:

$$r_{ad} = \frac{X_TVK_pS}{\text{SRT}} \tag{7–150}$$

Losses Due to Volatilization The removal of volatile organic compounds due to aeration (volatilization), discussed in detail in Sec. 16–4 in Chap. 16, is reviewed here briefly. The rate of loss due to volatilization can be modeled as follows:

$$r_{sv} = -K_La_s(S) \tag{7–151}$$

where r_{sv} = loss due to volatilization, mg/L·d
K_La_s = gas-liquid mass transfer coefficient, K_La, of organic compound, d^{-1}
S = concentration of organic compound in liquid, mg/L

The above equation is satisfactory to represent the stripping loss by aeration if a surface aerator is used, in which case the air content of the volatile compound is considered negligible. However, for diffused aeration the volatile compound would be captured by the rising bubbles with concentration changes with depth. For this case the following mass transfer expression applies (Bielefeldt and Stensel, 1999).

$$r_{sv} = Q_gS_{g,\text{VOC}} = Q_g(H)S_{L,\text{VOC}}\left\{1 - \exp\left[\frac{(\alpha K_La_{,\text{VOC}}V)}{Q_g(H)}\right]\right\} \tag{7–152}$$

where Q_g = gas flowrate through reactor, m^3/d
$S_{g,\text{VOC}}$ = VOC content in the gas leaving the reactor, g/m^3
H = Henry's constant of the VOC at the reactor temperature, $\text{L}_{\text{water}}/\text{L}_{\text{air}}$
$S_{L,\text{VOC}}$ = liquid concentration of the VOC, g/m^3
$K_La_{,\text{VOC}}$ = VOC mass transfer coefficient, d^{-1}
α = ratio of mass transfer in reactor mixed liquor to that in clean water
V = reactor volume, m^3

The gas-liquid mass transfer coefficient for the VOC can be estimated from the mass transfer coefficient for oxygen for the aeration system and the ratio of the VOC and oxygen diffusion coefficients:

$$K_{LA,\mathrm{VOC}} = \left(\frac{D_{\mathrm{VOC}}}{D_{O_2}}\right)^n \tag{7–153}$$

where D = the diffusion coefficient, $\mathrm{m^2/s}$

n = coefficient from 0.50 to 1.0 as function of aeration system

Modeling Biotic and Abiotic Losses

A number of models have been developed and evaluated that account for the fate of recalcitrant organic compounds in biological treatment processes (Melcer et al., 1995; Melcer et al., 1994; Monteith et al., 1995; Parker et al., 1993; Grady et al., 1997; and Lee et al., 1998a). In general, the models contain basic mechanisms and mass balances that account for the mass rate of the organic compound entering the treatment process, and leaving in the liquid effluent by biodegradation, by volatilization, and by adsorption on waste solids.

In the following discussion, all of these mechanisms as discussed above are combined into a general model to describe the fate of specific compounds in a biological treatment process. The following steady-state mass balance (i.e., accumulation = 0) across a complete-mix activated sludge process can be prepared to predict the fate of an organic compound subject to biotic and abiotic processes.

$$0 = \begin{array}{c}\text{organic}\\ \text{constituent}\\ \text{in influent}\end{array} - \begin{array}{c}\text{loss of organic}\\ \text{constituent due}\\ \text{to biodegradation}\end{array} - \begin{array}{c}\text{loss of organic}\\ \text{constituent due}\\ \text{to sorption}\end{array} - \begin{array}{c}\text{loss of organic}\\ \text{constituent due}\\ \text{to volatilization}\end{array} - \begin{array}{c}\text{loss of organic}\\ \text{constituent}\\ \text{in effluent}\end{array}$$

$$QS_o = r_{su} + r_{ad} + r_{sv} + QS \tag{7–154}$$

where QS_o = mass of compound in wastewater influent, g/d

r_{su} = biodegradation rate, g/d

r_{ad} = solids adsorption rate, g/d

r_{sv} = volatilization rate, g/d

QS = mass of compound in wastewater effluent, g/d

Substituting the appropriate reaction terms for each component of the mass balance yields the following expression:

$$QS_o = \left(\frac{1}{Y}\right)\frac{\mu_m(S)}{(K_s + S)}(X_s)(V) + \frac{X_T V K_p S}{\mathrm{SRT}} + K_L a_s S V + QS \tag{7–155}$$

The fate of the compound in the influent wastewater as a function of the solids concentration, liquid concentration, hydraulic retention time, τ, SRT, and rate terms is obtained by dividing Eq. (7–155) by Q:

$$S_o = \left(\frac{1}{Y}\right)\frac{\mu_m(S)}{(K_s + S)}(X_s)\tau + K_p S X_T\left(\frac{\tau}{\mathrm{SRT}}\right) + K_L a_s S(\tau) + S \tag{7–156}$$

Note in Eqs. (7–155) and (7–156), X_s is the biomass concentration capable of degrading the specific organic compound, and X_T is the total MLVSS concentration that includes all the biomass grown on various substrates plus the nonbiodegradable VSS. The value of X_s can be calculated as a function of the amount of substrate that is biodegraded and kinetic coefficients, and the system τ, and SRT. The following expression is used to calculate X_s

at steady state for a complete-mixed reactor with consideration for losses of the substrate by volatilization and adsorption:

$$X_s = \frac{Y[(S_o - S) - K_p S X_T(\tau/\text{SRT}) - K_L a_s S(\tau)]}{b(\tau) + (\tau/\text{SRT})} \tag{7–157}$$

For most cases where biodegradation is occurring and the loss is not overwhelming due to volatilization and/or solids adsorption, the liquid constituent concentration, based on Eq. (7–46), for a complete-mix reactor at steady state is given by

$$S = \frac{K_s[1 + b(\text{SRT})]}{\text{SRT}(\mu_m - b) - 1} \tag{7–158}$$

For the other exceptional cases, Eq. (7–156) and (7–157) can be solved simultaneously.

The approach outlined above can be used to estimate the fate of an organic compound in a complete-mix activated sludge reactor assuming steady-state conditions, a constant input of the organic constituent, and a fully acclimated culture. Predicting the fate of an organic constituent in an activated sludge treatment process is illustrated in Example 7–12.

EXAMPLE 7–12 Predicting the Fate of Benzene in an Activated Sludge Treatment Process

A complete-mix activated sludge system is used to treat domestic wastewater, but receives a wastewater discharge containing benzene. Given the following information on the activated sludge process design and biotic and abiotic rate information for benzene, what is the effluent soluble benzene concentration and the relative amounts of benzene lost through biodegradation, sorption to solids, volatilization, and in the liquid effluent?

1. Influent benzene concentration, $S_o = 2.0\ \text{g/m}^3$
2. System SRT $= 6.0$ d
3. Aeration tank retention time, $\tau = 0.25$ d
4. MLVSS concentration, $X_T = 2500\ \text{g/m}^3$
5. $K_p = 0.234 \times 10^{-3}\ \text{m}^3/\text{g}$
6. $K_L a_s = 3/\text{h} = 72/\text{d}$
7. $\mu_m = 2.0$ g VSS/g VSS·d
8. $K_s = 0.50\ \text{g/m}^3$
9. $b = 0.10$ VSS/g VSS·d
10. $Y = 0.60$ g VSS/g benzene

Solution

1. Determine the liquid benzene concentration using Eq. (7–158).

$$S = \frac{(0.5\ \text{g/m}^3)[1 + (0.10\ \text{g VSS/g VSS·d})(6.0\ \text{d})]}{(6.0\ \text{d})[(2.0 - 0.10)\ \text{g VSS/g VSS·d}] - 1} = 0.077\ \text{g/m}^3$$

2. Determine concentration of biomass degrading benzene *Xs* from Eq. (7–157):

$$X_s = \frac{Y[(S_o - S) - K_p S X_T(\tau/\text{SRT}) - K_L a_s S(\tau)]}{b(\tau) + (\tau/\text{SRT})}$$

$$X_s = \frac{\left\{\begin{matrix}(0.60\ \text{g/g})[(2.0 - 0.077)\text{g/m}^3] - (0.234 \times 10^{-3}\ \text{m}^3/\text{g})(0.077\ \text{g/m}^3) \times \\ (2500\ \text{g/m}^3)(0.25\text{d}/6.0\text{d}) - (72/\text{d})(0.077\ \text{g/m}^3)(0.25\text{d})\end{matrix}\right\}}{(0.10\ \text{g/g·d})(0.25\text{d}) + (0.25\text{d}/6.0\text{d})}$$

$$= 4.83\ \text{g/m}^3$$

3. Determine the loss of benzene due to biodegradation [1st term in Eq. (7–156)]:

$$\left(\frac{1}{Y}\right)\frac{\mu_m(S)}{(K_s + S)}(X_s)\tau = \left[\frac{1}{(0.6\text{ g/g})}\right]\left[\frac{(2.0/\text{d})(0.077\text{ g/m}^3)}{(0.5 + 0.077)\text{ g/m}^3}\right](4.83\text{ g/m}^3)(0.25\text{ d})$$

$$= 0.537\text{ g/m}^3$$

4. Determine the loss of benzene due to sorption [2nd term in Eq. (7–156)]:

$$\frac{K_p S X_T \tau}{\text{SRT}} = \frac{(0.234 \times 10^{-3}\text{ m}^3/\text{g})(0.077\text{ g/m}^3)(2500\text{ g/m}^3)(0.25\text{ d})}{6.0\text{ d}}$$

$$= 0.0019\text{ g/m}^3$$

5. Determine the loss of benzene due to volatilization [3rd term in Eq. (7–156)]:

$$(K_L a_s)(S)(\tau) = (72/\text{d})(0.077\text{ g/m}^3)(0.25\text{ d}) = 1.386\text{ g/m}^3$$

6. Summarize the losses due to the various mechanisms.

Pathway	Influent fate, g/m³	Fraction of total
Effluent	0.077	0.039
Biodegradation	0.537	0.268
Sorption	0.002	0.001
Volatilization	1.386	0.692
Total	2.002[a]	1.000

[a] 0.002 is due to round-off error.

a. For benzene, which is a volatile organic compound with a low solids partition coefficient, 69.2 percent of the influent benzene is transferred to the atmosphere, 26.8 percent is biodegraded, 3.9 percent remains dissolved in the liquid effluent, and 0.1 percent is sorbed onto the solids leaving the process.

b. The effect of the aeration system benzene K_La value on the relative amounts biodegraded or stripped to the atmosphere is illustrated in the following summary table:

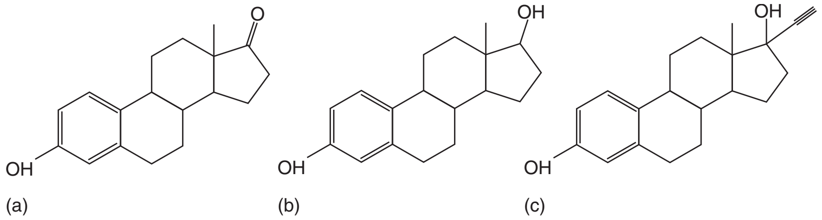
		K_La, h⁻¹			
Parameter	Unit	1.5	3.0	4.0	6.3
Effluent,	g/m³	0.077	0.077	0.077	0.052
Effluent	%	3.9	3.9	3.9	2.6
Biodegraded	%	61.4	26.8	3.7	0.0
Volatilized	%	34.6	69.2	92.3	97.3

7–16 BIOLOGICAL REMOVAL OF TRACE ORGANIC COMPOUNDS

Trace organic compounds (TrOCs) are present in domestic wastewater plant influent at ng/L to ug/L concentrations and include natural hormones, pharmaceuticals excreted by humans, and personnel care products such as shampoo, toothpaste, and fragrance substances. Pharmaceuticals include analgesics, anticonvulsants, beta blockers, antibiotics,

Figure 7–28

Chemical structure of estrogen compounds common in WWTPs: (a) E1 – Estrone, $C_{18}H_{22}O_2$, (b) E2 – 17β-estradiol, $C_{18}H_{24}O_2$, and (c) EE2 – 17α-ethinylestradiol, $C_{20}H_{24}O_2$.



and x-ray media. Some of these TrOCs along with other xenobiotic compounds contribute to endocrine disrupting compound (EDCs) activities in WWTP effluents. Compounds that stimulate estrogenic activity include natural hormones from humans and animals, the synthetic hormone 17α-Ethinylestradiol (EE2), Dieldrin, Methoxyclor, bisphenol A, phthalates, nonylphenol and octylphenol from the breakdown of detergents, polychlorobiphenyls (PCB), polyaromatic hydrocarbons (PAH), and dioxins (Combalbert and Hernandez-Raquet, 2010). From field studies on native fish populations the occurrence of intersex fish has been found in surface waters receiving effluent from WWTPs (Harshbarger et al., 2000; Hashimoto et al., 2000). The relative activity of some of the estrogen compounds found in wastewater, relative to 17β-Estradiol (E2) arbitrarily fixed at 100, is 246 for EE2, 2.5 for Estrone (E1) (see Fig. 7–28), 1.55 for genistein, 0.66 for bisphenol A, and 0.32 for nonylphenol (Pillon et al., 2005). The structure of E1, E2, and EE2 is illustrated on Fig. 7–28.

Removal of Trace Organic Compounds

The TrOCs in general are not volatile so that the main removal mechanisms in WWTPs are via biodegradation and adsorption to waste solids. The liquid-solids partition coefficient for estrogen compounds is relatively low, with Log Koc values at less than 3.5. As a concequence of the low K_{OC} values, most of the estrogen removal in secondary wastewater treatment is by biodegradation. Because of the low concentration of TrOCs in the influent wastewater, they can not support significant biogrowth, so that the TrOC biodegradation is done mainly by bacteria growing on other substrates. Cometabolic degradation of estrogens by ammonia oxidizing bacteria has been posed based on results of batch experiments at high ammonia and nitrite concentrations (Gaulke et al. 2008), but the main mechanism is by heterotrophic bacteria (Combalbert and Hernandez-Raquet, 2010). An example of results from full scale field studies showing the range of degradation ability in domestic wastewater treatment for a number of compounds of interest is presented in Table 7–16 (Stensel, 2011).

Steady-State Fate Model

A steady state model, similar to that given in Sec. 7–14 to describe the fate of xenobiotics, is presented for TrOCs to illustrate the key terms in TrOC removal in activated sludge processes. Because the TrOC compound concentrations are very low, a psuedo first-order biodegradation model has been used and is illustrated here for an estrogen (E) compound. An additional set of equations are also needed for estrogen and some other compounds that may enter the WWTP as conjugated compounds. Most of the estrogen excreted by humans is in urine as a conjugated compound. Deconjugation to free estrogen can occur in the wastewater collection and conveyance systems and in the WWTP. The rate of estrogen degradation is as follows:

$$r_{UE} = K_b X_{H,E}(E)V \tag{7–159}$$

Table 7–16

Example of TrOC removal in MBR activated sludge treatment at 30-d SRT (Stensel, 2011)

Compound	Average Influent Concentration, ng/L	Source
Highly biodegradable (>90 percent removal)		
E1, E2	30	Natural human hormones
EE2	110	Synthetic hormone
Acetaminophen	67,290	Analgesic
Naproxen	21,560	Analgesic
Tricolsan	1100	Antibacterial
Ibuprofen	13,490	Analgesic
Caffeine	50,680	Stimulant
Atenolol	3750	Beta blocker (blood pressure)
Moderately biodegradable (60–85 percent removal)		
Bisphenol A	290	Plasticize
Erythromycin	120	Antibiotic for bacteria
Trimethoprim	180	Antibiotic for bacteria
Oxybenzone	30	Ingredient in sunscreen
Poorly biodegradable (20–60 percent removal)		
Propranolol	31	Beta blocker (blood pressure)
Fluoxetine	40	Antidepressant
Gemfibrozil	3420	Antilipidemic (Cholesterol)
Sulfamethoxazol	1000	Antibiotic for bacteria
Metoprolol	390	Beta blocker (blood pressure)
Iopromide	3190	X-ray contrast
None or very poor biodegradation (unchanged or increase from deconjugation)		
Pentoxifylline	5	Improve blood flow
Dilcofenac	90	Analgesic
Dilantin	50	Anticonvulsant
Carbamazepine	250	Anticonvulsant

$$X_{H,E} = \eta_E X_T \tag{7–160}$$

where r_{UE} = estrogen removal rate by biodegradation, ng/d
$X_{H,E}$ = heterotrophic bacteria concentration capable of degrading estrogen, g/m^3
η_E = fraction of mixed liquor solids that are estrogen degraders
K_b = first order degradation rate coefficient, m^3/g·d
E = reactor soluble estrogen concentration, ng/m^3
V = reactor volume, m^3

Considering the production of free estrogen by deconjugation and removal of estrogen in waste solids by adsorption, the following steady state equations apply.

$$QE_o = k_b(\eta_E X_T)(E)V - K_c(\eta_c X_T)E_c V + \frac{K_{p,E}X_T(E)V}{(10^6)\text{SRT}} + (Q - Q_w)E \tag{7–161}$$

$$QE_{o,c} = K_c(\eta_c X_T)(E_c)V + \frac{K_{p,Ec}X(E_c)V}{(10^6)\text{SRT}} + (Q - Q_w)E_c \tag{7–162}$$

where E_o = influent estrogen concentration, ng/m^3
$E_{o,c}$ = influent conjugated estrogen concentration, ng/m^3
E_c = reactor soluble conjugated estrogen concentration, ng/m^3
η_c = fraction of mixed liquor solids that are estrogen-deconjugating bacteria
K_c = first order deconjugation coefficient, m^3/g·d
$K_{p,E}$ = liquid-solids partition coefficients for estrogen L/kg
$K_{p,EC}$ = liquid-solids partition coefficients for conjugated estrogen, L/kg
X_T = mixed liquor suspended solids concentration, g/m^3
Q = daily influent flowrate, m^3/d
Q_w = daily waste sludge flowrate, m^3/d

Until research finds a biomarker to identify the estrogen degrading- and estrogen deconjugating-bacteria, the kinetic values are normalized to the total mixed liquor concentration. First order degradation rate coefficients for EE2, range from 5-20 L/g MLSS·d. E1 and E2 degradation rates are about 5 times faster (Gaulke et al., 2009).

7–17 BIOLOGICAL REMOVAL OF HEAVY METALS

Metal removal in biological treatment processes is mainly by adsorption and complexation of the metals with the microorganisms. In addition, processes that result in transformations and precipitation of metals are possible. Microorganisms combine with metals and adsorb them to cell surfaces because of interactions between the metal ions and the negatively charged microbial surfaces. Metals may also be complexed by carboxyl groups found in microbial polysaccharides and other polymers or absorbed by protein materials in the biological cell. The removal of metals in biological processes has been found to fit adsorption characteristics as defined by the Freundlich isotherm model (see Sec. 11–7 in Chap. 11) (Mullen et al., 1989; Kunz et al., 1976). A significant amount of soluble metal removal has been observed in biological processes, with removals ranging from 50 to 98 percent depending on the initial metal concentration, the biological reactor solids concentrations, and system SRT. In anaerobic processes the reduction of sulfate to hydrogen sulfide can promote the precipitation of metal sulfides. A classic example is the addition of ferric or ferrous chloride to anaerobic digesters to remove sulfide toxicity by the formation of iron sulfide precipitates. The precipitation of heavy metals by hydrogen sulfide is discussed in Sec. 6–5 in Chap. 6.

PROBLEMS AND DISCUSSION TOPICS

7–1 Prepare a recipe for an inorganic medium to be used in a laboratory chemostat to grow 500, 1000, or 1200 mg VSS/d (value to be selected by instructor) of bacteria biomass, assuming that the chemical formula for the biomass can be described as $C_5H_7NO_2$. Determine the concentration of essential inorganic compounds as reported in Table 7–3 for a feed rate of 1 L/d. Assume that phosphorus is added as KH_2PO_4, sulfur as Na_2SO_4, nitrogen as NH_4Cl, and other cations added are associated with chloride.

7–2 Protein is a major component of bacterial enzymes. List the key cell components involved and the major steps that lead to protein production.

7–3 From the literature (e.g., *J. Appl. Environ. Microbiol.*) identify the key physiological, metabolic characteristics, and phylogenetic classification of a bacteria that may have a role in biological wastewater treatment or toxic degradation. Cite a minimum of 3 references.

7–4 From the literature, describe an application using molecular biology (e.g., molecular probes or other methods) techniques that can be related to biological wastewater treatment. Cite a minimum of 3 references.

7–5 A 1-L sample contains 22, 26, or 32 g (value to be selected by instructor) of casein ($C_8H_{12}O_3N_2$). If 18 g of bacterial cell tissue ($C_5H_7NO_2$) is synthesized per 50 g of casein consumed, determine the amount of oxygen required to complete the oxidation of casein to end products and cell tissue. The end products of the oxidation are carbon dioxide (CO_2), ammonia (NH_3), and water. Assume that the nitrogen not incorporated in cell-tissue production will be converted to ammonia.

7–6 A complete-mix suspended growth reactor, without a clarifier and recycle, is used to treat a wastewater flow containing only soluble organic substances. The influent BOD and COD are as follows:

		Wastewater		
Influent	Unit	1	2	3
BOD	mg/L	200	180	220
COD	mg/L	450	450	480

If the effluent dissolved BOD concentration is 2.5 mg/L, and the effluent volatile suspended solids concentration is 100 mg/L, determine (wastewater to be selected by the instructor): (a) the observed yield in terms of g VSS/g BOD, g VSS/g COD, and g TSS/g BOD, (b) the effluent total sCOD concentration including nonbiodegradable dissolved COD, and (c) the fraction of the influent BOD that is oxidized to CO_2 and H_2O. Assume the biodegradable COD/BOD ratio is 1.6 and 1.42 g O_2 eq/g biomass.

7–7 An aerobic complete-mix reactor (no recycle) with a volume of 1000 L receives a 500 L/d wastewater flow and has an effluent soluble COD concentration of 10 mg/L. For one of the wastewaters with the characteristics given below (to be selected by instructor), determine (a) the τ value for the reactor in days, (b) the oxygen used per day in (g/d), (c) the effluent volatile suspended solids concentration (assume biomass oxygen equivalent of 1.42 g O_2/g VSS), and (d) the observed yield in g VSS/g bsCOD removed.

		Wastewater		
Item	Unit	1	2	3
Influent sCOD	mg/L	1000	1800	600
Reactor oxygen uptake rate	mg/L·h	10	15	8

7–8 Using the half-reaction free energy values given in Table 7–6, calculate and compare the biomass yields (g VSS/g COD_r) for the degradation of methanol, carbohydrate mixture, or ethanol (constituent to be selected by instructor) with oxygen and nitrate as the electron acceptors. Assume ammonia is available for cell synthesis needs and 1.42 g O_2 eq/g biomass.

7–9 Using the half-reaction free energy values given in Table 7–6, calculate and compare the biomass yields (g VSS/g COD_r) for the degradation of methanol, or ethanol (constituent to be selected by instructor) with nitrate and nitrite as the electron acceptors. Assume ammonia is available for cell synthesis needs and 1.42 g O_2 eq/g biomass. Using the results, compare the amount of methanol (or ethanol) needed for denitrification of NO_3-N versus NO_2-N in g COD/g N.

7–10 Nitrate and sulfate are both available in an anaerobic laboratory chemostat with both nitrate-reducing and sulfate-reducing bacteria present. The chemostat is fed continuously a solution containing the electron acceptors in equal amounts, glucose, and a nutrient media. Which biological populations will remain after long-term operation? Explain.

7–11 For Example 7–3, use the half reactions to write a balanced equation of acetate oxidation by methanogenic bacteria.

7–12 For the synthesis yield values given in Table 7–7 for organic compound degradation, what are the respective f_e and f_s values?

7–13 Compare the end products of organic compound degradation under the following conditions, and discuss how the bacterial synthesis yields are affected by them: aerobic (oxygen as acceptor), fermentation (organic compound as electron acceptor), and methanogenesis (CO_2 as electron acceptor).

7–14 If bacterial cells are of the coccus type with a diameter of 1.0, 1.3, or 1.5 μm and are 80 percent water with 90 percent of the dry weight as organic, determine (cell diameter to be selected by the instructor): (a) the volume and organic mass of one cell and (b) the number of cells present in one liter of a biomass suspension with a concentration of 100 mg VSS/L.

7–15 For aerobic bacteria with an assumed generation time of 20, 30, or 60 min (time to be selected by instructor), how many bacteria would be present after 12 h, if 20 cells are present at time zero? Using the bacteria volume and mass from Problem 7–13 for a 1-μm diameter bacteria, what would be the dry weight of the bacteria after 12 h in mg volatile suspended solids?

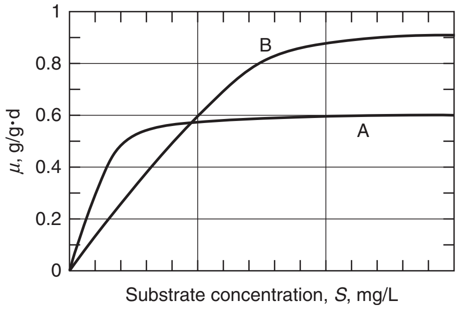
7–16 Consider a batch reaction with nitrifying bacteria in a chemostat. The initial concentration of nitrifying bacteria is 10 mg/L, and the initial substrate concentration is 50 mg NH_4-N/L. The NH_4-N is oxidized to NO_2-N, and the cell yield is 0.12 g VSS/g NH_4-N oxidized. The chemostat DO concentration is maintained at 3.0 mg/L. Other kinetic coefficients related to substrate utilization and growth are one of the following to be selected by instructor:

		Wastewater		
Coefficient	Unit	1	2	3
μ_{max}	g VSS/g VSS·d	0.60	0.75	0.60
K_n	mg/L	0.50	0.50	0.75
K_o	mg/L	0.50	0.50	0.50
b	g VSS/g VSS·d	0.08	0.08	0.04

What is the NH_4-N and biomass concentration at 0.50 d?

Plot the substrate and biomass concentration versus time up through 23 h. (Hint: one solution approach is to use a spreadsheet to solve for the biomass and substrate concentration at small time increments. Use time increments of 0.25 h).

7–17 Curves A and B represent the Monod kinetics for two different bacteria capable of degrading the same substrate. You are to operate a laboratory continuous flow CMAS reactor without recycle that is inoculated with bacteria A and B. In the first experiment (I) a high SRT is used (10 d or greater) and in the second (II) a very low SRT is used (about 1.1 d). Which bacteria will be dominant in experiments I and II? Explain why.



7–18 A complete-mix aerobic reactor without solids recycle is used to treat a wastewater containing 100 mg/L phenol (C_6H_6O) at 20°C. Using the following kinetic coefficients (coefficient set 1, 2, or 3 to be selected by instructor) determine (a) the minimal hydraulic retention time t in days at which the biomass can be washed out faster than they can grow, (b) the minimum τ value at 10°C, assuming the temperature-activity coefficient θ is 1.07 for k and 1.04 for b, (c) the effluent phenol and biomass concentration at a τ value of 4.0 d at 20°C, and (d) the amount of oxygen required in kg/d for a τ value of 4.0 d assuming a flowrate of 100 m^3/d. Plot the phenol and biomass concentration and the amount of oxygen required versus τ in days, for τ from 3.3 to 15 d at 20°C.

		Wastewater		
Coefficient	Unit	1	2	3
k	g phenol/g VSS·d	0.90	0.80	0.90
K_s	mg phenol/L	0.20	0.15	0.18
Y	g VSS/g phenol	0.45	0.45	0.40
b	g VSS/g VSS·d	0.10	0.08	0.06

7–19 Laboratory test reactors have been operated at different SRT values at steady state to obtain biological kinetic coefficients for a wastewater with soluble constituents only. The reactors are complete-mix and aerated with clarifiers and solids recycle. The τ value in all cases is 0.167 d and the SRT values were varied for the five tests. The influent and effluent soluble COD and reactor MLVSS concentrations are summarized as follows:

Test no.	SRT, d	S_o, mg COD/L	S, mg COD/L	X, mg VSS/L
1	3.1	400	10.0	3950
2	2.1	400	14.3	2865
3	1.6	400	21.0	2100
4	0.8	400	49.5	1050
5	0.6	400	101.6	660

From these results determine the values for the biokinetic coefficients, k, K_s, μ_m, Y, and b. (Note: calculate the solids production at each SRT.)

7–20 The following data were obtained using four bench-scale continuous-flow activated sludge units to treat a food-processing waste. Using these data, determine Y and b.

	Parameter		
Unit	X, g MLVSS/L	r_g, g MLVSS/L·d	U, g BOD/g MLVSS·d
1	18.81	0.88	0.17
2	7.35	1.19	0.41
3	7.65	1.42	0.40
4	2.89	1.56	1.09

7–21 Using the data given below for three different complete-mix activated sludge reactors, determine (reactor to be selected by instructor): (a) the system SRT, (b) how much oxygen is required in kg/d if the effluent soluble COD concentration = 5 mg/L, and (c) the oxygen uptake rate, expressed in mg/L·h, at steady state in the aeration tank. Assume 1.42 g COD/g VSS.

		Reactor		
Item	Unit	1	2	3
Aeration tank MLVSS	mg/L	3000	3000	3000
Aeration tank volume	m^3	1000	1000	1000
Influent flowrate	m^3/d	5000	5000	5000
Waste sludge flowrate	m^3/d	59	45	65
Waste sludge VSS concentration	mg/L	8000	8000	8000
Influent soluble COD concentration	mg/L	400	400	400

7–22 A complete-mix activated sludge process with secondary clarification and sludge recycle is used to treat a dairy wastewater at a flowrate of 1000 m^3/d with a degradable influent COD of 3000 mg/L and BOD of 1875 mg/L. The MLSS concentration is 2800, 3300, or 3500 mg/L (MLSS value to be selected by instructor), MLVSS/MLSS ratio is 0.80, effluent TSS concentration is 20 mg/L, t is 24 h, recycle MLSS concentration is 10,000 mg/L, and waste sludge flowrate from the recycle line is 85.5 m^3/d. Using the given information, determine (a) the system SRT, the F/M ratio in g BOD/g MLVSS·d, and the volumetric BOD loading rate (kg/m^3·d), (b) the observed yield in terms of g TSS/g BOD and g TSS/g COD, and (c) the synthesis yield, assuming that $b = 0.10$ g VSS/g VSS·d and $f_d = 0.15$ g VSS/g VSS.

7–23 A conventional activated sludge plant is operated at SRT values of 8, 10, or 12 d (value to be selected by instructor). The reactor volume is 8000 m^3 and the MLSS concentration is 3000 mg/L. Determine (a) the sludge production rate, (b) the sludge wasting flowrate when wasting from the reactor, and (c) the sludge wasting flowrate when wasting from the recycle line. Assume that the concentration of suspended solids in the recycle is equal to 10,000 mg/L, and the solids loss in the secondary clarifier effluent is minor and can be neglected.

7–24 A complete-mix activated sludge process with a clarifier and sludge recycle receives an influent wastewater flowrate of 2000 m^3/d and influent particulate concentration of 400, 500, or 600 mg VSS/L (value to be selected by instructor) that is entirely biodegradable. The volume of the activated sludge reactor is 500 m^3. The biokinetic coefficients for particulate degradation (Eq. 7–20) are $k_p = 2.2$ g VSS/g biomass·d and $K_x = 0.15$ g VSS/g biomass. The yield and endogenous decay coefficients are 0.50 g biomass/g VSS and 0.10 g VSS/g VSS·d, respectively. Using the given information: (a) develop a steady-state mass balance for particulate removal in the activated sludge system, (b) develop equations for the aeration tank particulate and biomass concentrations as a function of SRT (assume that the effluent contains no degradable particulates, particulates only leave the system via the waste sludge, and soluble COD is negligible), (c) determine the biomass and particulate concentrations in the aeration tank at SRT values of 3, 5, and 10 d, and (d) determine the percent removal of particulates at 3, 5, and 10 d.

7–25 A completely mixed activated sludge process is operated at a 10.5-d SRT, 12°C temperature, and a 3500 mg/L MLSS concentration to produce an effluent NH_4-N concentration of 1.0 mg/L. The average sludge production rate is 753 kg TSS/d, and the oxygen consumption rate is 1225 kg/d including that for nitrification. The system aeration rate (air supply) is controlled to maintain a DO concentration at 1.0 mg/L in the aeration basin. If the oxygen demand increases, the aeration blower air output is automatically increased to maintain a DO of 1.0 mg/L. The plant operator is thinking about tinkering with the SRT and asks you what changes would be expected if the SRT is increased to 15 d. Indicate if values for the following parameters will increase (I), decrease (D) or remain the same (S) and give reasons for your selection.

a. Sludge production rate, kg/d

b. Oxygen consumption rate, kg O_2/d

c. Effluent soluble biodegradable COD concentration, mg/L

d. Aeration tank MLSS concentration, mg/L

e. Effluent NH_4-N concentration, mg/L

f. Effluent NO_2-N concentration, mg/L

7–26 The following sets of kinetic coefficients (to be selected by instructor) are given for the treatment of a municipal wastewater with an influent degradable COD of 300 mg/L and influent nbVSS concentration of 100 mg/L. Using these data and assuming the effluent degradable COD concentration is negligible compared to the amount of COD removed, prepare plots of (a) the observed yield (as g VSS/g COD) removed as a function of SRT and (b) the g oxygen used/g COD removed as a function of SRT. On the plot in part (a) also show the fraction of the yield from cell debris and influent nbVSS.

		Coefficient set		
Coefficient	Unit	1	2	3
Y	g VSS/g COD	0.40	0.40	0.35
b	g VSS/g VSS·d	0.10	0.08	0.12
f_d	g VSS/g VSS	0.10	0.15	0.15

7–27 Design a complete-mix activated sludge process with recycle to treat an industrial wastewater with one of the following characteristics (to be selected by instructor) at peak month conditions.

		Wastewater		
Item	Unit	1	2	3
Flowrate	m^3/d	4000	4300	4000
BOD	mg/L	800	600	1000
nbVSS	mg/L	200	200	200
TKN	mg/L	30	30	40
Total phosphorus	mg/L	8	8	6
Temperature	°C	15	15	15

The relevant biokinetic coefficients and operating conditions are

$Y = 0.45$ g VSS/g COD	SRT = 10 d
$b = 0.10$ g VSS/g VSS·d	Return sludge = 8000 mg TSS/L
$\mu_m = 2.5$ g VSS/g VSS·d	Aeration tank MLSS = 2500 mg/L
$K_s = 20$ mg COD/L	Clarifier effluent TSS = 15 mg/L
$f_d = 0.10$ g VSS/g VSS	
bCOD = 1.6 (BOD)	

Using the given information and biokinetic coefficients, determine (a) the aeration tank volume (m^3), the amount of waste solids produced/d (kg/d), the oxygen requirement (kg/d), the aeration tank oxygen uptake rate (mg/L·h), the effluent soluble BOD concentration, the return sludge recycle ratio for the following design conditions, and the MLVSS to MLSS ratio, and (b) whether supplemental nitrogen or phosphorus is required and, if so, how much in mg/L? Assume the biomass contains 12 percent nitrogen and 2 percent phosphorus on a volatile suspended solids basis. Assume no nitrification occurs.

7–28 For the same industrial wastewater application given in Problem 7–27, powdered activated carbon (PAC) is added to the influent at a dose of 50 mg/L to sorb potential toxic substances. The SRT is still held at 10 d. Determine the MLSS concentration, the MLVSS/MLSS ratio, and the total daily sludge production in kg TSS/d with the PAC addition.

7–29 A complete-mix activated sludge system receives wastewater with one of the following characteristics (wastewater to be selected by instructor):

		Wastewater		
Item	Unit	1	2	3
Flowrate	m^3/d	6000	6000	6000
Biodegradable BOD	mg/L	300	400	500
Influent nbVSS	mg/L	100	100	150

The relevant design criteria are
Flowrate = 6000 m^3/d
Biodegradable COD = 300 mg/L
Influent nbVSS = 100 mg/L

The following biokinetic coefficients can be assumed:
$Y = 0.40$ g VSS/g COD
$b = 0.10$ g VSS/g VSS·d
$f_d = 0.10$ g VSS/g VSS
$\mu_m = 5.0$ g VSS/g VSS·d
$K_s = 20$ mg COD/L

If the system aeration oxygen transfer capacity is 52 kg O_2/h, what maximum SRT can be used so that the oxygen requirements can be met by the existing oxygen transfer capacity?

7–30 The kinetics for substrate utilization can be described by a first-order relationship (Eq. 7–18) ($r_{su} = kSX$). (a) Using the given first-order kinetic relationship instead of the Michaelis-Menten relationship for substrate utilization, derive a steady-state relationship that can be used to calculate the effluent soluble substrate concentration from a complete-mix suspended growth reactor. Verify that Eq. (7–42) can be used to determine the biomass (X) concentration. (b) For the following reactor conditions and biokinetic information, determine the SRT needed to provide an effluent soluble substrate concentration of 1.0 mg/L, and the biomass concentration.

S_o = 500 mg/L COD
τ = 0.25 d
Y = 0.50 g VSS/g COD removed
b = 0.06, 0.10, or 0.12 g VSS/g VSS·d (to be selected by instructor)
$r_{su} = -kSX$, where k = 0.504 g/g·d

7–31 An aerobic digester receives thickened waste activated sludge and holds it for a number of days for further aeration and solids destruction by endogenous decay of the biomass. The biomass concentration entering the digester is defined as X_o and is 24 g VSS/L. The influent flow also contains 6 g/L of inert nonbiodegradable VSS ($X_{I,o}$) for a total influent VSS concentration of 30 g/L. The digester biomass VSS concentration is X, and the inert VSS concentration is X_I. The digester volume is V, and the hydraulic retention time (V/Q) is 20 d. A membrane is installed in the digester, and digester liquid is drawn through the membrane to provide solids thickening within the digester. The membrane effluent liquid flow is defined as Q_M, and its VSS concentration zero. The biomass VSS endogenous decay rate is given as $r_{xd} = bX$, where: r_{xd} = the rate of biomass solids destruction (g VSS/L·d, and b = specific biomass endogenous decay rate, (g VSS/g VSS·d). Values for b and f_d = 0.10 g/g·d and 0.10 g/g

a. Write the mass balance equation for X and give equation to solve for X at steady state conditions.

b. Write the mass balance equation for $X_{I,o}$ and give equation to solve for $X_{I,o}$ at steady state conditions.

c. Write an equation defining the SRT in terms of the reactor volume (V), biomass concentration (X), and waste solids flowrate.

d. What is the value for X, $X_{I,o}$, SRT and percent reduction of influent biomass and influent total VSS, if the membrane liquid removal rate is equal to 50 percent of Q ($Q_M = 0.50Q$)

7–32 Consider a biofilm treating a liquid stream containing acetate and dissolved oxygen with a stagnant liquid layer above the biofilm. (a) Using the stoichiometric relationship developed for the biological degradation of acetate in Example 7–4, determine the maximum acetate concentration in the bulk liquid that can be satisfied before the aerobic degradation in the biofilm is limited by the surface flux rate of oxygen, where the bulk liquid DO concentration is 2.0, 3.0, or 4.0 mg/L (DO value to be selected by instructor). (b) Compare these results to the results of NH_4-N oxidation in Example 7–7. Why is the bulk liquid NH_4-N concentration so much lower at a DO concentration of 2.0 mg/L?

Given:
Acetate diffusivity coefficient = 0.9 cm^2/d
Oxygen diffusivity coefficient = 2.6 cm^2/d

7–33 An activated sludge system treating domestic wastewater is operated at a solids retention time of 10 d with a mixed-liquor temperature of 18°C. For many weeks nitrification has occurred, with an effluent NH_4-N concentration reported at less than 1.0 mg/L. After some time, the nitrification performance declines with effluent NH_4-N concentrations exceeding 10 mg/L. As the city engineer you are requested to investigate the cause of the decline in performance and to make recommendations for actions that will get the discharge quality back in compliance. Describe possible causes for the decline in nitrification efficiency and how you would evaluate the problem.

7–34 Using the data in Table 7–13, what SRT is needed to achieve a steady state effluent NH_4-N concentration of 1.0 mg/L for an aerobic suspended growth nitrifying system at 20°C and for an anammox suspended growth system at 30°C? Assume the aerobic system is not limited by dissolved oxygen and the anammox system is not limited by nitrite.

7–35 Using the half-reactions from Table 7–6 calculate the oxygen equivalent of nitrite (g O_2/g NO_2-N), for biological reaction with nitrite as the electron acceptor instead of oxygen.

7–36 An anoxic suspended growth reactor is operated at an SRT of 5.0 d treating clarifier effluent from an activated sludge nitrification process. Acetate is added as the electron donor. Given the following coefficients for acetate under nitrate reduction conditions, determine (a) How much acetate is needed, in kg/d, to remove the influent NO_3-N concentration of 40.5, 20.5 or 30.5 g/m^3 (to be selected by instructor) in a treatment flowrate of 4000 m^3/d, (b) The biomass production rate in kg/d.

The reactor effluent acetate concentration at the 5.0-d SRT is 2 mg/L. The effluent NO_3-N is 0.50 mg/L. The nitrogen for biomass growth is from the influent NO_3-N.

$Y = 0.3$ g VSS/g COD removed
$b = 0.08$ g VSS/g VSS·d

Nitrogen for biomass growth = 0.12 g N/g biomass VSS

Ignore the biomass debris production ($f_d = 0$). What is the COD of acetate? i.e. g COD/g acetate. Provide a mass balance and steady state expression for the reactor acetate COD, biomass, and NO_3-N concentration.

7–37 Two complete-mix suspended growth laboratory reactors with sludge recycle fed the same synthetic wastewater are operated in parallel at the same aerobic SRT. One reactor has an anaerobic/aerobic sequence to promote enhanced biological phosphorus removal, and the other is operated only with the aerobic portion. The influent flow contains 100, 200, or 300 mg/L acetate (to be selected by instructor). The phosphorus and volatile fraction contents of the two mixed liquors are as follows: The lower VSS/TSS ratio for the biological phosphorus removal reactor accounts for both polyphosphate and associated cations in the storage products.

Reactor	g P/g VSS	g VSS/g TSS
Aerobic only	0.015	0.85
EBPR	0.250	0.65

Using the following operating conditions and coefficients, how much phosphorus is removed from the influent for each system in mg/L, and what are the aerobic reactor MLVSS and MLSS concentrations? (Note: for this problem the coefficients are assumed equal for both types of organisms, but in practice they may be different.)

$Y = 0.40$ g VSS/g COD
$b = 0.10$ g VSS/g VSS·d
SRT = 5 d
$\tau = 3$ h
$f_d = 0.10$ g VSS/g VSS

7–38 A laboratory reactor is to be operated to study operating conditions that affect biological phosphorus removal. The influent phosphorus concentration will be 10, 20, or 30 mg/L (as selected by instructor). What minimum concentrations of magnesium, potassium, and calcium should be in the influent liquid?

7–39 For the enhanced biological phosphorus removal process shown in Figure 7–23, indicate the effect of the changes listed below (one at a time from a base case design) on the effluent soluble phosphorus concentration. Will it increase (I), decrease (D) or remain the same (S)? Give a reason for each selection. Note the base case is operated at a low SRT with no nitrification but sufficient for PAO growth.

a. The total system SRT is increased and nitrification occurs.

b. The fraction of rbCOD in the influent biodegradable COD increases from 20 percent of bCOD to 35 percent of bCOD.

c. It is summer and the activated sludge temperature is 25°C and the pH drops from 7.5 to 6.8 because the city budget for purchasing alkalinity was depleted due to an unexpected increase in alkalinity costs.

d. The aeration tank DO concentration drops long term from a normal level of 2.0 mg/L to between 0.30 and 0.50 mg/L due to an equipment failure.

7–40 An anaerobic treatment process is used to treat a flowrate of 500 m^3/d with an influent soluble COD concentration of 2000, 5000, or 9000 mg/L (value to be selected by instructor). The net biomass yield is 0.04 g VSS/g COD removed and 95 percent soluble COD removal occurs at a temperature of 30°C. Assuming the gas contains 65 percent methane, calculate the total gas flow in m^3/d. What is the energy value of the gas produced in kJ/d? (The heat value of methane is 50.1 kJ/g at 30°C.)

7–41 A professor claims that the effect of processing food waste in an anaerobic digester and using the methane for fuel has a lower greenhouse gas effect than if the food waste is composted and used for a beneficial use for application on agriculture land. Do you agree or disagree? Explain the basis for your position.

7–42 Based on a review of the literature (cite a minimum of two references) explain the importance of the syntrophic relationship between methanogens and acid fermenters in an anaerobic process. What is the effect (increase, decrease, or remain the same) on the gas production rate, percent methane in the gas, volatile fatty acid concentration, and pH if an upset occurs to create an imbalance between fermenters and methanogens?

7–43 Modify Eqs. (7–156), (7–157), and (7–158) based on using first-order kinetics for the substrate removal rate versus the Monod growth kinetic model, where: $r_{su} = kSX$. The first-order model is often used to describe the biodegradation kinetics of a number of priority pollutants.

7–44 Assume a complete-mix reactor is to be used to treat a wastewater containing a priority pollutant with the following characteristics and other easily degradable organic compounds. The priority pollutant is not very volatile so that losses due to stripping can be ignored. Using the following information determine (a) the fate of the compound in terms of biodegradation losses, and removal in the system effluent and waste sludge, and (b) the values computed in part (a) if the value for μ_m is 3 times higher.

Design data and coefficients:

System SRT (to be selected by instructor) 5, 10, or 15 d
Reactor MLVSS = 2000 mg/L
Reactor $\tau = 0.25$ d
Compound characteristics and biokinetic coefficients:
Influent concentration = 5.0 mg/L
$K_p = 15 \times 10^{-3}\ m^3/g$
$\mu_m = 2.0$ g VSS/g VSS·d
$Ks = 0.4\ g/m^3$
$Y = 0.6$ g VSS/g compound
$b = 0.08$ g VSS/g VSS·d

Suspended Growth Biological Treatment Processes

WORKING TERMINOLOGY

Term	Definition
Activated sludge process	Biological treatment process that involves the conversion of organic matter and/or other constituents in the wastewater to gases and cell tissue by a large mass of aerobic microorganisms maintained in suspension by mixing and aeration. The microorganisms form flocculent particles that are separated from the process effluent in a sedimentation tank (clarifier) and are returned subsequently to the aeration process or wasted.

Term	Definition
Aerobic (oxic) processes	Biological treatment processes that occur in the presence of free dissolved oxygen; oxygen is consumed by aerobic microorganisms in oxidation/reduction reactions to produce energy for cell growth and cell maintenance.
Anaerobic processes	Biological treatment processes that occur in the absence of oxygen.
Anoxic process	Biological treatment process that occurs in the absence of free dissolved oxygen where nitrate and nitrite are used as the main electron acceptors in biological oxidation/reduction reactions; denitrification is an example of an anoxic process.
Biomass	The total mass of solids in a reactor consisting mainly of organic matter and microorganisms.
Biological nutrient removal (BNR)	The term applied to the removal of nitrogen and phosphorus in biological treatment processes.
Denitrification	The biological process by which nitrate or nitrite is reduced to nitrogen and other gaseous end products.
Enhanced biological phosphorus removal (EBPR)	Removal of phosphorus by extraordinary storage in bacteria selected in anaerobic/aerobic process configuration and subsequent solids separation.
Hindered settling	Settling which occurs when the activated sludge flocs interfere with each other as they settle.
Facultative processes	Biological treatment processes in which the organisms can function in the presence or absence of molecular oxygen.
Fermentation	The conversion of organic matter to volatile fatty acids in the absence of oxygen, nitrate, and nitrite.
Membrane bioreactor (MBR)	A process that combines a suspended growth process with a membrane separation system within the process aeration tank; membrane separation is accomplished by either microfiltration or ultrafiltration.
Membrane flux	The rate of flow across a membrane per unit of surface area, $L/m^2 \cdot h$.
Mixed liquor suspended solids (MLSS)	The biomass contained in a treatment reactor used to bring about treatment of the organic material in wastewater.
Nitrification	The two-step biological process by which nitrogen (mostly in the form of ammonia) is converted to nitrite and then to nitrate.
Nocardioform foam	A thick layer of brown, biological foam caused by a filamentous bacteria that forms on the top of aeration tanks and secondary clarifiers.
Nonbiodegradable volatile suspended solids (nbVSS)	These are suspended solids contained in influent wastewater to activated sludge processes that are organic but not biodegradable. They impact sludge production.
Phosphorus accumulating organisms (PAOs)	Heterotrophic bacteria selected in EBPR processes that have the ability for high intracellular phosphorus storage.
Readily biodegradable COD (rbCOD)	Dissolved biodegradable organic substrates which are removed by bacteria much faster than colloidal or particulate degradable COD. The rbCOD impacts spatial oxygen demand, EBPR removal efficiency, and denitrification rates.
Sequencing batch reactor (SBR)	An SBR is a batch fill and draw activated sludge treatment process. It involves a treatment sequence of fill, react, settling, supernatant decanting, and idle. Activated sludge aeration and liquid solids separation occurs in the same tank.
Simulation models	Mathematical models, based on a set of equations, used to assess the effects of kinetics and changes in the wastewater characterizes on process performance.
Simultaneous nitrification and denitrification (SNdN)	Nitrogen removal occurs in same activated sludge floc or in a biofilm due to nitrification in aerobic outer layer and denitrification in interior due to the lack of dissolved oxygen and presence of nitrate or nitrite.

Term	Definition
Sludge production	The amount of solids produced during the biological processing of wastewater including influent nonbiodegradable solids and the biomass resulting from the conversion of organic.
Sludge yield	The amount of solids produced relative to the amount of BOD or COD removed during the biological processing of wastewater.
Solids flux analysis	A method used to determine the area required for hindered settling based on an analysis of the solids (mass) flux.
Solids retention time (SRT)	The average period of time in which solids remain in a suspended growth process (also called sludge age).
Staged process	Processes which occur with more than one independent reactor or compartment in series.
Surface overflow rate	The hydraulic flowrate applied relative to the clarifier surface area ($m^3/m^2 \cdot d$).
Suspended growth processes	Biological treatment processes in which microorganisms responsible for the conversion of organic matter or other constituents in the wastewater to gases and cell tissue are maintained in suspension within the liquid.
Volumetric organic loading rate	The amount of BOD or COD applied to the aeration tank volume per day (e.g., kg BOD or COD/$m^3 \cdot d$).

The theory of biological wastewater treatment is presented and discussed in detail in Chap. 7. Biological treatment processes, as noted in Chap. 7, may be classified as aerobic and anaerobic suspended growth, attached growth, and various combinations thereof. The focus of this chapter is on suspended growth treatment processes as exemplified by the activated sludge process for BOD and nitrification and for nitrogen and phosphorus removal. Attached growth and combined processes are discussed in Chap. 9, and suspended and attached growth anaerobic processes are considered in Chap. 10. Included in this chapter are (1) introduction to the activated sludge process. (2) wastewater characterization, (3) fundamentals of process selection, design, and control, (4) selector types and design considerations, (5) use of simulation models for activated sludge process design considerations, (6) processes for BOD removal and nitrification, (7) processes for biological nitrogen removal, (8) processes for enhanced biological phosphorus removal, (9) aeration tank design for activated sludge processes, (10) analysis of liquid separation for activated sludge processes with clarifiers, (11) design considerations for secondarily clarifiers, and (12) solids separation for membrane bioreactors. Aerated lagoons, non-aerated lagoons, and stabilization ponds are not covered in this text, as they are used mainly for small rural communities where sufficient land is available and discharge requirements may not be as stringent as in urban areas. Detailed design information on aerated lagoons and stabilization ponds may be found in the 4th edition of this textbook (Tchobanoglous et al., 2003). Additional sources of information may be found in Crites and Tchobanoglous (1998) and Reed et al. (1995).

8–1 INTRODUCTION TO THE ACTIVATED SLUDGE PROCESS

To provide a basis for the process designs presented in the subsequent sections of this chapter, it will be useful to consider (1) a brief summary of the historical development of the activated sludge process, (2) a description of the basic process, (3) a brief review of the evolution of the activated sludge process, and (4) an overview of recent process developments.

Historical Development of Activated Sludge Process

The activated sludge process is now used routinely for the biological treatment of municipal and industrial wastewaters. The antecedents of the activated sludge process date back to the early 1880s in England, to the work of Dr. Angus Smith, who investigated the aeration of wastewater in tanks, which hastened the oxidation of the organic matter. The aeration of wastewater was studied subsequently by a number of investigators, and in 1910 Black and Phelps reported that a considerable reduction in putrescibility could be secured by forcing air into wastewater in basins. In experiments with aerated wastewater, conducted at the Lawrence Experiment Station during 1912 and 1913, Clark and Gage found that growths of organisms could be cultivated in bottles and in tanks partially filled with roofing slate spaced about 25 mm (1 in.) apart and that these growths greatly increased the degree of purification obtained (Clark and Adams, 1914).

The results of the work at the Lawrence Experiment Station, with respect to the treatment of wastewater, were so striking that knowledge of them led Dr. G. J. Fowler of the University of Manchester, England to suggest that experiments along similar lines be conducted at the Manchester Sewage Works where Ardern and Lockett carried out valuable research on the subject. During the course of their experiments, Ardern and Lockett found that the sludge played an important part in the results obtained by aeration, as announced in their paper of May 3, 1914 (Ardern and Lockett, 1914). The process was named *activated sludge* by Ardern and Lockett because it involved the production of an activated mass of microorganisms capable of aerobic stabilization of organic material in wastewater (Metcalf & Eddy, 1935).

Basic Process Description

By definition, the basic activated sludge treatment process, as illustrated on Figs. 8–1(a) and (b), consists of the following three basic components: (1) a reactor in which the microorganisms responsible for treatment are kept in suspension and aerated; (2) liquid-solids separation unit, usually in a sedimentation tank; and (3) a recycle system for returning solids removed from the liquid-solids separation unit back to the reactor. Numerous process configurations have evolved employing these components. An important feature of the activated sludge process is the formation of flocculent settleable solids that can be removed by gravity settling in sedimentation tanks. In most cases, the activated sludge process is employed in conjunction with physical and chemical processes that are used for the preliminary and primary treatment of wastewater (discussed in Chap. 5), and post treatment, including disinfection (Chap. 12), and possibly filtration (Chap. 11).

Historically, most activated sludge plants have been used to treat wastewaters that have been pretreated by primary sedimentation, as shown on Figs. 8–1(a) and (b). Primary sedimentation is most efficient at removing settleable solids, whereas the biological processes are essential for removing soluble, colloidal, and particulate (suspended) organic substances; for nitrification and denitrification; and for biological phosphorus removal. For applications such as treating wastewater from smaller-sized communities, primary treatment is often not used as more emphasis is placed on simpler and less operator-intensive treatment methods. Primary treatment is omitted frequently in areas of the world that have hot climates, where odor problems from primary tanks and primary sludge can be significant. For these applications, various modifications of conventional activated sludge processes are used, including sequencing batch reactors, oxidation ditch systems, and membrane bioreactors.

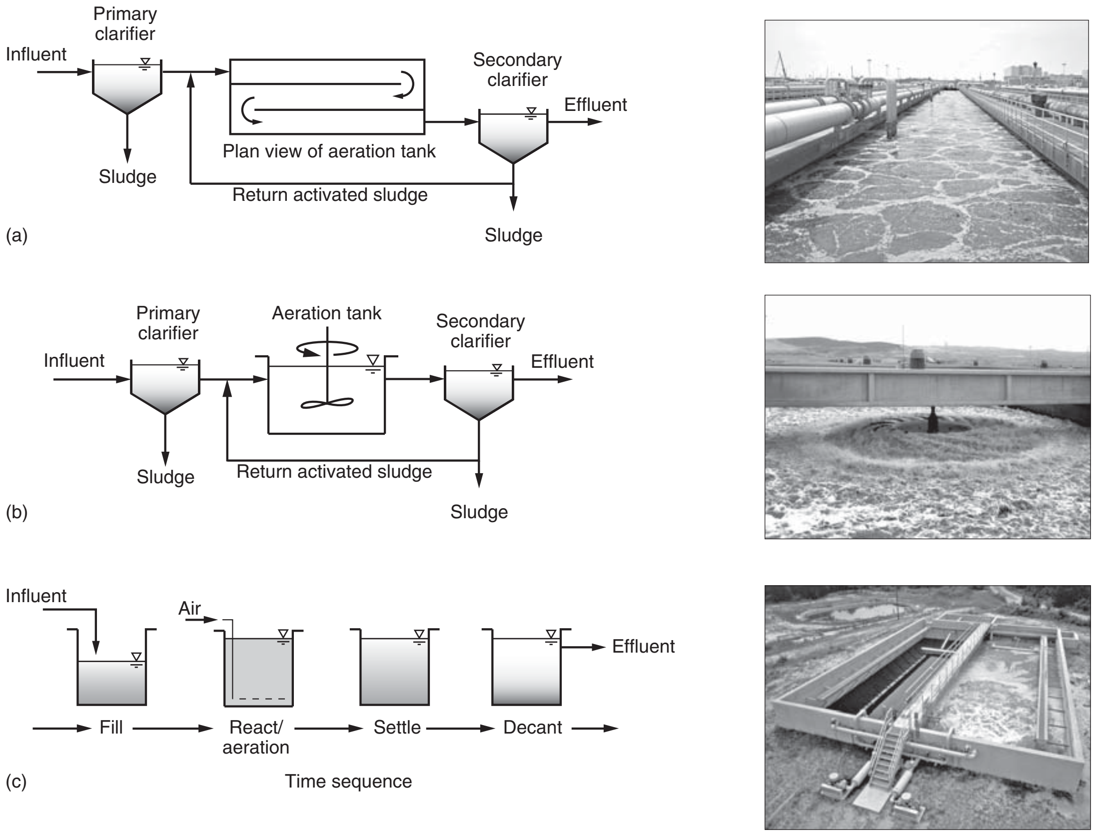

Figure 8–1

Typical activated sludge processes with different types of reactors: (a) schematic flow diagram of plug-flow process and view of plug-flow reactor, (b) schematic flow diagram of complete-mix process and view of complete-mix activated sludge reactor, and (c) schematic diagram of sequencing batch reactor process and view of sequencing batch reactor.

Evolution of the Conventional Activated Sludge Process

Prior to the 1980s, the principal objective of activated sludge process designs was aimed mainly at achieving a "secondary treatment" standard of 85 percent BOD and TSS removal. Since then, more emphasis has been placed on meeting more stringent discharge limits as well as the removal of nutrients (nitrogen and phosphorus). Thus, a number of activated sludge processes and design configurations have evolved in response to (1) the need for higher-quality effluents from wastewater treatment plants; (2) the need to remove nutrients; (3) increased discoveries and understanding of microbial processes and fundamentals; (4) technological advances in equipment, materials, electronics, and process control; and (5) the continual need to reduce capital and operating and energy costs for municipalities and industries. Many activated sludge processes used today and expected to be used in the future may incorporate nitrification, biological nitrogen removal, and/or biological phosphorus removal. Typically, reactors in series, operated under aerobic, anoxic, and anaerobic conditions are used. The general types of activated sludge processes used (i.e., plug flow, complete mix, and sequencing batch reactor), illustrated on Fig. 8–1, are considered in the following discussion.

Plug-Flow Process Configurations. Since the process came into common use in the early 1920s and up until the late 1970s, the type of activated sludge process used most commonly was the one in which a plug-flow reactor with large length to width ratios (typically $>$ 10:1) was used [see Fig. 8–1(a)]. In considering the evolution of the activated sludge process, it is important to note that the discharge of industrial wastes to domestic wastewater collection systems increased in the late 1960s. The use of a plug-flow process became problematic when industrial wastes were introduced because of the toxic effects of some of the discharges.

Complete-Mix Process Configurations. The complete-mix reactor was developed, in part, because the larger volume allowed for greater dilution and thus mitigated the effects of toxic discharges. The more common type of activated sludge process in the 1970s and early 1980s tended to be single-stage, complete-mix activated sludge (CMAS) processes [see Fig. 8–1(b)], as advanced by McKinney (1962). For some nitrification applications, two-stage systems (each stage consisting of an aeration tank and clarifier) were used with the first stage designed for BOD removal, followed by a second stage for nitrification.

Comparing Plug Flow and Complete Mix Process Configurations. In comparing the plug-flow [see Fig. 8–1(a)] and complete-mix activated sludge (CMAS) [see Fig. 8–1(b)] processes, the mixing regimes and tank geometry are quite different. In the CMAS process, the mixing of the tank contents is sufficient so that ideally the concentrations of the mixed-liquor constituents, soluble substances (i.e., COD, BOD, NH_4-N), and colloidal and suspended solids do not vary with location in the aeration basin. The plug-flow process involves relatively long, narrow aeration basins, so that the concentration of soluble substances and colloidal and suspended solids varies along the reactor length. Although process configurations employing long, narrow tanks are commonly referred to as plug-flow processes, in reality, true plug flow does not exist. Depending on the type of aeration system, back mixing of the mixed liquor can occur and, depending on the layout of the reactor and the system reaction kinetics, nominal plug flow may be described more appropriately by the series of complete-mix reactors as discussed in Chap. 4.

Sequencing Batch Process Configuration. With the development of simple inexpensive program logic controllers (PLCs) and the availability of level sensors and automatically operated valves, the sequencing batch reactor (SBR) process [see Fig. 8–1(c)] became used more widely by the late 1970s, especially for smaller communities and industrial installations with intermittent flows. In recent years, however, SBRs are being used for larger cities. The SBR is a fill-and-draw type of reactor system involving a single complete-mix reactor in which all steps of the activated sludge process occur. Mixed liquor remains in the reactor during all cycles, thereby eliminating the need for separate sedimentation tanks.

Other Activated Sludge Processes. Other activated sludge processes that have found application, with their dates of major interest in parentheses, include the oxidation ditch (1950s), contact stabilization (1950s), Krause process (1960s), pure oxygen activated sludge (1970s), Orbal process (1970s), deep shaft aeration (1970s), and sequencing batch reactor process (1980).

Development of Selectors. Activated sludge process designs before and until the late 1970s generally involved the configurations shown on Figs. 8–1(a) and (b). These designs very often suffered from solids settling problems in the secondary clarifiers due to the proliferation of filamentous-type bacteria. In the early 1980s researchers and practicing engineers advanced the concept of a "biological selector" in activated sludge design, which was first introduced in a patent by Davidson (1957) to select for good settling "floc-forming" activated sludge over filamentous bacteria. Selectors are smaller single or multi-staged aerated reactors in front of the main activated sludge treatment aeration basin. The selector concept is also inherent in designs with single or multi-staged anoxic or anaerobic reactors before the main aeration tank to select for conditions for denitrification of nitrate/nitrite or for phosphorus-storing bacteria. The anoxic or anaerobic reactors also serve as selectors resulting in the development of good settling activated sludge. Selectors are considered in detail in Sec. 8–4.

Membrane Bioreactor Process Configuration. A membrane bioreactor (MBR) is an activated sludge system with membranes located at the end of the activated sludge basin(s) for liquid-solids separation in lieu of using secondary clarifiers (see Fig. 8–2). In the integrated MBR system shown on Fig. 8–2 the key component is the microfiltration or ultrafiltration membrane that is immersed directly into the activated sludge reactor. The membranes are mounted in modules (sometimes called cassettes) that can be lowered into the bioreactor. The modules are comprised of the membranes, support structure for the membranes, feed inlet and outlet connections, and an overall support structure. The membranes are subjected to a vacuum (less than 50 kPa) that

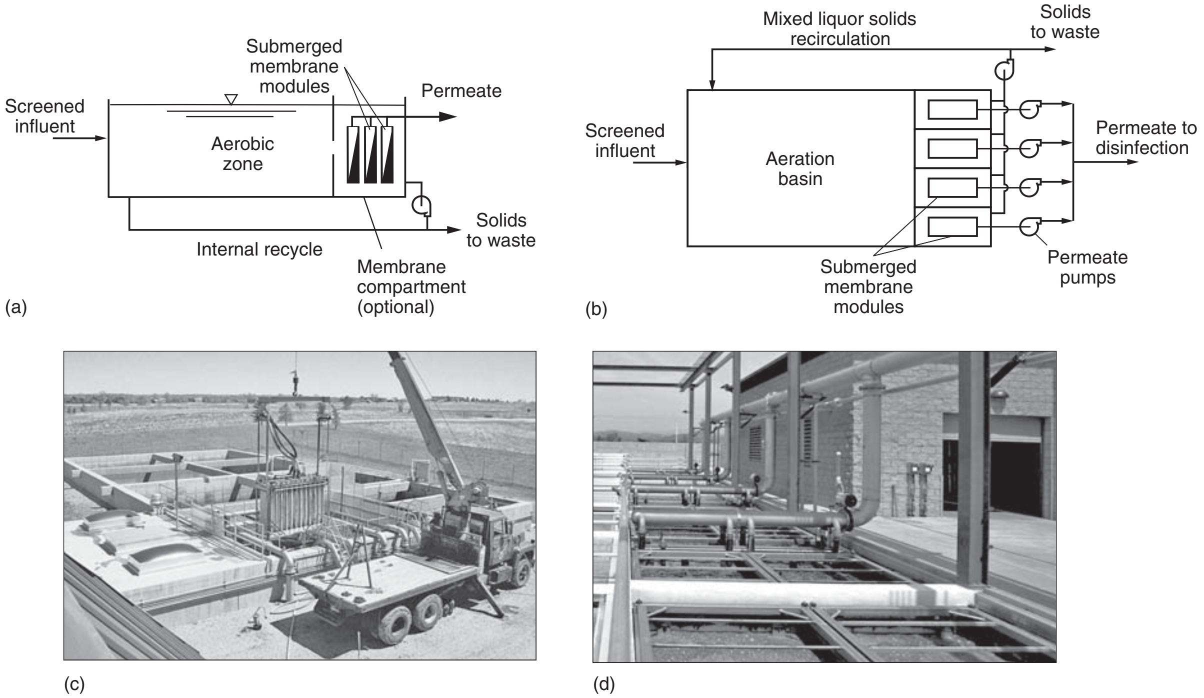

Figure 8–2

Membrane bioreactor (MBR). A multi-staged activated sludge system with membranes for liquid-solids separation: (a) section through MBR with separate compartment for the membranes, (b) plan view of MBR, (c) view of membrane cassettes being placed in separate compartment, and (d) view of separate membrane compartment.

draws water (permeate) through the membrane while retaining solids in the reactor. To minimize the accumulation of solids and fouling on the exterior of the membranes, compressed air is introduced through a distribution manifold at the base of the membrane module. As the air bubbles rise to the surface, scouring of the membrane surface occurs; the air also provides oxygen to maintain aerobic conditions and solids suspension within the reactor.

Implementation of MBR Process. In 1969, U.S. Patent 3,472,765 was issued to William E. Budd and Robert W. Okey of Dorr-Oliver for a process that integrated complete-mix activated sludge process with membrane technology. Membrane separation for activated sludge treatment was first demonstrated at Pikes Peak, CO, in 1974 by Dorr Oliver, but it was not economically feasible for widespread use until membrane materials and manufacturing methods improved. In addition, the initial designs employed cross-flow membrane separation units located outside the activated sludge tanks, which had high energy requirements for pumping mixed liquor across the membrane to control fouling. Placement of the membrane separation unit in the activated sludge reactor and using coarse bubble aeration, in the late 1980s, was less energy intensive and led to future MBR applications (Yamamoto et al., 1989). The lower energy MBR system was first commercialized with flat plate membranes by Kubota for wastewater treatment in Japan in 1990. About three years later an MBR system using Zenon's hollow fiber ZeeWeed® system was installed at Stoney Creek, Ontario Canada. The first MBR installation for biological wastewater treatment in the U.S. was in 1998 at the Arapohoe County Lone Tree Creek WWTP in Colorado. The use of ultrafiltration (UF) and microfiltration (MF) membranes in MBR systems for activated sludge treatment was well accepted in the late 1990s and early 2000s.

MBR Process Advantages and Disadvantages. The use of membrane liquid-solids separation provides many advantages compared to activated sludge processes with gravity clarifiers. These are (1) a much smaller area requirement (less than 50%) due to operation with a higher mixed liquor concentration (typically 8000 to 12,000) and the reduced space for membrane separation compared to clarifiers, (2) simpler process operation with no concerns about the effect of filamentous activated sludge, (3) a reclaimed water quality effluent due to complete suspended solids capture across the membrane separation, and (4) a lower disinfection dose requirement due to the low turbidity effluent. Disadvantages are an increased energy cost, the need for future membrane replacement, and the cleaning and operational demands for membrane fouling control.

MBR Process Applications. The most frequent applications for MBRs have been for domestic wastewater treatment and water reuse, ranging in flows from small housing developments and apartments to large centralized wastewater treatment facilities. The largest facility, as of 2008, is the King County, Washington Brightwater wastewater treatment plant, at an average design flowrate of 117,000 m^3/d (Judd, 2008a). MBR designs have also been used for industrial wastewater treatment applications, including food and beverage processing, chemical plants, automotive plants, dairy wastewater, oil refinery wastewater, landfill leachate and pharmaceuticals, and also in anaerobic treatment processes (Yang et al., 2006).

Process applications of MBRs are described along with similar applications using activated sludge and clarifiers for nitrification, nitrogen removal and enhanced biological phosphorus removal in Secs. 8–7 and 8–8. Design considerations associated with the use of gravity clarifiers or membranes for activated sludge liquid-solids separation are discussed in Secs. 8–10, 8–11, and 8–12. Membrane systems used in advanced wastewater applications including membrane materials, membrane designs, and operating conditions are discussed in Sec. 11–6 in Chap. 11.

Nutrient Removal Processes

Over the past 10 years, achieving higher nutrient (nitrogen and phosphorus) removals has gained importance in the implementation of the activated sludge treatment process. As a result, a number of biological nutrient-removal configurations have been developed including those using activated sludge with secondary clarifiers or membranes for liquid-solids separation. Nearly all of the various activated sludge process modifications, whether with secondary clarifiers or membranes, are based on the same fundamental principles of biological treatment as described previously in Chap. 7. Processes used in full-scale operation are described in Secs. 8–6, 8–7, and 8–8; design examples for the processes most commonly used are also included.

A key element in the new nutrient removal designs is the use of internal recycle from the aeration or anoxic tanks to upstream reactors (see Fig. 8–3), in contrast to recycle in the past being only from the secondary clarifier underflow to the head of the activated sludge aeration tank as shown on Figs. 8–1(a) and (b). The process efficiency benefits of using reactors in series as well as staged reactors has also been recognized and implemented in full-scale designs. However, because the design and operation of activated sludge nutrient removal processes has become more complex, computer modeling is an increasingly important tool to incorporate the large number of components and reactions necessary to evaluate activated sludge performance in nutrient removal application. The use of simulation models for suspended growth systems is discussed in Sec. 8–5.

(From H. D. Stensel.) (Coordinates 27.5256 N 82.5959 W, view at altitude 360 m, since then, an oxidation ditch has been built alongside.)

8–2 WASTEWATER CHARACTERIZATION

Activated sludge process design requires determining (1) the influent characteristics of the wastewater, (2) the aeration tank volume, (3) the sludge production rate, (4) the oxygen supply rate needed, and (5) the effluent concentration of important parameters. To design an activated sludge treatment process properly, characterization of the wastewater is perhaps the most critical step in the process. For biological nutrient-removal processes, wastewater characterization is essential for predicting performance. Wastewater characterization is an important element in the evaluation of existing facilities for optimizing performance and available treatment capacity. Flowrate characterization is also important including diurnal, seasonal, and wet-weather flowrate variations (see Chap. 3). Without comprehensive wastewater characterization, facilities may either be under- or overdesigned, resulting in inadequate or inefficient treatment.

Key Wastewater Constituents for Process Design

Wastewater characteristics of importance in the design of the activated sludge process can be grouped into the following categories: (1) carbonaceous constituents, (2) nitrogenous compounds, (3) phosphorus compounds, (4) total and volatile suspended solids (TSS and VSS), and (5) alkalinity. Typical wastewater constituents quantified for use in desktop designs of wastewater treatment processes are reported in Table 8–1. Desktop designs, based on assuming steady- state operating conditions, are useful to determine reasonable values for the key activated sludge design parameters listed above. However for biological nutrient removal (BNR) processes with multiple reactors in series (including anaerobic, anoxic, and aerobic zones) and internal recycle streams, and/or for process analyses under variable flowrate and load conditions, simulation models with differential equations that can be used to account for all forms of the constituents of concern in the wastewater and biological reactors are most useful. When simulation models are used, the number of wastewater constituents evaluated must be increased. The constituents that must be considered are summarized in Table 8–2 along with the nomenclature used in this textbook and common to the International Water Association (IWA) activated sludge process simulation models (Henze et al., 1995). The following letters represent the state of the wastewater constituent: S is soluble, C is colloidal, X is particulate, and T is total of the individual constituents ($S + C + X$).

Table 8–1

Example of typical domestic wastewater characterization parameters and typical values

Component	Concentration, mg/L[a]
COD	508
sCOD	177
BOD	200
TSS	195
VSS	150
TKN	35
NH_4-N	20
NO_3-N	0
Total phosphorus	5.6
Alkalinity	200 (as $CaCO_3$)

[a] Typical medium strength wastewater, from Table 3–18.

Table 8–2

Definition of terms used to characterize important wastewater constituents used for the analysis and design of biological wastewater treatment processes

Constituent[a,b]	Symbol[c]	Definition
BOD		
BOD		Total 5-d biochemical oxygen demand
sBOD		Soluble 5-d biochemical oxygen demand
UBOD		Ultimate biochemical oxygen demand
COD		
TCOD	COD_T	Total chemical oxygen demand
bCOD		Biodegradable chemical oxygen demand
pCOD		Particulate chemical oxygen demand
sCOD		Soluble chemical oxygen demand
nbCOD		Nonbiodegradable chemical oxygen demand
rbCOD	S_S	Readily biodegradable chemical oxygen demand
bsCOD		Biodegradable soluble chemical oxygen demand
b_{COL}COD	X_{COL}	Biodegradable colloidal chemical oxygen demand
sbCOD	X_S	Slowly biodegradable chemical oxygen demand
bpCOD	X_{SP}	Biodegradable particulate chemical oxygen demand
nbpCOD	X_I	Nonbiodegradable particulate chemical oxygen demand
nbsCOD	S_I	Nonbiodegradable soluble chemical oxygen demand
Nitrogen		
TKN		Total Kjeldahl nitrogen
bTKN		Biodegradable total Kjeldahl nitrogen
sTKN		Soluble (filtered) total Kjeldahl nitrogen
ON		Organic nitrogen
NH_4-N	S_{NH4}	Ammonia nitrogen
bON		Biodegradable organic nitrogen
nbON		Nonbiodegradable organic nitrogen
pON		Particulate organic nitrogen
bpON	X_{NS}	Biodegradable particulate organic nitrogen
nbpON	X_{NI}	Nonbiodegradable particulate organic nitrogen
sON		Soluble organic nitrogen
bsON	S_{NS}	Biodegradable soluble organic nitrogen
nbsON		Nonbiodegradable soluble organic nitrogen
TP		Total phosphorus
PO^4	S_{PO4}	Orthophosphate
bpP	X_P	Biodegradable particulate phosphorus
nbpP	X_{PI}	Nonbiodegradable particulate phosphorus
bsP	S_P	Biodegradable soluble phosphorus
nbsP	S_{PI}	Nonbiodegradable soluble phosphorus
Suspended solids		
TSS		Total suspended solids
VSS		Volatile suspended solids
nbVSS		Nonbiodegradable volatile suspended solids
iTSS		Inert total suspended solids

[a] Note: b = biodegradable; i = inert; n = non; p = particulate; s = soluble.

[b] Measured constituent values, based on the terminology given in this table, will vary depending on the technique used to fractionate a particular constituent.

[c] Commonly used symbol for constituents in IWA activated sludge models.

The subscripts S and I are used to indicate whether the constituent component is biodegradable (S) or nonbiodegradable/inert (I). Other subscripts are used to indicate the specific constituent under S and *X*. For the simulation models the carbonaceous material is quantified in terms of COD. The terms presented in Table 8–2 are introduced, discussed, and applied in the following paragraphs. In the text of this chapter, the units of expression for constituent concentrations are given in mg/L. In the examples, however, constituent concentrations are expressed as g/m^3 (which is equivalent to mg/L) for ease of use in process computations, thus eliminating one unit conversion step.

Carbonaceous Constituents. Carbonaceous constituents measured by BOD or COD analyses are critical to the activated sludge process design. Higher concentrations of degradable COD or BOD result in (1) a larger aeration tank volume, (2) greater required oxygen transfer rates, and (3) greater rates of sludge production. While BOD is the common parameter used to characterize carbonaceous constituents in wastewater, COD is the biodegradable carbonaceous parameter used in most comprehensive computer simulation design models. In these models, a COD mass balance is used to account for the fate of carbonaceous COD material between the amount oxidized, the amount in the effluent, and the amount in waste solids as biomass or nondegraded influent VSS. The various forms of the COD in wastewater are shown on Fig. 8–4 and defined in Table 8–2. The measurement methods and the relative amounts of different forms of COD are illustrated on Fig. 8–5.

COD Fractions. Unlike BOD, some portion of the COD is not biodegradable, so the COD is divided into *biodegradable* and *nonbiodegradable* concentrations. The next level of interest is how much of the COD in each of these categories is *dissolved* (*soluble)*, and how much is *particulate*, comprised of colloidal and suspended solids. The *nonbiodegradable soluble COD* (nbsCOD) will be found in the activated sludge effluent, and nonbiodegradable particulates will contribute to the total sludge production.

Using the nomenclature in Table 8–2, the total COD can be presented as the sum of the wastewater characterization constituents.

$$\text{TCOD} = \text{rbCOD} + \text{sbCOD} + \text{nbsCOD} + \text{nbpCOD} \tag{8–1}$$

$$\text{COD}_T = S_S + X_S + S_I + X_I \tag{8–2}$$

$$X_S = X_{\text{COL}} + X_{\text{SP}} \tag{8–3}$$

Figure 8–4

Fractionation of COD and wastewater. Information on the COD fractions is used in computer simulation models for activated sludge processes.

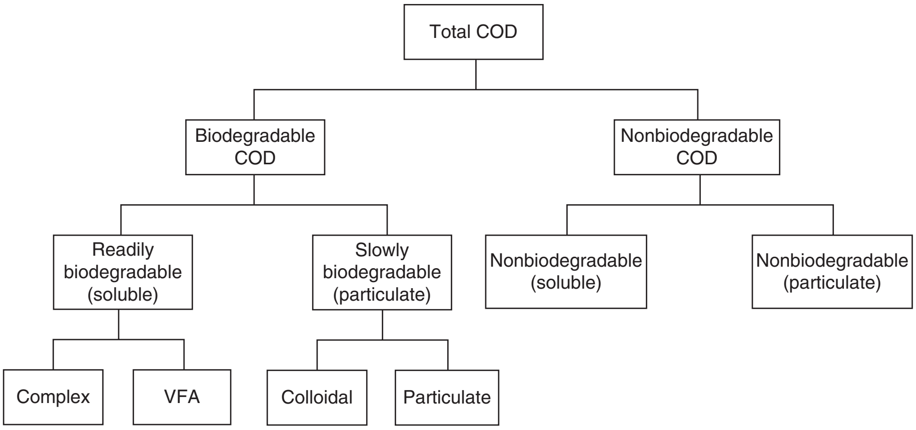

Figure 8–5

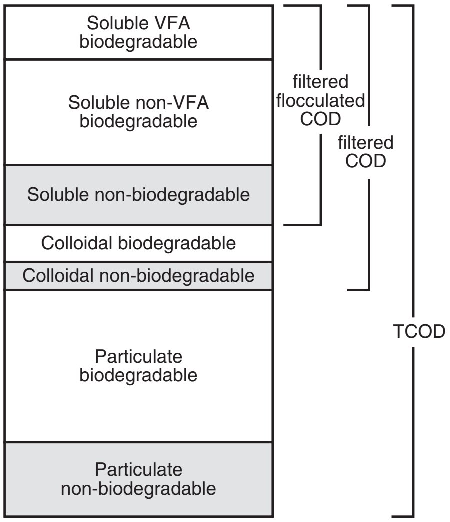
Schematic of COD components and separation methods used to obtain components.



Understanding the fractions of biodegradable COD that are measured as soluble readily biodegradable COD (rbCOD), and slowly biodegradable particulate is extremely important for activated sludge process design. The rbCOD portion is assimilated quickly by the biomass, while the particulate and colloidal COD must first be dissolved by extracellular enzymes and are thus assimilated at much slower rates. The rbCOD fraction of the COD has a direct effect on the activated sludge biological kinetics and process performance. Process applications where the rbCOD concentration affects the process design and performance are summarized in Table 8–3.

For conventional plug-flow or staged aerobic activated sludge reactors, a greater oxygen transfer rate will be required toward the front of the aeration tank where there is a greater influent rbCOD concentration. The rbCOD concentration has a significant effect on the denitrification rate in preanoxic zones in biological nitrogen-removal processes,

Table 8–3

Biological processes affected by readily biodegradable COD (rbCOD) concentration in influent wastewater

Process	Effect of rbCOD
Activated sludge aeration	For plug flow or staged aeration zones, there will be a higher oxygen demand toward the front of the tank with higher fraction of rbCOD in the influent COD.
Biological nitrogen removal	For preanoxic tank, there will be a higher denitrification rate with a higher fraction of rbCOD in the influent COD. Can result in smaller anoxic tank volume.
Enhanced biological phosphorus removal	Greater influent rbCOD concentration results in a greater amount of enhanced biological phosphorus removal.
Activated sludge selector	Higher fraction of rbCOD in influent COD provides more COD for floc-forming bacteria in selector. Can have a greater impact on improving sludge volume index (SVI).

where it will be consumed before the aeration zone. The greater the amount of rbCOD, the faster will be the nitrate reduction rate. For enhanced biological phosphorus removal (EBPR), the rbCOD can be converted rapidly to acetate via fermentation in the anaerobic zone for uptake by the phosphorus-storing bacteria. The rbCOD concentration in the influent wastewater must be known to predict more accurately the performance of enhanced biological phosphorus removal.

A further step in the characterization of the influent COD is illustrated on Fig. 8–4. The rbCOD consists of volatile fatty acids and complex soluble COD in the influent wastewater that can be fermented to volatile fatty acids (VFAs). Wastewaters that are more septic, for example, from collection systems in warm climates with minimal slopes, will contain higher concentrations of VFAs. The performance of EBPR processes is improved for wastewaters with higher influent VFA concentrations.

bCOD/BOD Ratio. BOD test data are necessary to obtain the total biodegradable COD (bCOD). Grady et al. (1999) noted that the bCOD/BOD ratio is greater than the ultimate BOD to BOD ratio (UBOD/BOD), because not all of the bCOD is oxidized in the BOD test. Some of the bCOD is converted into biomass, which can still remain as cell debris and active cells at the end of the long incubation time for the UBOD determination. For domestic wastewater with a measured UBOD/BOD ratio of 1.5, the bCOD/BOD ratio may be 1.6 to 1.7, depending on the biomass yield and cell debris fraction. The bCOD/BOD can be estimated using the following equation, which is based on the fact that the bCOD consumed in the BOD test equals the oxygen consumed (UBOD) plus the oxygen equivalent of the remaining cell debris [bCOD = UBOD + $1.42(f_d)(Y_H)$bCOD] after long-term incubation:

$$\frac{\text{bCOD}}{\text{BOD}} = \frac{\text{UBOD/BOD}}{1.0 - 1.42 f_d (Y_H)} \tag{8–4}$$

where f_d = fraction of cell mass remaining as cell debris, g/g
Y_H = synthesis yield coefficient for heterotrophic bacteria, g VSS/g COD used

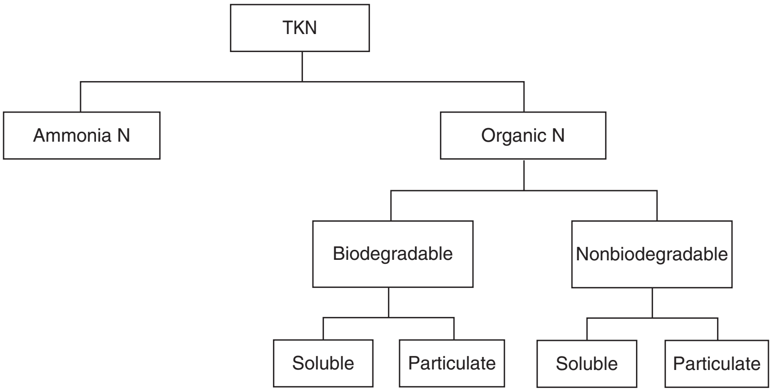
For example, using values typical of domestic wastewater (UBOD/BOD = 1.5, $f_d = 0.15$, $Y_H = 0.40$), the bCOD/BOD ratio is 1.64.

Because the *nonbiodegradable particulate COD* (nbpCOD) is organic material, it will also contribute to the VSS concentration of the wastewater and mixed liquor in the activated sludge process, and is referred to here as the *nonbiodegradable volatile suspended solids* (nbVSS). The influent wastewater will also contain nonvolatile influent suspended solids that add to the MLSS concentration in the activated sludge process. These solids are influent *inert* TSS (iTSS) and can be quantified by the difference in influent wastewater TSS and VSS concentrations.

Nitrogenous Constituents. The composition of nitrogen in wastewater is illustrated on Fig. 8–6. The total Kjeldahl nitrogen (TKN) is a measure of the sum of the ammonia and organic nitrogen. About 60 to 70 percent of the influent TKN concentration will be as NH_4-N, which is readily available for bacterial synthesis and nitrification. Organic nitrogen is present in both soluble and particulate forms, and some portion of each of these is nonbiodegradable. The particulate degradable organic nitrogen will be removed more slowly than the soluble degradable organic nitrogen because a hydrolysis reaction is necessary first. The nonbiodegradable organic nitrogen is assumed to be 6 to 7 percent of the nonbiodegradable VSS as COD in the influent wastewater (Melcer et al., 2003). The particulate nonbiodegradable nitrogen will be captured in the activated sludge floc and exit in the waste sludge, but

Figure 8–6

Fractionation of nitrogen in wastewater. Information on the nitrogen fractions is used in the detailed design of nitrification and denitrification processes.



the soluble nonbiodegradable nitrogen will be found in the secondary clarifier effluent. The soluble nonbiodegradable organic nitrogen contributes to the effluent total nitrogen concentration and typically ranges from 1 to 2 mg/L as N (Parkin and McCarty, 1981; Urgun-Demirtus et al., 2008). Some soluble nonbiodegradable organic nitrogen (0.1 to 0.3 mg/L at SRTs from 8 to 15 d) can be produced from endogenous respiration (Czerwionka et al., 2012).

Alkalinity. The concentration of alkalinity is an important wastewater characteristic that affects the performance of biological nitrification processes. Adequate alkalinity is needed to achieve complete nitrification. In some cases where a wastewater sample is not available, the total alkalinity of the wastewater may be estimated from information on the alkalinity of the potable water plus the alkalinity contributed through domestic use (see Table 3–16).

Measurement Methods for Wastewater Characterization

Special procedures are used to quantify the rbCOD, nbVSS, and soluble organic nitrogen (sON) and nonbiodegradable organic nitrogen (nbON) concentrations in wastewaters. Some of the methods and techniques used to quantify these constituents are discussed below.

Readily Biodegradable COD. The rbCOD concentration can be determined by a batch oxygen uptake rate test as described by Ekama et al. (1986) or a relatively simple chemical-physical test procedure. The latter is the most commonly used method and involves determining what is referred to as a *flocculation-filtration COD* (ffCOD) concentration in an influent wastewater sample. Separation techniques for characterization of wastewater COD are illustrated on Fig. 8–5.

The ffCOD method is based on a procedure presented by Mamais et al. (1993) in an attempt to separate the colloidal and particulate COD from the true soluble COD in the wastewater sample. The ffCOD test is applied to both the wastewater sample and a secondary effluent sample or a settled supernatant sample after sufficient contact and aeration of the wastewater sample with activated sludge. The soluble COD measured in the secondary effluent sample is the nonbiodegradable soluble COD (nbsCOD) as the rbCOD would be removed by the activated sludge process. The floc/filtration method is used widely at wastewater-treatment facilities because of its simplicity. As long as the selected procedure is compatible with the design models used to evaluate the activated sludge process, a useful design approach is possible.

The procedure is based on the assumption that suspended solids and colloidal material can be captured and removed effectively by flocculation with a zinc hydroxide precipitate to leave only truly dissolved organic material after filtration. The steps in the method for each sample are as follows: (1) 1 mL of a 100 g/L $ZnSO_4$ solution is added to 100 mL of sample with vigorous mixing for 1 min, (2) the pH is raised to about 10.5 using 6M (molar) NaOH, with 5 to 10 min of gentle mixing for floc formation, (3) the sample is settled for 10 to 20 min and the supernatant is withdrawn and filtered using a 0.45-μm membrane filter, and (4) the filtrate is analyzed for COD concentration. The difference in COD concentration between the wastewater and activated sludge treated sample is the rbCOD.

Nonbiodegradable Volatile Suspended Solids. The concentration of nonbiodegradable volatile suspended solids (nbVSS) in wastewater can be estimated from analyses for COD, sCOD, BOD, sBOD, and VSS concentration, and by assuming a constant COD/VSS ratio for both biodegradable and nonbiodegradable VSS:

$$\text{nbVSS} = \left[1 - \left(\frac{\text{bpCOD}}{\text{pCOD}}\right)\right]\text{VSS} \qquad (8\text{–}5)$$

$$\frac{\text{bpCOD}}{\text{pCOD}} = \frac{(\text{bCOD/BOD})(\text{BOD} - \text{sBOD})}{\text{COD} - \text{sCOD}} \qquad (8\text{–}6)$$

where bpCOD = concentration of biodegradable particulate COD, mg/L
pCOD = concentration of particulate COD, mg/L
sCOD = concentration of soluble COD, mg/L

Care must be taken in sample handling and analyses to obtain reliable nbVSS concentration data. A sufficient number of composite samples must be obtained to assure that the results are representative of the wastewater characteristics. Samples must be well mixed when taken for analyses, and for small sample volumes, the pipettes must have wide openings at the tip to better capture solids. When small sample volumes are used, for example, with the HACH COD analysis, treating the sample first in a high-speed blender is often done. The filtration pore size to obtain soluble samples for COD and BOD analyses is the same as that used for the TSS/VSS filtration.

A simplified approach that is used more often in lieu of the above procedure is based on the assumption that the g COD per g VSS is the same for the biodegradable and nonbiodegradable VSS. The nbVSS is then determined using the following equations.

$$\text{nbpCOD} = \text{TCOD} - \text{bCOD} - \text{nbsCODe} \qquad (8\text{–}7)$$

$$\text{VSS}_{\text{COD}} = \frac{\text{TCOD} - \text{sCOD}}{\text{VSS}} \qquad (8\text{–}8)$$

$$\text{nbVSS} = \frac{\text{nbpCOD}}{\text{VSS}_{\text{COD}}} \qquad (8\text{–}9)$$

where nbsCODe = filtered COD in activated sludge effluent, mg/L
VSS_{COD} = g COD/ g VSS

Nitrogen Compounds. For the nitrogen compounds, the soluble organic nitrogen concentration is of interest from the standpoint of its effect on the effluent total nitrogen concentration. The fractionation of nitrogen in wastewater is illustrated on Fig. 8–6. A filtered sample from the plant effluent or from a bench-scale treatability reactor can be used to determine the total effluent soluble organic nitrogen concentration by the difference between the TKN concentration of the filtered sample and the effluent NH_4-N concentration. The nonbiodegradable soluble organic nitrogen (nbsON) cannot be determined directly, but from a practical standpoint and considering the low concentration of effluent soluble organic nitrogen, the total effluent soluble organic nitrogen concentration from activated sludge treatment with SRTs between 5 and 10 d usually provides a sufficient estimate.

The *nonbiodegradable particulate organic nitrogen* (nbpON) can be estimated by an analysis of the influent VSS for organic nitrogen and the estimated amount of nbVSS. The fraction of nitrogen in the VSS is as follows.

$$f_N = \frac{(\text{TKN} - \text{sON} - \text{NH}_4\text{-N})}{\text{VSS}} \tag{8–10}$$

$$\text{nbpON} = f_N\,(\text{nbVSS}) \tag{8–11}$$

where f_N = fraction of organic nitrogen in VSS, g N/g VS.
TKN = total TKN concentration, mg/L.
sON = soluble (i.e., filtered) organic nitrogen concentration, mg/L
nbpON = nonbiodegradable particulate organic nitrogen concentration, mg/L
Other terms as defined previously.

Summary Tabulation. In summary, the wastewater COD and nitrogen components can be tabulated as follows:

$$\text{TCOD} = \text{bCOD} + \text{nbCOD} \tag{8–12}$$

$$\text{bCOD} \approx 1.6(\text{BOD}) \tag{8–13}$$

$$\text{nbCOD} = \text{nbsCOD} + \text{npbCOD} \tag{8–14}$$

$$\text{bCOD} = \text{sbCOD} + \text{rbCOD} \tag{8–15}$$

$$\text{TKN} = \text{NH}_4 - \text{N} + \text{ON} \tag{8–16}$$

$$\text{ON} = \text{bON} + \text{nbON} \tag{8–17}$$

$$\text{nbON} = \text{nbsON} + \text{nbpON} \tag{8–18}$$

where the terms are as defined in Table 8–2.

The application of the above equations in determining the characteristics of a wastewater is illustrated in Example 8–1.

Example 8–1 **Wastewater Characterization Evaluation** Given the following wastewater characterization results, determine concentrations for the following:

1. bCOD (biodegradable COD)
2. nbpCOD (nonbiodegradable particulate COD)
3. sbCOD (slowly biodegradable COD)
4. nbVSS (nonbiodegradable VSS)
5. iTSS (inert TSS)
6. nbpON (nonbiodegradable particulate organic nitrogen)
7. Total degradable TKN

Influent wastewater characteristics:

Constituent	Concentration, mg/L
BOD	200
TCOD	420
sCOD	170
rbCOD	80
TSS	220
VSS	200
TKN	40
NH_4-N	26
Alkalinity	200 (as $CaCO_3$)

Activated sludge effluent:

Constituent	Concentration, mg/L
sCODe	30.0
sON	1.2

Solution

1. Determine biodegradable (bCOD) using Eq. (8–13).

$$\text{bCOD} \approx 1.6(\text{BOD})$$

$$= 1.6(200 \text{ mg/L}) = 320 \text{ mg/L}$$

2. Determine the nbpCOD.
   a. Determine the nbCOD using Eq. (8–12).

$$\text{nbCOD} = \text{TCOD} - \text{bCOD}$$

$$\text{nbCOD} = (420 - 320) \text{ mg/L} = 100 \text{ mg/L}$$

   b. Determine the nbpCOD using Eq. (8–14).

$$\text{nbpCOD} = \text{nbCOD} - \text{sCOD}_e$$

$$= (100 - 30) \text{ mg/L} = 70 \text{ mg/L}$$

3. Determine the sbCOD using Eq. (8–15).

$$\text{sbCOD} = \text{bCOD} - \text{rbCOD}$$

$$= (320 - 80) \text{ mg/L} = 240 \text{ mg/L}$$

4. Determine the nbVSS.
   a. Determine the VSS_{COD} ratio using Eq. (8–8).

$$\text{VSS}_{\text{COD}} = \frac{\text{TCOD} - \text{sCOD}}{\text{VSS}}$$

$$\text{VSS}_{\text{COD}} = \frac{420 - 170}{200} = 1.25 \text{ gCOD/gVSS}$$

b. Determine the nbVSS using Eq. (8–9).

$$\text{nbVSS} = \frac{\text{nbpCOD}}{\text{VSS}_{\text{COD}}}$$

$$\text{nbVSS} = \frac{70}{1.25} = 56 \text{ mg/L}$$

5. Determine the inert TSS.

$$\text{iTSS} = \text{TSS} - \text{VSS} = (220 - 200) \text{ mg/L} = 20 \text{ mg/L}$$

6. Determine the nbpON.

a. Determine the organic N content of VSS using Eq. (8–10).

$$f_N = \frac{(\text{TKN} - \text{sON} - \text{NH}_4\text{-N})}{\text{VSS}}$$

$$f_N = \frac{(40 - 1.2 - 26)\text{mg/L}}{200 \text{ mg/L}} = 0.064$$

b. Determine the nbpON using Eq. (8–11).

$$\text{nbpON} = f_N(\text{nbVSS})$$

$$\text{nbpON} = 0.064(90 \text{ mg/L}) = 5.8 \text{ mg/L}$$

7. Determine total degradable TKN.

$$\begin{aligned} \text{bTKN} &= \text{TKN} - \text{nbpON} - \text{nbsON} \\ &= (40 - 5.8 - 1.2) \text{ mg/L} \\ &= 33.0 \text{ mg/L} \end{aligned}$$

Recycle Flows and Loadings

The impact of recycle flows must also be quantified and included in defining the influent wastewater characteristics to the activated sludge process. The possible sources of recycle flows include digester supernatant flows (if settling and decanting are practiced in the digestion operation), recycle of centrate or filtrate from solids dewatering equipment, backwash water from effluent filtration processes, and water from odor-control scrubbers. Depending on the source, a significant BOD, TSS, and NH_4-N load may be added to the influent wastewater. The levels of BOD and TSS concentrations possible for various solids processing unit operations are given in Table 15–1 in Chap. 15.

Compared to untreated wastewater or primary clarifier effluent, the BOD/VSS ratio is often much lower for recycle streams. In addition, a significant NH_4-N load can be returned to the influent wastewater from anaerobic digestion-related processes. Concentrations of NH_4-N in the range of 1000 to 2000 mg/L are possible in centrate or filtrate from the dewatering of anaerobically digested solids. Thus, the ammonia load from a return flow of about one-half percent of the influent flow can increase the influent TKN load to the activated sludge process by 10 to 20 percent. In all cases, a mass balance for flow and important constituents, such as BOD, TSS/VSS, nitrogen compounds, and phosphorus should be done to account for all contributing flows and loads to the activated sludge process. The separate treatment of return flows is considered in Chap. 15.

8–3 FUNDAMENTALS OF PROCESS SELECTION, DESIGN, AND CONTROL

The purpose of this section is to introduce (1) overall considerations in treatment process implementation, (2) important factors in process selection and design, (3) process control issues, (4) operational problems associated with the activated sludge secondary clarifier process, and (5) operational problems associated with the MBR process. The information presented in this section is applied to the analysis and design of alternative activated sludge processes in the remainder of this chapter. Many of the equations presented in this chapter were derived previously in Chap. 7 and are summarized in this section for convenient reference.

Overall Considerations in Treatment Process Implementation

The selection of an activated sludge treatment process is always based on a review a number of local factors that will govern the final choice. The principal factors that must be considered are summarized in Table 8–4. The relative importance of the factors presented in Table 8–4 is site specific. Current and future treatment needs are typically driven by regulatory requirements with regard to the impact of the point discharge to surface or groundwater or reclaimed water quality. Wastewater characteristics were considered previously in Sec. 8–2. Flowrates and their variation are discussed in Chap. 3. Local environmental conditions, space constraints, and costs are site-specific. Energy considerations are discussed in Chap. 17. Important factors in the selection of a specific activated sludge process are discussed in this section.

Important Factors in Process Selection and Design

In the selection and design of the activated sludge process, consideration must be given to (1) the type of activated sludge process and reactor configuration, (2) applicable kinetic relationships, (3) solids retention time and loading, (4) sludge production rate, (5) oxygen demand rate and transfer, (6) nutrient requirements, (7) other chemical requirements, (8) activated sludge settling characteristics, (9) liquid-solids separation of mixed liquor, and (10) effluent characteristics.

Selection of Activated Sludge Process and Reactor Configuration. The many different types of activated sludge processes that can be selected are dependent on treatment needs required to meet effluent discharge limits. In general, the reactor types employed are plug flow, complete-mix, and batch (e.g., sequencing batch reactor). Regardless of the type of reactor or reactor combination used, a critical element in the performance of the various activated sludge processes that employ secondary clarification for liquids-solids separation is the settleability of the mixed liquor suspended solids (MLSS). In turn, the settleability of the MLSS depends on the nature of the microorganisms that comprise the MLSS. Occasionally, a proliferation of filamentous bacteria can occur. When a proliferation of filamentous bacteria occurs, the MLSS biological flocs do not settle well, which can result in a high solids levels in the secondary clarifiers and the loss of solids in the final clarifier overflow. The term *bulking sludge* is used to describe the poor settling sludge. Bulking sludge is considered further in Sec. 8–4 along with another type of bulking, known as *viscous bulking*.

Table 8–4

General considerations for the selection of the type of suspended growth reactor

Factor	Description
Treatment needs	Treatment requirements and process selection can be categorized according to effluent discharge water quality needs, which may range from secondary treatment for BOD removal, nitrification to achieve low effluent ammonia concentration, anoxic-aerobic processes to provide nitrogen removal, and anaerobic-anoxic-aerobic processes to provide nitrogen and phosphorus removal.
Future treatment needs	Potential future treatment needs can have an impact on present process selection. For example, if water reuse is anticipated in the future, the process selection should favor designs that can easily accommodate nitrogen removal and effluent filtration.
Sludge settleability	Activated sludge *selector* designs can be used that control filamentous bacteria growth that leads to poor sludge settling and thickening in secondary clarifiers. Some selector designs are inherent in nitrogen and phosphorus removal processes.
Effect of reaction kinetics	Both completely-mixed and plug flow reactor configurations with similar volumes have been commonly used for BOD removal designs as both require a minimum SRT to provide acceptable sludge settling properties. Staged-reactors or plug flow designs can exploit reaction kinetic advantages for nitrification or preanoxic tanks to result in less volume than that for a single completely-mixed tank. Such designs require that the aeration equipment provides a high enough oxygen transfer rate in the first stage or at the front of a plug-flow tank to meet the oxygen demand for BOD removal and nitrification. The aeration equipment design must account for different oxygen demand rates along the length of the aeration tank. The oxygen demand is less variable and lower in completely-mixed tanks.
Wastewater characteristics	Wastewater characteristics are affected by contributions from domestic and industrial sources and inflow/infiltration flows. Large variations in wastewater concentrations due to wet weather or seasonal loads can affect process selection. Wastewater alkalinity and pH are also important for nitrification and enhance biological phosphorus removal processes.
Local environmental conditions	Temperature is an important environmental condition that affects treatment performance and lower rates occur at lower temperatures. The size of the facility and plant staffing are also important and smaller plants with less staffing favor processes that are simpler to operate and are more robust to influent wastewater variations. Concerns for aesthetics for facilities with close neighbors can affect process selection.
Toxic or inhibitory substances	Industrial pretreatment standards and enforcement provide substantial protection against biological process upsets from toxic or inhibitory substances disposed into the collection system. If potential exists for shock industrial toxic loads, completely-mixed activated sludge processes with greater design safety factors are considered.
Space	Space limitations for new or existing plant retrofits often limits the candidate processes that can be considered. Membrane bioreactors, integrated fixed film activated sludge, and biological aerated filter processes are good candidates for limited space.
Cost	Construction and operating costs are very important considerations in selecting the type and size of biological reactors. Because the associated settling facilities are an integral part of the activated sludge process, the selection of the reactor and the solids separation facilities must be considered as a unit.

Prior to the 1970s, filamentous bulking was considered an inevitable consequence of activated sludge treatment, but work by Chudoba et al. (1973) with staged versus complete-mix activated sludge reactors led to the concept that reactor configuration designs, now termed selectors, could be used to control filamentous bulking and improve sludge-settling characteristics. Because of their impact on the operation of the activated sludge process, the use of selectors is now a common design element of the activated sludge process. Selector types and designs are considered in detail in Sec. 8–4.

Kinetic Relationships. As developed in Chap. 7, kinetic relationships are used to determine biomass growth and substrate utilization rates, and to define process performance. The derivation of important kinetic relationships may be found in Chap. 7 and their application is demonstrated for various designs in this chapter.

Selection of Solids Retention Time and Loading Criteria. Certain design and operating parameters distinguish one activated sludge process from another. The common parameters used are the solids retention time (SRT), the food to biomass (F/M) ratio (also known as food to microorganism ratio), and the volumetric organic loading rate. While the SRT is the basic design and operating parameter, the F/M ratio and volumetric loading rate values are useful for comparison to historical data and typical observed operating conditions. The F/M and volumetric loading parameters are described in Chap. 7.

Solids Retention Time. The SRT, in effect, represents the average period of time during which the sludge has remained in the system. As presented previously in Chap. 7, SRT is the most critical parameter for activated sludge design and operation as SRT affects the treatment process performance, aeration tank volume, sludge production, and oxygen requirements. For BOD removal, SRT values generally range from 3 to 5 d, depending on the mixed-liquor temperature. At 18 to 25°C an SRT value close to 3 d is desired where only BOD removal is required and to discourage nitrification and eliminate the associated oxygen demand. To limit nitrification, some activated sludge plants have been operated at SRT values of 1 d or less. At 10°C, SRT values of 5 to 6 d are common for BOD removal only. Temperature and other factors that affect SRT in various treatment applications are summarized in Table 8–5.

Table 8–5

Typical minimum SRT ranges for activated sludge treatment[a]

Treatment goal	SRT range, d	Factors affecting SRT
Removal of soluble BOD in domestic wastewater	1–2	Temperature
Conversion of particulate organics in domestic wastewater	2–5	Temperature
Develop flocculent biomass for treating domestic wastewater	2–3	Temperature
Provide complete nitrification	3–18	Temperature/inhibitory substances
Biological phosphorus removal	2–4	Temperature
Aerobic digestion of waste activated sludge	20–40	Temperature
Degradation of xenobiotic compounds	5–50	Temperature/specific bacteria/ compounds

[a] SRT is based on aerobic volume.

SRT Values for Nitrification. Because nitrification performance is temperature-dependent, the design SRT for nitrification must be selected with caution as variable nitrification growth rates have been observed at different sites, presumably due to the presence of inhibitory substances (Barker and Dold, 1997; Fillos et al., 2000). For desktop nitrification designs, which are based on constant influent flow and TKN concentration, a safety factor is used to increase the SRT above that calculated from nitrification kinetics and the required effluent NH_4-N concentration. A factor of safety is used for two reasons: (1) to allow flexibility for operational variations in controlling the SRT, and (2) to provide for additional nitrifying bacteria to handle peak TKN loadings. The influent TKN concentration and mass loading can vary throughout the day (a peak to average TKN loading of 1.3 to 1.5 is not unusual, depending on plant size) and can also be affected by return flows from digested and dewatered biosolids processing. By increasing the design SRT, the inventory of nitrifying bacteria is increased to meet the NH_4-N concentration at the peak load so that the effluent NH_4-N concentration requirement is achieved.

Typical SRT Factors of Safety for Nitrification. Typically, the value of the factor of safety is equal to the peak/average TKN load. Because use of the peak/average TKN load is conservative, the NH_4-N concentration during the normal loading period will be lower with the net effect of a composite effluent NH_4-N concentration that is somewhat lower than the design goal. Dynamic simulation models can be used to optimize the design SRT value to meet target effluent NH_4-N concentrations, subject to changing influent flow and TKN concentrations (Barker and Dold, 1997). The steady-state solution approach described in Sec. 8–6 has resulted in reasonable designs, and can provide a starting point for using simulation models to analyze and design activated sludge nitrification processes.

Sludge Production. The design of the sludge-handling and disposal/reuse facility depends on the prediction of sludge production for the activated sludge process. If the sludge-handling facilities are undersized, treatment process performance may be compromised. Sludge will accumulate in the activated sludge process if it cannot be processed fast enough by an undersized sludge-handling facility. Eventually, the sludge inventory capacity of the activated sludge system will be exceeded and excess solids will exit in the secondary clarifier effluent, potentially violating TSS discharge limits. The sludge production relative to the amount of BOD removed also affects the aeration tank size. Two methods are used to determine sludge production as a function of SRT. The first method is based on an estimate of an observed sludge production yield from published data for domestic water, and the second is based on wastewater characterization information with consideration to the various sources of sludge production.

Sludge Production Based on Observed Yield. The use of observed yield is often satisfactory for determining an initial activated sludge process design and for estimating sludge production rate. The quantity of sludge produced daily (and thus wasted daily at steady state) can be estimated using Eq. (8–19). For a given wastewater, the Y_{obs} value will vary depending on whether the substrate is defined as BOD, bCOD, or COD.

$$P_{X,\text{VSS}} = Y_{\text{obs}}(Q)(S_o - S)(1\ \text{kg}/10^3\ \text{g}) \tag{8–19}$$

where $P_{X,\text{VSS}}$ = net waste activated sludge produced each day, kg VSS/d
Y_{obs} = observed yield, g VSS/g substrate removal
Q = influent flowrate, m^3/d
S_o = influent substrate concentration, mg/L
S = effluent substrate concentration, mg/L

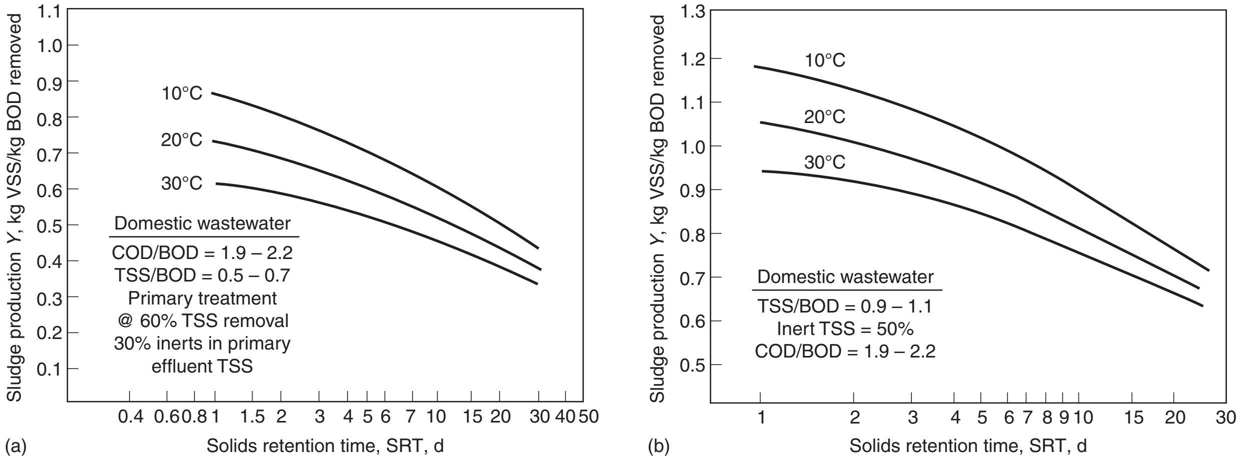


Figure 8–7

Net solids production as a function of solids retention time (SRT) and temperature: (a) with primary treatment and (b) without primary treatment.

Observed volatile suspended solids yield values, based on BOD, are illustrated on Fig. 8–7. The observed yield decreases as the SRT is increased due to biomass loss by more endogenous respiration. The yield is lower with increasing temperature as a result of a higher endogenous respiration rate at higher temperature. The yield is higher when no primary treatment is used as more nbVSS remains in the influent wastewater. The temperature correction value θ for endogenous respiration [see Eq. (2–25)] is 1.04 between 20 and 30°C, and 1.12 between 10 and 20°C. A θ value of 1.04 has been adopted in this text for the temperature effect on endogenous decay.

Sludge Production Based on Wastewater Characteristics. With sufficient wastewater characterization, a more accurate prediction of sludge production can be made. The following equation, based on Eq. (7–54) in Chap. 7, accounts for the heterotrophic biomass growth, cell debris from endogenous decay, nitrifying bacteria biomass, and nonbiodegradable volatile suspended solids and can be used to estimate sludge production. The subscripts H and n are used to distinguish the synthesis yield and decay coefficients between heterotrophic bacteria and nitrifying organisms.

$$P_{X,\mathrm{VSS}} = \underbrace{\frac{QY_{\mathrm{H}}(S_o - S)(1\ \mathrm{kg}/10^3\ \mathrm{g})}{1 + b_{\mathrm{H}}(\mathrm{SRT})}}_{\substack{\text{(A)}\\ \text{Heterotrophic}\\ \text{Biomass}}} + \underbrace{\frac{(f_d)(b_{\mathrm{H}})QY_{\mathrm{H}}(S_o - S)\mathrm{SRT}(1\ \mathrm{kg}/10^3\ \mathrm{g})}{1 + b_{\mathrm{H}}(\mathrm{SRT})}}_{\substack{\text{(B)}\\ \text{Cell}\\ \text{debris}}}$$

$$+ \underbrace{\frac{QY_n(\mathrm{NO}_x)(1\ \mathrm{kg}/10^3\ \mathrm{g})}{1 + b_n(\mathrm{SRT})}}_{\substack{\text{(C)}\\ \text{Nitrifying bacteria}\\ \text{biomass}}} + \underbrace{Q(\mathrm{nbVSS})(1\ \mathrm{kg}/10^3\ \mathrm{g})}_{\substack{\text{(D)}\\ \text{Nonbiodegradable}\\ \text{VSS in influent}}} \tag{8–20}$$

where NO_x = concentration of $\mathrm{NH_4}$-N in the influent flow that is nitrified, mg/L
b_n = endogenous decay coefficient for nitrifying organisms, g VSS/g VSS·d
Other terms as defined previously.

The total mass of dry solids wasted/day includes TSS and not just VSS. The TSS includes the VSS plus inorganic solids. Inorganic solids in the influent wastewater ($\text{TSS}_o - \text{VSS}_o$) contribute to inorganic solids and are an additional solids production term that must be added to Eq. (8–20). The biomass terms in Eq. (8–20) (A, B, and C) contain inorganic solids and the VSS fraction of the total biomass is about 0.85, based on the cell composition given in Table 7–4. Thus, Eq. (8–20) is modified as follows to calculate the solids production in terms of TSS:

$$P_{X,\text{TSS}} = \frac{A}{0.85} + \frac{B}{0.85} + \frac{C}{0.85} + D + \underbrace{Q(\text{TSS}_o - \text{VSS}_o)}_{\substack{\text{(E)} \\ \text{Influent Inert TSS}}} \tag{8–21}$$

where TSS_o = influent wastewater TSS concentration, mg/L
VSS_o = influent wastewater VSS concentration, mg/L

The daily mass of solids in the aeration tanks is determined from the SRT. The daily sludge production can be computed by Eqs. (7–56) and (7–57).

$$(X_{\text{VSS}})(V) = (P_{X,\text{VSS}})\ \text{SRT} \tag{7–56}$$

$$(X_{\text{TSS}})(V) = (P_{X,\text{TSS}})\ \text{SRT} \tag{7–57}$$

By selecting an appropriate MLSS concentration, the aeration volume can be determined using Eq. (7–57). Concentrations of MLSS selected range from 1200 to 4000 mg/L, but must be compatible with the sludge settling characteristics and clarifier design as discussed later in Sec. 8–10.

Oxygen Requirements. The oxygen required for the biodegradation of carbonaceous material is for the amount of bCOD oxidized to provide energy during bCOD consumption for cell synthesis plus the oxygen consumed during the endogenous respiration by the biomass produced. The calculation of the oxygen required for a completely mixed activated sludge system [see Fig. 8–8(a)] involves a simple mass balance on the bCOD removal across the system in which the bCOD removed is equal to the oxygen used plus the

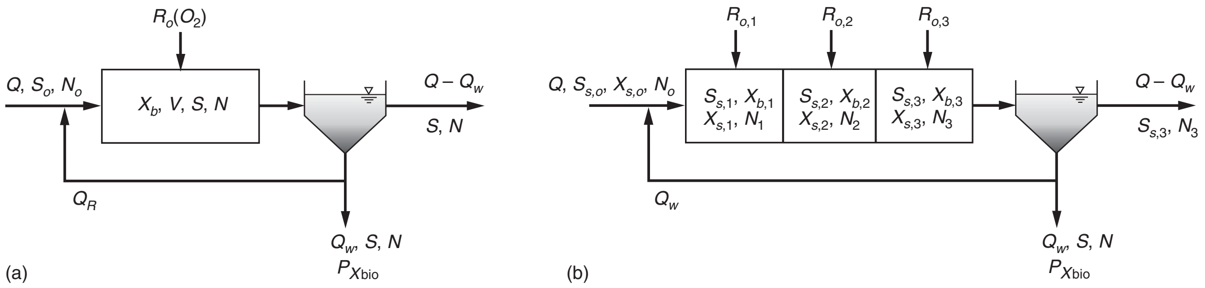

Figure 8–8

Schematic showing components used in oxygen demand rate analysis for completely-mixed activated sludge and staged activated sludge processes: (a) single stage reactor and (b) reactors in series.

bCOD in the excess biomass produced. The biomass produced ($P_{x,\text{bio}}$) is component A plus B in Eq. 8–20 and thus the total oxygen required, R_o, is as follows as shown in Chap. 7:

$$R_o = Q(S_o - S) - 1.42P_{x,\text{bio}} \tag{7–61}$$

$$R_o = Q(S_o - S) - 1.42\left[\frac{QY_{\text{H}}(S_o - S)}{1 + b_{\text{H}}(\text{SRT})} + \frac{f_d\,(b_{\text{H}})QY_{\text{H}}(S_o - S)\text{SRT}}{1 + b_{\text{H}}(\text{SRT})}\right] \tag{8–22}$$

As an approximation, for BOD removal only, the oxygen requirement will vary from 0.90 to 1.3 kg O_2/kg BOD removed for SRTs from 5 to 20 d, respectively (WEF, 2010).

Oxygen Required for Nitrification. When nitrification is included in the process, the total oxygen requirements will include the oxygen required for removal of carbonaceous material plus the oxygen required for ammonia and nitrite oxidation to nitrate (see Sec. 7–9 in Chap. 7) as follows:

$$R_o = Q(S_o - S) - 1.42\,P_{x,\text{bio}} + 4.57\,Q(\text{NO}_x) \tag{8–23}$$

where R_o = total oxygen required, g/d
$P_{X,\text{bio}}$ = biomass as VSS wasted, g/d [parts A, B, and C of Eq. (8–20)]
NO_x = Amount of NO_3-N produced from nitrification of NH_4-N, g/m^3
Other terms as defined previously.

As shown in Eq. (8–23), NO_x is the amount of TKN oxidized to nitrate. A nitrogen mass balance for the system that accounts for the influent TKN, nitrogen removed for biomass synthesis, and unoxidized effluent nitrogen is done to determine NO_x. Unless a careful wastewater characterization study is done to determine the nonbiodegradable particulate and soluble nitrogen (nbpON and nbsON), these components are ignored. Ignoring these terms results in predicting a slightly higher NO_x concentration (5 to 15 percent) and a more conservative oxygen requirement estimate using Eq. (8–23). The nitrogen mass balance, based on the assumption that biomass (which can be represented by the formula $C_5H_7NO_2$) contains 0.12 g N/g biomass, is as follows:

$$\begin{array}{ccccccc} \text{Nitrogen Oxidized} & = & \text{nitrogen in influent} & - & \text{nitrogen in effluent} & - & \text{nitrogen in cell mass} \\ Q(\text{NO}_x) & = & Q(\text{TKN}_o) & - & QN_e & - & 0.12\text{P}_{x,\text{bio}} \end{array}$$

$$\text{NO}_x = \text{TKN} - N_e - 0.12P_{x,\text{bio}}/Q \tag{8–24}$$

where NO_x = nitrogen oxidized, mg/L
TKN_o = influent TKN concentration, mg/L
N_e = effluent NH_4-N concentration, mg/L
Other terms as defined previously.

Equation (8–24) can be solved for the NO_x concentration by estimating the effluent NH_4-N concentration from the nitrification process design.

Oxygen Required for Staged Systems. For activated sludge systems with aerobic reactors in series, the calculation for the oxygen requirement in each reactor is different than above and more complex. The oxygen requirement is highest in the first stage of activated sludge systems with reactors in series [see Fig. 8–8(b)] and decreases in subsequent stages. The amount needed in each stage is a function of (1) the rate of soluble and particulate bCOD removed, (2) the rate of NH_4-N oxidized, and (3) the rate of oxygen used for endogenous respiration. For example, the R_o for reactor 2 shown on Fig. 8–8(b) is as follows:

$$\begin{aligned} R_{o,2} &= (Q + Q_R)(1 - Y_H)[(S_{s,1} - S_{s,2}) + (X_{s,1} - X_{s,2})] \\ &\quad + (Q + Q_R)\,4.57\,(NO_2 - NO_1) + 1.42 b_H (X_{b,2}) V_2 \end{aligned} \tag{8–25}$$

where $R_{o,2}$ = oxygen demand rate in reactor 2, g/d
S_s = soluble bCOD concentration, g/m^3
X_s = particulate bCOD concentration, g/m^3
Y_H = synthesis yield, g biomass COD/g bCOD removed
NO = NO_3-N concentration, g/m^3
X_b = biomass concentration, g VSS/m^3
V = reactor volume, m^3
Q_R = return activated sludge recycle flowrate, m^3/d

The oxygen demand for each stage cannot be determined without first calculating the soluble and particulate bCOD, biomass and the NO_3-N concentration in each stage (assumes that no appreciable NO_2-N is present). These values can be obtained from mass balance equations for each of these constituents, but simulation models, discussed in Sec. 8–4, provide a more efficient solution method.

As an estimate for the design of a 3-stage activated sludge system treating domestic wastewater, Eq.(8–23) can be used to estimate the total oxygen demand rate for the system. Then a distribution of that demand as 60, 25, and 15 percent for reactors 1, 2, and 3, respectively, may be used.

The oxygen demand rate for an activated sludge aeration basin will vary during the day due to diurnal loading changes. The hourly rate can be 1.3 to 1.8 times the rate based on the average daily loading depending on the magnitude of the diurnal changes in influent BOD and TKN concentrations and flowrate.

Nutrient Requirements. If a biological system is to function properly, nutrients must be available in adequate amounts. As discussed in Chaps. 2 and 7, the principal nutrients are nitrogen and phosphorus. Using the formula $C_5H_7NO_2$, for the composition of cell biomass, about 12.4 percent by weight of nitrogen will be required. The phosphorus requirement is 1.5 to 2.0 percent by weight of the cell biomass. These are typical values, not fixed quantities, because it has been shown that the percentage distribution of nitrogen and phosphorus in cell tissue varies with the system SRT and environmental conditions. The amount of nutrients required can be estimated based on the daily biomass production rate [terms A, B, and C in Eq. (8–21)]. It should be noted that nutrient limitations can occur when the concentrations of inorganic nitrogen as N and orthophosphate as P are less than 0.1 mg/L (de Barbadillo et al., 2006). As a general rule, for SRT values greater than 7 d, about 5 g nitrogen and 1 g phosphorus will be required per 100 g of BOD to provide an excess of nutrients.

Other Chemical Requirements. In addition to the nutrient requirements, alkalinity is a major chemical requirement needed for nitrification. The amount of alkalinity required for nitrification, taking into account cell growth, is about 7.14 g $CaCO_3$/g NH_4-N [see Eq. (7–91) in Chap. 7]. In addition to the alkalinity required for nitrification, additional alkalinity must be available to maintain the pH in the range from 6.8 to 7.4. Typically the amount of residual alkalinity required to maintain pH near a neutral point (i.e., pH $\sim$ 7) is between 70 and 80 mg/L as $CaCO_3$, based on the equilibrium relationship between the gas phase CO_2, bicarbonate alkalinity, and pH.

Liquid-Solids Separation of Mixed Liquor. Liquid-solids separation of the activated sludge mixed liquor and return of activated sludge to the activated sludge treatment reactors is critical to the process function and performance. The two methods used for liquid-solids separation are gravity settling in secondary clarifiers and membrane separation. Both methods provide solids thickening for return activated sludge flows and sludge wasting, but differ in the quality of the secondary treatment effluent TSS concentration. With well designed biological nutrient removal facilities secondary clarifier effluent TSS concentrations may range from 4 to 10 mg/L. The effluent from a membrane separation system is termed *permeate* and has no measureable TSS concentration after the liquid passes through the membrane separation unit which have membrane pore sizes of about 0.02 or 0.40 μm, depending on the choice of membranes. Each method has issues with regard to the effect of activated sludge mixed liquor characteristics on performance and design. Specific information on the design of secondary clarifiers and membrane separation is presented in Secs. 8–10 and 8–12, respectively.

Effluent Characteristics. The major parameters of interest that determine the effluent quality from biological treatment processes consist of organic compounds, suspended solids, and nutrients as indicated in Table 8–6. The biodegradable soluble organic concentration is minimal in effluents from systems with complete nitrification and SRT values above 5.0 d, and is likely within the detection limit of the BOD test, which is about 2.0 mg/L. Most of the BOD is in particulate form associated with biomass contained in the effluent VSS concentration.

Table 8–6

Effluent characteristics for biological wastewater treatment processes

Category	Characteristics	Key constituents
Soluble COD	Biodegradable	Remaining influent bsCOD
		Metabolic intermediates
		bsCOD from cell lysis
	Nonbiodegradable	Influent nbsCOD
		Metabolic products
		Nonbiodegradable colloids
Particulate COD	Biodegradable	Biomass VSS
		Non-captured influent VSS
	Nonbiodegradable	Biomass cell debris
		Non-captured influent nbVSS
Nitrogen	Inorganic	NH_4-N, NO_3-N, NO_2-N
	Organic	Dissolved organic N
		Particulate organic N in VSS
Phosphorus	Inorganic	PO_4-P
	Organic	Dissolved organic P
		Particulate organic P in VSS

With a proper secondary clarifier design and good settling sludge, the effluent suspended solids will typically be in the range of 4 to 10 mg/L. Assuming a sBOD of 2.0 mg/L, a VSS/TSS ratio of 0.85, and an effluent TSS of 6 mg/L, the final effluent BOD concentration, BODe, can be estimated as follows:

$$\mathrm{BOD_e} = \mathrm{sBOD} + \left(\frac{0.60 \text{ g BOD}}{\text{g UBOD}}\right)\left(\frac{1.42 \text{ g UBOD}}{\text{g VSS}}\right)\left(\frac{0.85 \text{ g VSS}}{\text{g TSS}}\right)(\text{TSS, mg/L}) \tag{8–26}$$

$$\mathrm{BOD_e} = 2 \text{ mg/L} + (0.60)(1.42)(0.85)(6 \text{ mg/L})$$

$$\mathrm{BOD_e} = 10.2 \text{ mg/L}$$

Because the MBR processes produce an effluent with non-detectable TSS, the BOD concentration is also minimal.

Effluent nitrogen contains inorganic and organic forms. The effluent dissolved organic nitrogen (DON) may range from 0.5 to 2.0 mg/L (Urgun-Demirtas et al., 2007), and thus can be a very significant fraction of the effluent total nitrogen concentration for system confronted with permits with stringent effluent TN concentrations (typically below 3.0 mg/L).

Process Control

To maintain high levels of treatment performance with the activated sludge process under a wide range of operating conditions, special attention must be given to process control. The principal approaches to process control are (1) maintaining a target SRT, (2) maintaining target dissolved oxygen levels in the aeration tanks, and (3) regulating the return activated sludge (RAS) flowrate. The waste activated sludge (WAS) rate is selected to meet the SRT. The SRT is the most common control parameter, but in some cases the WAS rate is adjusted to meet a target MLSS concentration. Thus, higher WAS rates result in a lower SRT and vice versa. Return activated sludge is important in maintaining the MLSS concentration and controlling the sludge blanket level in the secondary clarifier. Aeration tank oxygen uptake rates (OURs) are useful for understanding the process operating conditions and oxygen transfer requirements, and in some cases, have been used in process control algorithms. Routine microscopic observations are important for monitoring the microbial characteristics and for early detection of changes that might negatively impact sludge settling and process performance.

SRT Control. To maintain a given SRT, the excess activated sludge produced each day must be wasted. The most common practice for both activated sludge/secondary clarifier and MBR systems is to waste sludge from the return sludge line because RAS is more concentrated and requires smaller waste sludge pumps than if wasting was done by removing mixed liquor from the aeration tank. In some activated sludge/secondary clarifier applications, such as for smaller flow systems with minimal operating staff, WAS is taken directly from the aeration tank. Though this method requires a larger wasting volume, advantages are that the waste solids concentration is more uniform and the SRT control can be based on volumetric wasting without the need for measuring suspended solids in the aeration tank, effluent and return sludge. The waste sludge may be discharged to various types of thickening processes alone or combined with sludge removed from primary clarification tanks. The actual amount of liquid that must be pumped to achieve SRT process control depends on the method used and the location from which the wasting is to be accomplished.

Wasting from Return Line. For example, if SRT is used for process control and wasting is from the return sludge line, the wasting rate can be computed by modifying the terms of Eq. (7–31) (see Table 8–10).

$$\text{SRT} = \frac{VX}{(Q_W X_R + Q_e X_e)} \tag{8–27}$$

where V = volume of the reactor, m^3
X = aeration tank solids concentration, mg/L
Q_W = waste sludge flowrate from the return sludge line, m^3/d
X_R = concentration of sludge in the return sludge line, mg/L
Q_e = effluent flowrate from the secondary clarifier, m^3/d
X_e = effluent TSS concentration, mg/L

The daily manual wasting flowrate out of the RAS line is then

$$Q_W = \frac{VX}{X_R(\text{SRT})} - \frac{Q_e X_e}{X_R} \tag{8–28}$$

If it is assumed that the concentration of solids in the effluent from the settling tank is low, then Eq. (8–28) reduces to

$$\text{SRT} \approx \frac{VX}{Q_W X_R} \tag{8–29}$$

and

$$Q_W \approx \frac{VX}{X_R(\text{SRT})} \tag{8–30}$$

At higher operating SRT values, the effect of solids loss in the effluent flow on the SRT is less significant. To determine the waste flowrate using Eq. (8–30), the solids concentration in both the aeration tank and the return line must be measured.

Wasting from Aeration Tank. If wasting is done from the aeration tank and the solids in the settled effluent are again neglected, then the rate of pumping can be estimated using the following relationship:

$$\text{SRT} = \frac{V}{Q_W} \tag{8–31}$$

or

$$Q_W = \frac{V}{\text{SRT}} \tag{8–32}$$

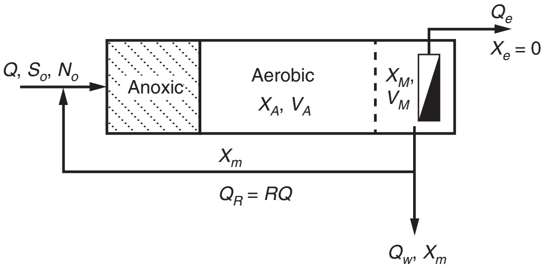
where Q_W = waste sludge flowrate from the aeration tank, m^3/d

Thus, the process may be controlled by daily wasting of a quantity of flow equal to the volume of the aeration tank divided by the SRT.

Wasting from MBR. The WAS flowrate needed to maintain a target aerobic SRT in an MBR system can be set strictly on the system aerobic volumes and return sludge recycle ratio. Such systems typically have an aerobic tank before the aerobic membrane

Figure 8–9

Schematic showing waste activated sludge flow from an anoxic/aerobic MBR.



liquid-solids separation tank (see Fig. 8–9). In some cases the aerobic tank prior to the membrane separation tank is referred to as a preaeration tank. The aerobic SRT is by definition:

$$\mathrm{SRT} = \frac{X_A V_A + X_M V_M}{Q_W X_M} \tag{8–33}$$

where V_A = volume of preaeration tank(s) before membrane tank, m^3
V_M = volume of aerated membrane separation tank, m^3
X_A = solids concentration in preaeration tank, mg/L
X_M = solids concentration in membrane tank, mg/L

The solids concentration is thicker in the membrane tank due to the removal of permeate. The preaeration and membrane tank solids concentration can be related by mass balance, and ignoring the relatively small increase in solids concentration in the flow through the tank due to the removal of influent solids and bsCOD.

$$(RQ)X_M + Q(0) = (Q + RQ)X_A \tag{8–34}$$

and thus

$$X_A = \left(\frac{R}{1 + R}\right)X_M \tag{8–35}$$

substituting for X_A in Eq. (8–33) yields

$$\mathrm{SRT} = \frac{\left(\frac{R}{1 + R}\right)V_A + V_M}{Q_W} \tag{8–36}$$

and

$$Q_W = \frac{\left(\frac{R}{1 + R}\right)V_A + V_M}{\mathrm{SRT}} \tag{8–37}$$

Using Eq. (8–37), the daily WAS flowrate from an MBR system can be set for a given return activated sludge recycle ratio and SRT.

It should be noted that the SRT can be treated as an average value for a system operation and need not be maintained with an exact wasting rate each day. The SRT can be averaged over a time period equal to the target SRT value.

Dissolved Oxygen Control. Aeration equipment must be designed to supply the oxygen demand rate of the microorganisms in the activated sludge system under a wide range of flowrates and loads, while at the same time assuring that some minimum DO concentration is met. In DO control systems, the output of the aerator is adjusted to meet changing demands based on DO concentration measurements in the aeration tank. For example, when the influent BOD and ammonia load drops, the aeration tank DO concentration rises. The control system should be designed to sense DO concentration changes and makes appropriate adjustments to change the aeration rate to lower the DO to its target range so that energy is not wasted at lower loads. At higher loads the DO concentration will start to drop and the aeration output must be increased to keep the desired elevated DO concentration.

When aeration occurs at a lower DO concentration in the aeration basin, less energy is needed because of the higher driving force between the saturated DO concentration and the aeration basin DO concentration. However, if the DO concentration is too low, filamentous organisms may predominate and the settleability and quality of the activated sludge may be poor. In general, the dissolved oxygen concentration in the aeration tank should be maintained at about 1.5 to 2.0 mg/L in all areas of the aeration tank. A minimum DO concentration of about 0.7 mg/L is required to initiate nitrification. Operation at DO concentrations below 1.0 mg/L can save energy and is done in some designs to provide simultaneous nitrification and denitrification. However, the aerobic biological reaction rates are lower, requiring greater tank volume. Higher DO concentrations (2.0 to 3.0 mg/L) provide a small additional increase in nitrification rates. Values of DO above 4 mg/L result in little or no improvement in performance, but do increase aeration costs significantly, and can potentially result in the growth of foaming organisms.

Return Activated Sludge Control. The purpose of the return of activated sludge is to maintain the necessary concentration of activated sludge in the aeration tank and to keep the sludge blanket in the secondary clarifier at a low safe depth. Sufficient return sludge pumping capacity is needed, along with sufficient clarifier depth (3.7 to 6.5 m), to maintain the blanket below the effluent weirs. Return sludge pumping rates of 50 to 75 percent of the average design wastewater flowrate are typical, and the design average capacity is typically 100 to 150 percent of the average design flowrate (recycle ratio of 1.0 to 1.5). The use of variable speed pump drives allows operation between 50 to 150 percent of the influent flowrate.

Impact of SVI on RAS. Higher return activated sludge (RAS) recycle ratios (4.0 to 6.0) are used in MBR systems (Fig. 8–9) to take advantage of the fact that the system can operate at higher MLSS concentrations (8000–12,000 mg/L) than for activated sludge/secondary clarifier systems. Clarifier thickener capabilities typically limit the return sludge concentrations to between 6000 and 12,000 mg/L.

When the activated sludge has good settling properties (see Fig. 8–10) thickening occurs readily in the clarifier and a wide range of RAS ratios are possible, while keeping the clarifier sludge blanket below 0.15 to 0.30 m. Sludges that settle well typically have a sludge volume index (SVI) value equal to or less than 120, although the exact value will vary from plant to plant. For poorer settling sludge, higher recycle rates may be needed. The SVI test is considered in greater detail in Sec. 8–10 which deals with the liquid-solids separation for activated sludge with clarifiers.

Relationship between RAS and MLSS. The relationship between the RAS ratio and aeration tank MLSS concentration can be evaluated by mass balance. A certain MLSS

Figure 8–10

Field test for determining the sludge volume index (SVI).

concentration is necessary for a given aeration tank volume and SRT as shown by Eq. (7–57). The appropriate boundaries for two mass-balance analyses are illustrated on Fig. 8–11. Assuming the sludge-blanket level in the settling tank remains constant and that the solids in the effluent from the settling tank are negligible, the mass balance around the settling tank shown on Fig. 8–11(a) is as follows:

Accumulation = inflow − outflow

$$0 = X(Q + Q_R) - Q_R X_R - Q_W X_R - Q_e X_e \tag{8–38}$$

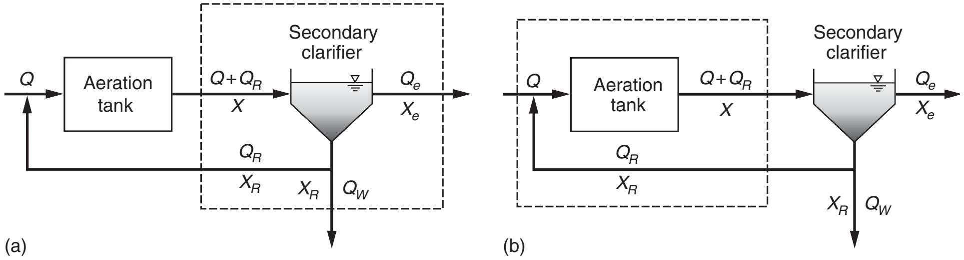
where X = mixed-liquor suspended solids, mg/L
Q = secondary influent flowrate, m^3/s
Q_R = return sludge flowrate, m^3/s
X_R = return activated sludge suspended solids, mg/L
Q_W = waste activated sludge flowrate, m^3/s
Q_e = effluent flowrate, m^3/s
X_e = effluent suspended solids, mg/L

Assuming X_e is negligible and that $Q_W X_R$ is related to the SRT [Eq. (8–28)], solving Eq. (8–38) for Q_R yields

$$Q_R = \frac{[XQ - (XV/\text{SRT})]}{X_R - X} \tag{8–39}$$

Figure 8–11

Definition sketch for suspended solids mass balances for return sludge control: (a) secondary clarifier mass balance and (b) aeration tank mass balance.



The recycle ratio ($Q_R/Q = R$) is then

$$R = \frac{1 - (\tau/\text{SRT})}{(X_R/X) - 1} \tag{8–40}$$

The required RAS pumping rate can also be estimated by performing a mass balance around the aeration tank [see Fig. 8–11(b)]. The solids entering the tank will equal the solids leaving the tank if new cell growth can be considered negligible. At SRT above 8–10 d, this is a reasonable assumption. Solids enter the aeration tank in the return sludge and in the influent to the secondary process. However, if the influent solids are negligible compared to the MLSS, the mass balance around the aeration tank results in the following expression:

Accumulation = inflow − outflow

$$0 = X_R Q_R - X(Q + Q_R) \tag{8–41}$$

Solving for the return activated sludge ratio R yields X

$$Q_R/Q = R = \frac{X}{X_R - X} \tag{8–42}$$

Thus, based on Eqs. (8–40) and Eq. (8–42) for a given RAS solids concentration (X_R), a certain RAS ratio is needed to meet the required aeration tank solids concentration (X) for the target SRT. If the solids do not settle and thicken well in the clarifier, X_R is lower and a higher RAS ratio is needed. The SVI sludge settleability test can be used to approximate X_R for adjusting the RAS ratio:

$$X_R = \frac{1}{\text{SVI}}\left(\frac{1\text{ g}}{1\text{ mL}}\right)\left[\frac{(10^3\text{ mg/1 g})}{(1\text{ L}/10^3\text{ mL})}\right] = \frac{10^6}{\text{SVI}} \tag{8–43}$$

where X_R = estimated RAS concentration, mg/L

Sludge Blanket Level. Sludge blanket depth is a useful operational parameter to assess changes in the settling characteristics. Optimal depths usually range between 0.3 and 0.6 m (1 and 2 ft). The sludge blanket method of control requires considerable operator attention because of the diurnal flow and sludge production variations and changes in the settling characteristics of the sludge. The most common method of determining the blanket level is the use of a long tube core sampler.

Oxygen Uptake Rates. Microorganisms in the activated sludge process use oxygen as they consume the substrate. The rate at which they use oxygen, known as the oxygen uptake rate (OUR), is a measure of the biological activity due to the loading on the aeration tank. Values for the OUR are obtained by performing a series of DO measurements over a period of time with mixing but no aeration, and the measured results are reported conventionally as mg O_2/L·min or mg O_2/L·h. Oxygen uptake is most valuable for plant operations when combined with VSS data. The combination of OUR with MLVSS yields a value termed the specific oxygen uptake rate (SOUR) or respiration rate and is reported as mg O_2/g MLVSS·h. Changes in SOUR values may also be used to assess the presence of toxic or inhibitory substances in the influent wastewater or load changes.

Microscopic Observations. Routine microscopic observations provide valuable monitoring information about the condition of the microbial population in the activated sludge process. Specific information gathered includes changes in floc size and density, the status of filamentous organism growth, the presence of *Nocardioform* bacteria, and the

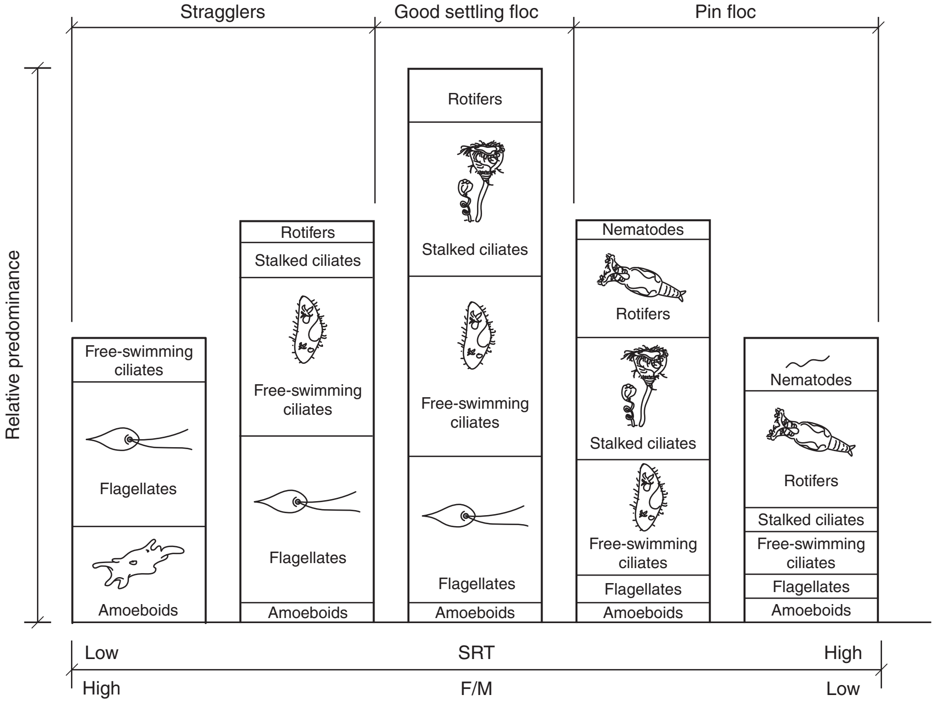


Figure 8–12

Relative predominance of microorganisms versus solids retention time (SRT) and F/M ratio. (Adapted in part from WEF, 1996.)

type and abundance of higher life-forms such as protozoans and rotifers. Changes in these characteristics can provide an indication of changes in the wastewater characteristics or of an operational problem. Examples of the changes in predominance of microorganisms versus F/M ratio and SRT are shown on Fig. 8–12. A decrease in the protozoan population may be indicative of DO limitations, operation at a lower SRT, or inhibitory substances in the wastewater. At very high SRT, small-diameter *pin floc* may develop to lead to a higher effluent suspended solids concentration. Early detection of filamentous or *Nocardioform* growth, as discussed below, will allow time for corrective action to be taken to minimize potential problems associated with excessive growth of these organisms.

Operational Problems in Activated Sludge Systems with Secondary Clarifiers

The most common problems encountered in the operation of an activated sludge/secondary clarifier plant are filamentous bulking sludge, viscous bulking sludge, *Nocardioform foaming,* and rising sludge. Because few plants have escaped these problems, it is appropriate to discuss their nature and possible plant operations responses.

Bulking Sludge. The issue of bulking sludge, which was introduced in Sec. 7–8, is always of concern for activated sludge/secondary clarifier systems. In extreme bulking sludge conditions, the sludge blanket cannot be contained and large quantities of MLSS are carried along with the clarifier effluent, potentially resulting in violation of permit requirements, inadequate disinfection, and clogging of effluent filters. The two principal types of sludge bulking problems are related to *filamentous bulking*, caused by the growth of filamentous organisms, and *viscous bulking*, caused by the presence of an excessive amount of extracellular biopolymer. The occurrence of both types of bulking, along with other forms of filamentous bulking, is considered in the following discussion. However,

Table 8–7

Filamentous bacteria found in activated sludge and associated process conditions[a]

Filament type identified	Cause of filament growth
Sphaerotilus natans, Halsicomenobacter hydrossis, Microthrix parvicella, type 1701.	Low dissolved oxygen concentration
M. parvicella, types 0041, 0092, 0675, 1851	Low F/M
H. hydrossis, Nocardia spp., Nostocoida limicola, S. natans, Thiothrix spp., types 021N, 0914	Complete mix reactor conditions
Beggiatoa, Thiothrix spp., types 021N, 0914	Septic wastewater/sulfide available
S. natans, Thiothrix spp., type 021N, possible *H. hydrossis*, types 0041, 0675	Nutrient deficiency
Fungi	Low pH

[a] From Eikelboom (1975).

before discussing the occurrence of bulking, it will be helpful to consider the general characteristics of filamentous bacteria.

Characteristics of Filamentous Bacteria. In filamentous growth, bacteria form filaments of single-cell organisms that attach end-to-end, and the filaments normally protrude out of the sludge floc. This structure, in contrast to the preferred dense floc with good settling properties, has an increased surface area to mass ratio, which results in poor settling. Methods have been developed for the identification and classification of filamentous bacteria found commonly in activated sludge systems (Eikelboom, 2000). The classification system is based on morphology (size and shape of cells, length and shape of filaments), staining responses, and cell inclusions. Common filamentous organisms are summarized in Table 8–7, along with the operating conditions that favor their growth. Identifying the specific type of filamentous organism which may help identify an operating or design condition that encourages their growth (Jenkins et al., 2004). Examples of good and poor settling with floc containing filamentous bacteria are illustrated on Fig. 8–13.

Occurrence of Filamentous Sludge Bulking. Many types of filamentous bacteria exist, but the types that occur most frequently are related to wastewater characteristics, reactor design limitations, and operational issues. Individual items associated with each of these categories are identified in Table 8–8. Activated sludge reactor operating conditions (low DO, low F/M, and complete-mix operation) clearly have an effect on the development of filamentous populations. One of the kinetic features of filamentous organisms that relates to these conditions is that they are very competitive at low substrate concentrations whether it be organic substrates, DO, or nutrients. Thus, lightly loaded complete-mix activated sludge systems or low DO (<0.5 mg/L) operating conditions provide an environment more favorable to filamentous bacteria than to the desired floc-forming bacteria.

Occurrence of Viscous Sludge Bulking. Another type of bulking that can occur, known as *viscous bulking*, is caused by the presence of an excessive amount of extracellular biopolymer, which results in a sludge with a slimy, jellylike consistency (Wanner, 1994). As the biopolymers are hydrophilic, the activated sludge is highly water-retentive. The resultant sludge has a low density with low settling velocities and poor compaction. Viscous bulking is usually found with nutrient-limited systems or in a very high F/M loading condition with wastewater having a high amount of rbCOD.

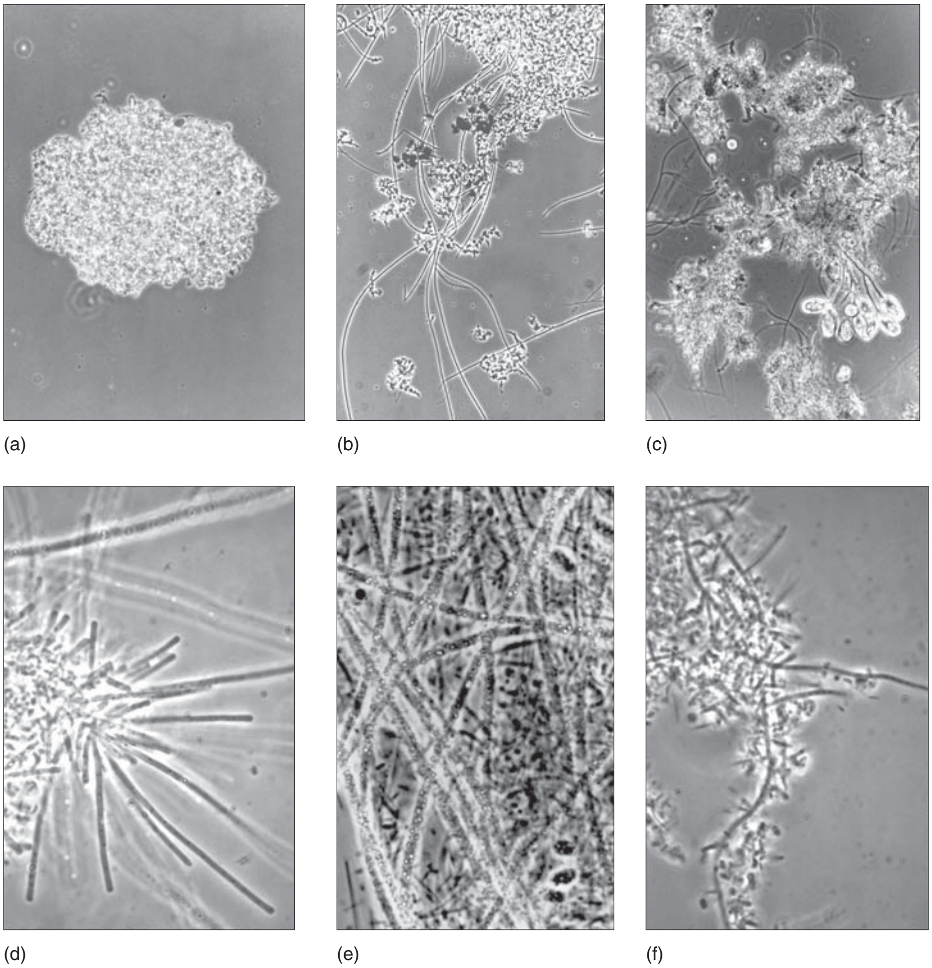

Figure 8–13

Examples of good and poor settling floc particles: (a) nonfilamentous good settling floc, (b) floc particles bridged by filamentous microorganisms, (c) floc particles with limited filamentous microorganisms in secondary form, (d) filaments extending from floc causing poor settling, (e) *Thiothrix* filaments with sulfur granules, and (f) type 1701 filamentous microorganism observed under low-dissolved oxygen conditions. (Courtesy of Dr. David Jenkins, University of California, Berkeley.)

Occurrence of Beggiatoa and Thiothrix Bulking. Filamentous bacteria such as *Beggiatoa* and *Thiothrix* grow well on hydrogen sulfide and reduced substrates, respectively, that would be found in septic wastewaters (Wanner, 1994). When the influent wastewater contains fermentation products such as volatile fatty acids and reduced sulfur compounds (sulfides and thiosulfate), *Thiothrix* can proliferate. Prechlorination of the wastewaters has been done in some cases to prevent their growth. Besides causing bulking problems in activated sludge systems, *Beggiatoa* and *Thiothrix* can create problems in fixed-film systems, including trickling filters and rotating biological contactors.

Control of Bulking Sludges. In the control of bulking, where a number of variables are possible causes, a checklist of items to investigate is valuable. The following items are recommended: (1) wastewater characteristics, (2) dissolved oxygen content, (3) process loading, and (4) internal plant overloading. One of the first steps to be taken when sludge settling characteristics change is to view the mixed liquor under the microscope to determine what type of microbial growth changes or floc structure changes can be related to the development of bulking sludge. A reasonable quality phase-contrast microscope with magnification up to 1000 times (oil immersion) is necessary to view the filamentous bacteria structure and size.

Table 8–8

Treatment plant designs and operational factors that can affect sludge bulking

Factor	Description
Wastewater characteristics	Variations in flowrate
	Variations in composition
	pH
	Temperature
	Septicity
	Nutrient content
	Nature of waste components
Design limitations	Limited air supply
	Poor mixing
	Short circuiting (aeration tanks and clarifiers)
	Clarifier design (sludge collection and removal)
	Limited return sludge pumping capacity
Operational issues	Low dissolved oxygen
	Insufficient nutrients
	Low F/M
	Insufficient soluble BOD

Wastewater Characteristics. The nature of the components found in wastewater or the absence of certain components, such as trace elements, can lead to the development of a bulked sludge (Wood and Tchobanoglous, 1975). If it is known that industrial wastes are being introduced into the system either intermittently or continuously, the quantity of nitrogen and phosphorus in the wastewater should be checked first, because limitations of both or either are known to favor bulking. Nutrient deficiency is a classic problem in the treatment of industrial wastewaters containing high levels of carbonaceous BOD. Highly septic influent wastewaters with high sulfide content can encourage the growth of *Beggiatoa* and *Thiothrix* filamentous bacteria. Wide fluctuations in pH are also known to be detrimental in plants of conventional design. Variations in organic waste loads due to batch-type operations can also lead to DO concentration and bulking problems and should be checked.

Dissolved Oxygen Concentration. Limited dissolved oxygen has often been associated with bulking sludge conditions. If the problem is due to limited oxygen, it can usually be confirmed by operating the aeration equipment at full capacity or by decreasing the system SRT, if possible, to reduce the oxygen demand. The aeration equipment should have adequate capacity to maintain at least 2 mg/L of dissolved oxygen in the aeration tank under normal loading conditions. If 2 mg/L of oxygen cannot be maintained, installation of improvements to the existing aeration system may be required.

Low DO filaments can be generated in anaerobic and anoxic selector zones under periods of low organic loads in high DO in the influent wastewater. A combination of wet weather infiltration/inflow and headworks designs that create cascading flow and aeration can cause this problem.

Internal Plant Overloading. To avoid internal plant overloading, recycle loads should be controlled so they are not returned to the plant flow during times of peak hydraulic and organic loading. Examples of recycle loads are centrate or filtrate from sludge dewatering operations and supernatant from sludge digesters. As a minimum, flow and/or load equalization can be used to mitigate the impacts associated with return flows. The treatment of return flows is considered in Chap. 15.

Temporary Control Measures. In an emergency situation or while the aforementioned factors are being investigated, chlorine and hydrogen peroxide may be used to provide temporary help. Chlorination of return sludge has been practiced quite extensively as a means of controlling bulking. A typical design for a low (5 to 10 h) τ system uses 0.002 to 0.008 kg of chlorine per kg MLSS/d (Jenkins et al., 2004). Although chlorination is effective in controlling bulking caused by filamentous growths, it is ineffective when bulking is due to light floc containing bound water. Chlorination normally results in the production of a turbid effluent until such time as the sludge is free of the filamentous forms. Chlorination of a nitrifying sludge can often result in the loss of nitrification or reduce efficiency due to their slower growth rate compared to heterotrophic bacteria. The use of chlorine also raises issues about the formation of trihalomethanes and other chloroorganic compounds with potential health and environmental effects. Hydrogen peroxide has also been used in the control of filamentous organisms in bulking sludge. Dosage of hydrogen peroxide and treatment time depend on the extent of the filamentous development.

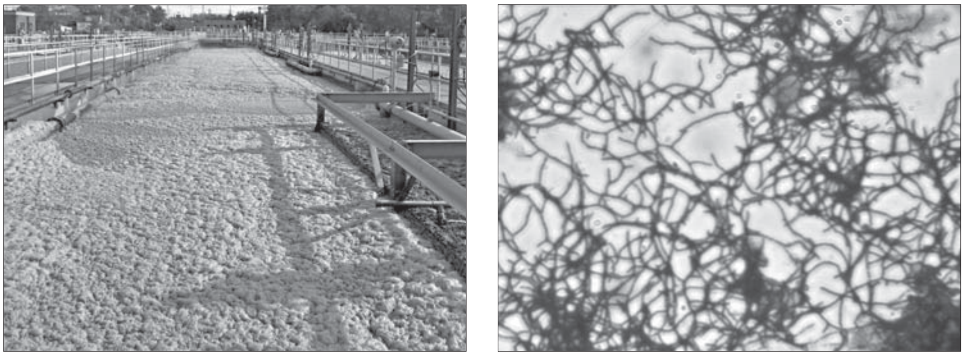
Nocardioform Foam. Two bacteria genera, the *Nocardioforms* type named *Gordonia amarae* and *Candidatus* "*Microthrix parvicella*" are associated with extensive foaming in activated sludge processes. These organisms have hydrophobic cell surfaces and attach to air bubbles, where they stabilize the bubbles to cause foam. The organisms can be found at high concentrations in the foam above the mixed liquor. Both types of bacteria can be identified microscopically.

Characteristics of Nocardioforms. They have a short filamentous structure, which is typically contained within the floc particles. *Microthrix parvicella*, has thin filaments extending from the floc particles. Foaming on an activated sludge basin and a microscopic view of *Nocardioform* foam are shown on Fig. 8–14. The foam is thick, has a brown color, and can build up in thickness of 0.5 to 1 m.

Occurrence of Nocardioform Foam. *Nocardioform* foaming can occur with both diffused and mechanical aeration, but is more pronounced with fine bubble diffused aeration and with higher air flowrates. *Nocardioform* foaming is also a common occurrence in anoxic/aerobic BNR processes. The presence of *Nocardioforms and Microthrix* has also been

Figure 8–14

Nocardioform foam: (a) example of foam on an aeration tank and (b) microscopic observation of gram stain Nocardioform foam filaments.



(a) (b)

associated with fats and edible oils in wastewater. Problems of *Nocardioform* foaming in the activated sludge can also lead to foaming in anaerobic and aerobic digesters that receive the waste-activated sludge. Both *Nocardioform* and *M. parvicella* growth is common where surface scum is trapped in either the aeration basin or secondary clarifiers. Aeration basins that are baffled with flow from one cell to the next occurring under the baffles, instead of over the top, encourage such organism growth and foam collection. By accumulating in the reactor, foam causing organisms gain a competitive advantage of having a longer effective SRT than the other activated sludge organisms.

Control of *Nocardioform* Foam. Methods that can be used to control *Nocardioform* foam include (1) avoiding trapping foam in the secondary treatment process, (2) surface wasting of activated sludge, (3) avoiding the recycle of skimmings into the secondary treatment process, (4) using chlorine spray on the surface of the foam, and (5) reducing the oil and grease content from discharges to the collection system from restaurants, truck stops, and meatpacking facilities. The addition of a small concentration of cationic polymer has been used with some success for controlling *Nocardioforms* foaming (Shao et al., 1997).

Of the above methods, the first three have been found to be most effective. As noted above, submerged weirs can be used in place of underflow baffles to limit the accumulation of foam causing bacteria. Coupled with surface wasting, foam causing bacteria lose the competitive advantage as they are removed from the reactor. The surface wasting strategy for foam control was recommended by Barnard in 1998 and successful surface foam control was reported for a full-scale BNR plant evaluation at the Groos WWTP in Norway (Ydstebo et al., 2000). Parker et al. (2011) reported on the application of this foam control method for a number of activated sludge WWTPs and termed the in-tank design as a *classifying selector*. Biological nitrogen removal processes for New York City have included both surface wasting as a routine sludge wasting method, and chlorine spray hoods across the tank width towards the end of the first pass of a 4-pass plug flow system (Mahoney et al., 2007). The chlorine, which is typically applied at a concentration of 2000 to 3000 mg/L, is effective at killing the foam causing bacteria on the activated sludge surface.

Rising Sludge. Occasionally, sludge that has good settling characteristics will be observed to rise or float to the surface after a relatively short settling period. The most common cause of this phenomenon is denitrification, in which nitrites and nitrates in the wastewater are converted to nitrogen gas. As nitrogen gas is formed in the sludge layer, much of it is trapped in the sludge mass. If enough gas is formed, the sludge mass becomes buoyant and rises or floats to the surface. Rising sludge can be differentiated from bulking sludge by noting the presence of small gas bubbles attached to the floating solids and the presence of more floating sludge on the secondary clarifier surface. Rising sludge is common in short SRT systems, where the temperature encourages the initiation of nitrification, and the mixed liquor is very active due to the low sludge age.

Controlling Rising Sludge. Rising sludge problems may be overcome by (1) increasing the return activated sludge withdrawal rate from the clarifier to reduce the detention time of the sludge in the clarifier, (2) decreasing the rate of flow of aeration liquor into the offending clarifier if the sludge depth cannot be reduced by increasing the return activated sludge withdrawal rate, (3) where possible, increasing the speed of the sludge-collecting mechanism in the settling tanks, and (4) decreasing the SRT to bring the activated sludge out of nitrification. For warm climates where it is very difficult to operate at a low enough SRT to limit nitrification, an anoxic/aerobic process will eliminate the problem of rising sludge and provide a more stable operation.

Operational Problems with MBR Systems

The principal operational problems with MBR treatment processes are foaming and fouling. Each of these is considered briefly below and in Sec. 8–12 which deals with liquid solids separation by membranes.

Foaming. Similar to activated sludge and secondary clarifier systems, *Nocardioform* foaming can occur in MBR systems operated with fine pore diffused aeration. The procedures described for dealing with foaming issues in activated sludge and secondary clarifier systems also apply to MBR systems.

Fouling. MBR systems must be operated in a preventative maintenance mode to avoid operating problems from fouled membranes. The WWTP capacity can be compromised due to the lower flux associated with fouled membrane. Membrane fouling is prevented by employing the cleaning and operating procedures provided by the membrane supplier, maintaining the upstream fine screening equipment, and operating the system within acceptable SRT and mixed liquor concentration limits. Improper screening would allow the accumulation of hair and fibrous material in the membranes, which cannot be removed by the normal membrane cleaning program. A lower SRT of about 8.0 d is normally recommended to prevent excessive fouling due to the release of microbial substances from a younger activated sludge. Excessively long SRTs may result in a higher amount of free bacteria and floc fines to increase fouling rates.

Concentrations of MLSS in the range 8000 to 14,000 mg/L are normally within acceptable operating ranges. Very high MLSS concentrations require a much lower flux to maintain a balance between the amount of solids directed to the membrane surface versus the solids removal rate by the air scour. If excessive MLSS concentrations (>18,000 mg/L) exist under operation at normal design flux values, the membranes can become what is termed "sludged up" and special cleaning methods may be needed to regain the expected operating flux.

Certain wastewater substances must be prevented from entering the treatment facility or MBR system to maintain proper membrane operation. Cooking oils and grease can collect on membrane surfaces and lead to excessive fouling that can only be removed by special membrane cleaning methods.

8–4 SELECTOR TYPES AND DESIGN CONSIDERATION

A selector is a small tank (30 to 60 min contact time) or a series of tanks located before the process aeration tank in which the incoming wastewater is mixed with return sludge under aerobic, anoxic, or anaerobic conditions. The purpose of including a selector as part of the activated sludge process is to create a condition that favors the growth of floc-forming bacteria and suppress the growth of filamentous bacteria that cause sludge bulking as described in the previous section. The use of selector designs in activated sludge is, as noted previously, more common because of the many other advantages, such as nitrogen and phosphorus removal, in addition to improved sludge settling. By improving sludge settling, the activated sludge treatment capacity may be increased, as higher MLSS concentrations are usually possible. The hydraulic capacity of the secondary clarifiers is also increased. The cause of sludge bulking and the types and design considerations for the selectors used for the control of filamentous bacteria are described in this section.

Selector Types and Design Considerations

The concept of a selector involves the use of a specific bioreactor design that favors the growth of floc-forming bacteria instead of filamentous bacteria to provide an activated sludge with better settling and thickening properties. Various types of anaerobic, aerobic and anoxic selectors are shown on Figs. 8–15(a), 8–15(b), and 8–15(c), respectively.

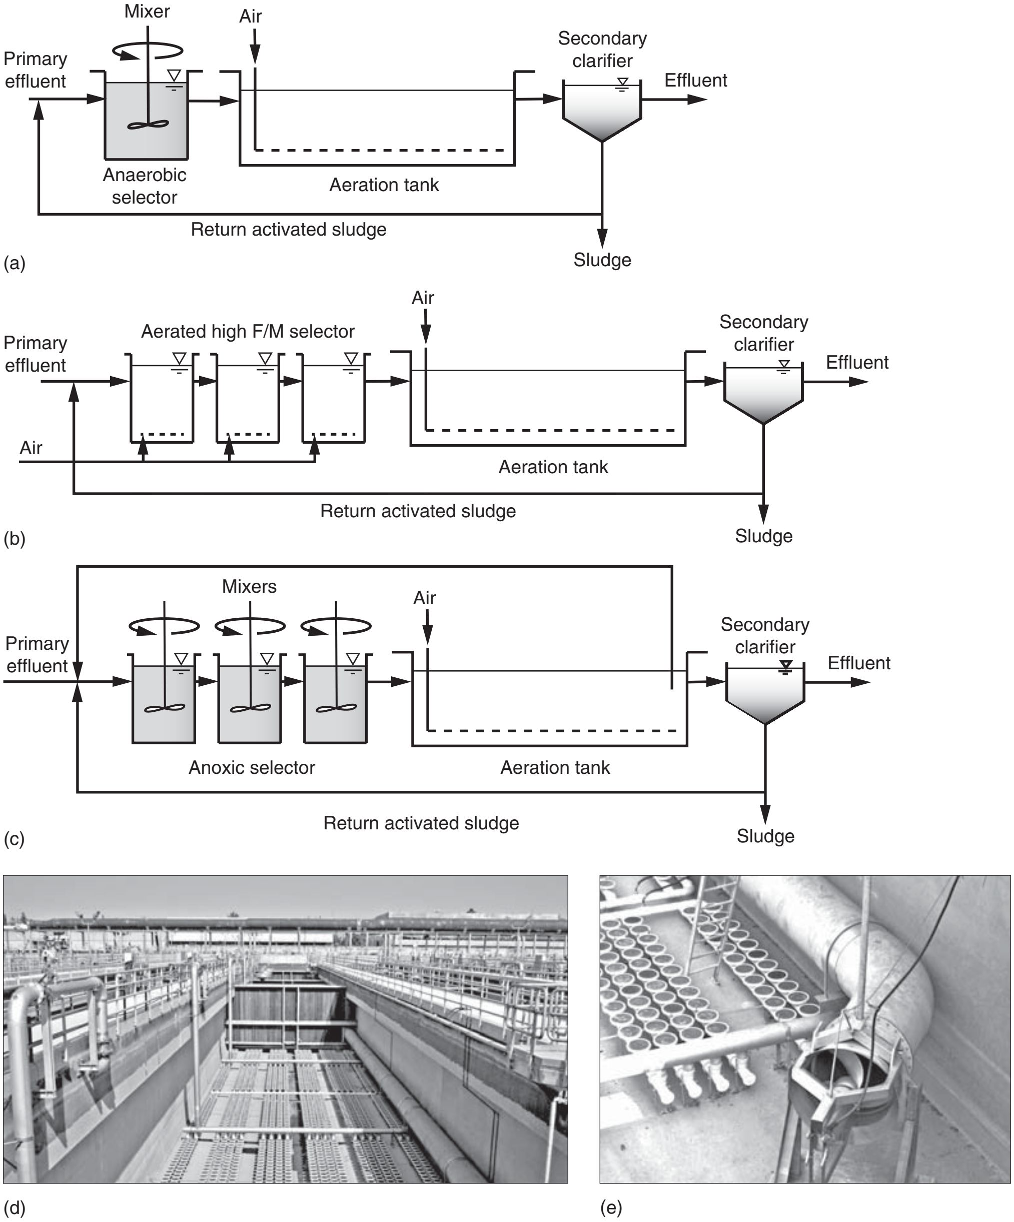


Figure 8–15

Typical selector configurations: (a) anaerobic/aerobic, (b) high F/M, (c) anoxic selector, (d) view of plug-flow reactor (taken from end of aeration tank) with anoxic selectors. The pipe in the bottom right is used to return mixed liquor suspended solids to anoxic selectors as shown in (c) above and (e) axial-flow pump at end of aeration than used to used to pump the return mixed liquor to the anoxic selectors.

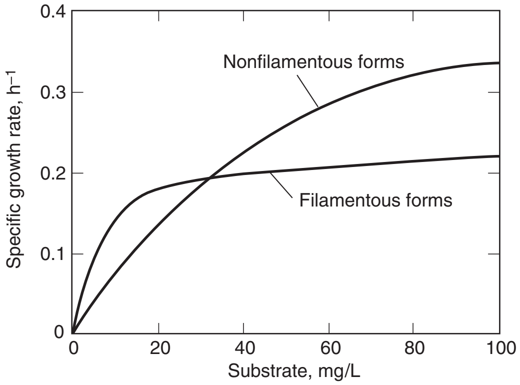

Figure 8–16

Illustration of kinetic base selector model with higher specific growth rate for filamentous bacteria at low substrate concentrations.

The selector reactor precedes the activated sludge aeration tank and may be designed as a separate reaction stage for a complete-mix reactor or as individual compartments in a plug-flow system. Sequencing batch reactors may also be operated to employ the selector concept. The goal in the selector is to have most of the influent rbCOD consumed by the floc-forming bacteria, instead of the filamentous bacteria. Selector designs, as described below, are based on either kinetic or metabolic mechanisms (Albertson, 1987; Jenkins et al., 2004; and Wanner, 1994). The kinetics-based selector designs are called *high F/M selectors*, and the metabolic-based selectors are either anoxic or anaerobic processes.

Kinetics-Based Selector. Selector designs based on a biokinetic model provide for reactor substrate concentrations that result in faster substrate uptake by the floc-forming bacteria. While filamentous bacteria are more efficient for substrate utilization at low substrate concentrations, the floc-forming bacteria have higher growth rates at high soluble substrate concentrations as illustrated on Fig. 8–16. An alternative diffusion mechanism to the kinetic mechanism has been posed and yields the same apparent result on the effect of rbCOD substrate concentration on population selection (Martins et al., 2003). In the diffusion case it is hypothesized that filamentous bacteria selection is related to substrate gradient in the floc and not to differences in biokinetics between filamentous and floc-forming bacteria. At low substrate concentrations the filaments gain an advantage based on their morphology as they can extend from the floc and have easier access to substrate in the bulk liquid. A series of reactors at relatively low τ values (min) is used to provide high soluble substrate concentrations, in contrast to feeding influent wastewater to aeration tanks with τ values on the order of hours.

In kinetic or high F/M selectors, a typical design as shown in Table 8–9 uses at least three reactors in series with the first two of equal volume and the third at twice the volume. The F/M ratio is calculated for the first reactor using the volume and MLSS concentration at that reactor and the influent wastewater flowrate and COD concentration. The F/M

Table 8–9

Design loadings for 3-staged aerobic and anoxic selectors

	Aerobic		Anoxic
Selector zone	F/M, g COD/g MLSS•d	O_2 transfer rate, $gO_2/g•h$	F/M, g COD/g MLSS•d
1	12	15–35	6
2	6	15–35	3
3	3	15–35	1.5

value shown for the second reactor includes the volume of the first and second reactor and the applied loading as the product of the influent flowrate and COD concentration. The amount of oxygen required is about 15 to 25 percent of the soluble COD removal rate (Jenkins et al., 2004) and an oxygen transfer supply rate of 15–20 mg O_2/g mass·h at DO concentrations less than 0.20 mg/L and 30–35 mg O_2/g mass·h at a DO concentration > 1.0 mg/L (Albertson, 1991). The use of selector reactors in series is also advantageous for maximizing rbCOD removal under varying influent flow and loading conditions.

The ability of the high F/M selectors to perform successfully at low or zero DO concentration is due to the fact that a portion of the influent rbCOD is taken up into cell storage due to the elevated substrate concentration (Dionisi et al., 2002). If the loading to the first reactor is too high (F/M $>$ 8 g BOD/g MLSS·d), a viscous, nonfilamentous-type bulking can develop (Albertson, 1987).

A sequencing batch reactor (SBR) can also act as a very effective high F/M selector, depending on the wastewater strength and feeding strategy. For high-strength wastewaters with a relatively large fraction of the SBR volume occupied by the influent wastewater, a high initial F/M ratio can occur. The subsequent reaction by the batch process is equal to that for a plug-flow reactor.

Metabolic-Based Selector. With biological nutrient-removal processes, improved sludge-settling characteristics and minimal filamentous bacteria growth has often been observed. The anoxic or anaerobic metabolic conditions used in these processes favor growth of the floc-forming bacteria. The filamentous bacteria cannot use nitrate or nitrite for an electron acceptor as fast as floc-forming bacteria, thus yielding a significant advantage to denitrifying floc-forming bacteria. Similarly, the filamentous bacteria do not store polyphosphates and thus cannot consume acetate in the anaerobic contact zone in enhanced biological phosphorus removal designs, giving an advantage for substrate uptake and growth to the phosphorus accumulating organisms (PAOs). In some wastewater-treatment facilities (Seattle South Plant and San Francisco, for example), an anaerobic selector has been used for SVI control in low SRT activated sludge systems designed for BOD removal, even though phosphorus removal is not required.

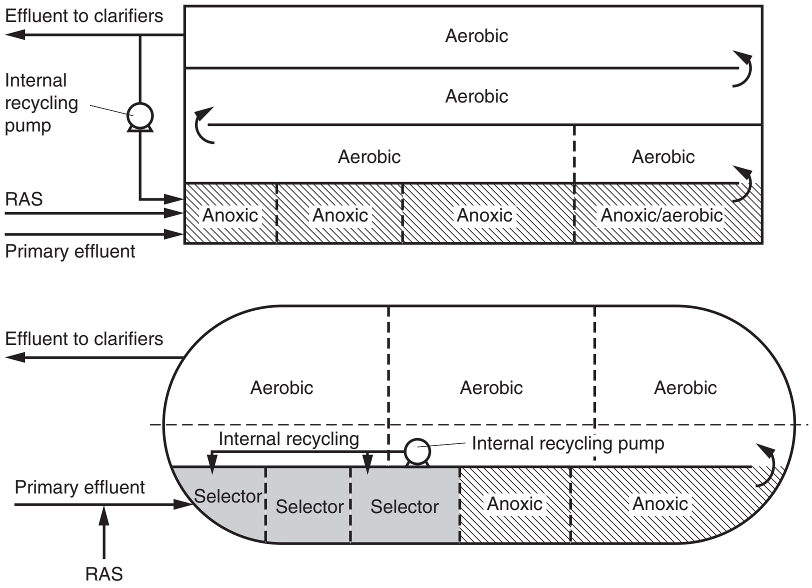
Where nitrification is used and phosphorus removal is not required, staged high F/M gradient or the single-stage anoxic selectors have been used. For the high F/M anoxic or anaerobic selectors, the resultant mixed-liquor SVI may be in the range of 65 to 90 mL/g, and for single-tank anoxic selectors, SVI values in the range of 100 to 120 mL/g are more commonly obtained. Examples of wastewater plant retrofits to anoxic selectors are shown on Fig. 8–17. The use of multiple stages in the aerobic zone in addition to the anoxic zone has been shown to improve sludge settleability with resulting lower SVI values (Albertson 1991, Kruit et al., 2002, and Xin et al., 2008).

Poor Settling Even With Use of Selector

The use of bioselectors has resulted in improved sludge settling characteristics (Albertson 1991, and Parker et al., 2004), but poor settling has also been found on occasion in spite of a bioselector installation. Possible reasons are (1) an inadequate selector design in terms of volume, staging and/or mixing, (2) inadequate aeration or SRT in the downstream aerobic treatment zone, (3) septic influent wastewater with a high sulfide content, and (4) the persistence of certain filamentous organisms that are less impacted by the bioselector design. These include *Microthrix parvicella*, which may be able to take up long chain fatty acids in anoxic zones. *M. parvicella* can be controlled by reducing the aerobic basin SRT, using staged anoxic and aerobic zones, maintaining DO $>$ 2.0 mg/L in the aerobic zones, and eliminating foam-trapping areas (Jenkins et al., 2004).

Figure 8–17

Examples of full-scale wastewater treatment plant modifications to anoxic/aerobic treatment for nitrogen removal with staged anoxic selector zones.



8–5 ACTIVATED SLUDGE PROCESS DESIGN CONSIDERATIONS

Activated sludge design involves performing mass balances on key constituents and the application of fundamental kinetic relationships. These calculations can be done using desktop calculations, spreadsheets and/or computer simulation models. It is common today to use steady-state spreadsheet calculations to aid in the understanding of the process to be designed and to provide a basic starting point in the design to be used in computer simulation models for dynamic process analysis and design optimization. The purpose of this section is to provide a summary of steady-state design approaches and an introduction computer simulation modeling, including common model parameters and reactions and the universal matrix model format that is used to describe reaction components, stoichiometry, and kinetics.

Steady-State Design Approach

The fundamental principles of wastewater characterization, biological treatment and process analysis were presented in Chap. 7 and in Secs. 8–2 and 8–3. The activated sludge system SRT has been presented as a fundamental process parameter that can be used to determine the effluent substrate concentration, sludge wasting rate, and total oxygen demand rate. The principal relationships between SRT and the basic design and performance parameters presented in the previous sections are summarized in Table 8–10, along with equations to determine the aeration tank volume as a function of SRT and MLSS concentration. These equations are appropriate for determining process design and effluent concentrations for steady-state operating conditions at constant flow and influent wastewater constituent concentrations.

Impact of Diurnal Variations in Wastewater Characteristics. As reported in Chap. 3, wastewater flowrates and concentrations are not constant, but vary diurnally. When operating at a given SRT, the effluent substrate concentration will be higher

Table 8–10

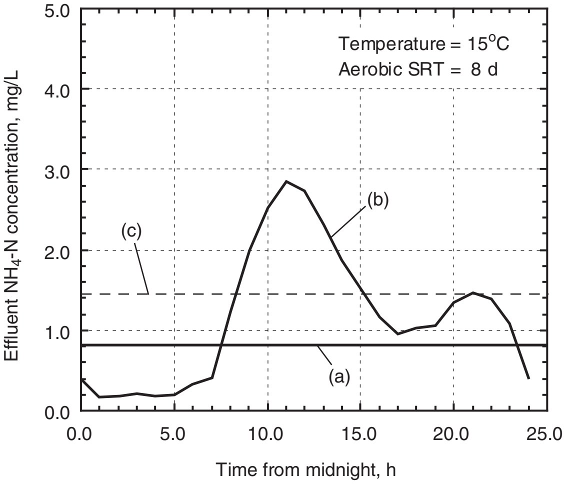
Summary of equations used in the analysis of suspended growth processes

Application	Equation	Eq. No.
Temperature	$k_T = k_{20}\theta^{(T-20)}$	1–44
Rate of sCOD Utilization	$r_{SU} = \dfrac{kXS}{K_S + S}$	7–12
	$\mu_{\max} = Yk$	7–16
Rate of NH_4-N Oxidation	$r_{NH_4} = \left(\dfrac{\mu_{\max,AOB}}{Y_{AOB}}\right)\left(\dfrac{S_{NH_4}}{S_{NH_4} + K_{NH_4}}\right)\left(\dfrac{S_o}{S_o + K_{o,\,AOB}}\right)X_{AOB}$	7–101
Rate of NO_3-N Utilization	$r_{NO_3} = \left(\dfrac{1 - 1.42Y_H}{2.86}\right)\left[\dfrac{\mu_{H,\,\max}S_s}{Y_H(K_s + S_s)}\right]\left(\dfrac{S_{NO_2}}{K_{NO_2} + S_{NO_2}}\right)\left(\dfrac{K'_o}{K'_o + S_o}\right)(\eta)X$	7–133
Specific Growth Rate and SRT	$\mu_{AOB} = \mu_{\max,\,AOB}\left(\dfrac{S_{NH_4}}{S_{NH_4} + K_{NH_4}}\right)\left(\dfrac{S_o}{S_o + K_{o,\,AOB}}\right) - b_{AOB}$	7–94
	$\text{SRT} = \dfrac{1}{\mu_{AOB}}$	7–98
	$\text{SF} = \text{SRT}_{des}/\text{SRT}_{min}$	7–73
Biomass Production, Heterotrophs (VSS)	$P_{X,\,bio} = \dfrac{QY_H(S_o - S)}{1 + b_H(\text{SRT})} + \dfrac{(f_d)(b_H)QY_H(S_o - S)\text{SRT}}{1 + b_H(\text{SRT})}$	8–20 (A+B)
Sludge Production ($P_{x,VSS}$)	$P_{x,VSS} = P_{X,bio} + \dfrac{QY_n(NO_X)}{1 + b_n(SRT)} + Q(\text{nbVSS})$	8–20
Sludge Production ($P_{x,TSS}$)	$P_{x,TSS} = \dfrac{P_{X,bio}}{0.85} + \dfrac{QY_n(NO_X)}{0.85[1 + b_n(\text{SRT})]} + Q(\text{nbVSS}) + Q(\text{TSS}_o - VSS_o)$	8–21
Reactor Mass and Volume	$Mass = X_{VSS}(V) = (P_{X,VSS})\text{SRT}$	7–56
	$Mass = X_{TSS}(V) = (P_{X,TSS})\text{SRT}$	7–57
SRT	$\text{SRT} = \dfrac{VX}{(Q - Q_w)X_e + Q_wX_R}$	8–27
	$\text{SRT} = \dfrac{V}{Q_w}$	8–31
	$\text{SRT} = \dfrac{\left(\dfrac{R}{1 + R}\right)V_A + V_M}{Q_w}$	8–36
CMAS Effluent bsCOD	$S = \dfrac{K_s[1 + b_H(\text{SRT})]}{\text{SRT}(Y_Hk - b_H) - 1}$	7–46
CMAS Biomass	$X = \left(\dfrac{\text{SRT}}{\tau}\right)\left[\dfrac{Y_H(S_o - S)}{1 + b_H(\text{SRT})}\right]$	7–42
CMAS Oxygen Req'd	$R_o = Q(S_o - S) - 1.42P_{x,bio} + 4.57Q(NO_X)$	8–23
Ammonia oxidized	$NO_X = \text{TKN} - N_e - 0.12P_{x,\,bio}/Q$	8–24
Stage Reactor Oxygen Req'd	$R_{o,2} = (Q_1)(1 - Y_H)[(S_{s,1} - S_{s,2}) + (X_{s,1} - X_{s,2})] + (Q_1)4.57(NO_2 - NO_1) + 1.42b_H(X_{b,2})V_2$	8–25
Food to Mass Ratio	$F/M = \dfrac{QS_o}{VX}$	7–62
Organic Loading	$L_{org} = \dfrac{(Q)(S_o)}{(V)}$	7–69

All terms as defined previously.

Figure 8–18

Comparison of effluent NH_4-N concentrations from nitrification activated sludge systems operated at the same temperature and SRT with the same average influent flowrate and TKN loading: (a) effluent NH_4-N concentration with constant influent conditions, (b) effluent NH_4-N concentration versus time with diurnal variations in influent flowrate and concentration, and (c) value of the 24-h composite NH_4-N concentration with diurnal variations in influent flowrate and concentration.



at the higher loading periods and lower at the lower loading periods. An example of the effect of diurnal load variations on effluent NH_4-N concentrations for a nitrification activated sludge process operated with an 8-d aerobic SRT and 15°C temperature is illustrated on Fig. 8–18. The average influent BOD and TKN concentrations used for calculations in this example are 220 mg/L and 35 mg/L, respectively. Assuming constant flow and loadings, the steady state effluent NH_4-N concentration, calculated using Eqs. (7–94) and (7–98), is 0.82 mg/L. The diurnal load was based on the diurnal flowrate and BOD variations for domestic wastewater shown on Fig. 3–11. Using the same kinetic parameters and coefficient values in a dynamic simulation model, the effluent NH_4-N concentration will vary from 0.2 to 2.8 mg/L over the 24 h period, and the flow-weighted composite effluent NH_4-N concentration is 1.45 mg/L. To assure that the daily composite effluent sample substrate concentration is at or below the desired design value, the design SRT that yields the target steady state effluent substrate concentration is multiplied by a design safety factor (typically 1.3 to 1.5 for domestic wastewater treatment) so that a sufficient biomass is available to handle the higher loadings.

Impact of Using Staged Reactors. Use of steady-state equations is satisfactory for the design of completely mixed activated sludge (CMAS) processes, but is not used as easily to determine substrate concentrations and oxygen demand rates in each stage of activated sludge process designs with multiple reactors in series. Staged reactors are common for biological nutrient removal and nitrification process designs. As indicated on Fig. 8–8(b), the bsCOD and pbCOD concentrations vary from stage to stage and accordingly their degradation rates vary. The necessary calculations of process behavior under varying load conditions for single-stage CMAS systems or CSTRs in series, including aerobic, anoxic, and anaerobic conditions, can be accomplished more readily with computer simulation models.

Use of Simulation Models

Simulation models can be used to account for the kinetics and changes in constituent concentrations in each mixed tank of an activated sludge process. Computer modeling provides the tool to incorporate the large number of components and reactions to evaluate activated sludge performance under both dynamic and steady-state conditions, and to easily design multiple-staged processes as well as single-stage complete-mix processes.

Historical Development of Activated Sludge Model. The development of the first comprehensive activated sludge model (ASM1) by the International Water Association (IWA) task group (Henze et al., 1987) was a major step forward in the use of computer simulation models for activated sludge process analysis and design. Limited to carbon oxidation, nitrification and denitrification, the ASM1 model was followed by the ASM2 and ASM2d models, which included fermentation, enhanced biological phosphorus removal, and chemical phosphorus removal (Henze et al., 1995, Barker and Dold, 1997). Further model structure modifications have been made in ASM3 (Gujer et al., 1999, and Henze et al., 2000). Commercial software packages that include these models are used commonly by wastewater process engineers for the process design of different activated sludge system configurations.

General Model Characteristics. The components included in activated sludge simulation models are termed *state variables.* The principal components are summarized in Table 8–11 along with brief descriptions of the types of reactions causing their production or depletion. Activated sludge process models used today are much more complex and now include BOD removal, nitrification, denitrification, and phosphorus removal. The reactions involved in these processes are carried out by different types of bacteria that include a mixture of heterotrophic bacteria that are phosphorus-storing and non-phosphorus-storing, and among these, bacteria that can and cannot use nitrate as an electron acceptor, as well as autotrophic nitrifying bacteria. The impact of wastewater components such as fermentable soluble COD, acetate, biodegradable particulate COD, inert particulate and soluble COD, inorganic nitrogen, and soluble phosphorus on oxygen consumption and sludge production rates are now included.

Important Model Features. The models are based on growth as opposed to substrate utilization. Monod specific growth rate kinetics are used to model the growth of autotrophic or heterotrophic bacteria. Substrate, oxygen, and nutrient utilization rates are related to the growth rates by stoichiometric factors. Another important feature of the models is that COD is used as the common measure of organic substrate and biomass so that a COD balance exists for substrate utilization, biomass growth, and oxygen consumption. The models also use the lysis-regrowth model for endogenous respiration instead of a net endogenous decay coefficient as presented in this chapter for activated sludge design. In the lysis-regrowth model, endogenous decay results in the release of biomass particulate material, some of which is biodegradable and is hydrolyzed to provide a source of rbCOD. Another portion remains as cell debris, similar to what has been incorporated for endogenous respiration in the activated sludge design model presented in this chapter. To compute the same amount of sludge production as the endogenous respiration model, the decay coefficient value in the lysis-regrowth model is higher.

Inclusion of Nitrite. The ASM1, ASM2, ASM2d, and ASM3 models do not include nitrite as a state variable, because most of the ammonia oxidized in many activated sludge processes is complete to nitrate with very little nitrite present. However, nitrite is included in many simulation models today because it may represent an important fraction of ammonia oxidation under certain process conditions, including higher temperatures (>25°C), the initial stages of a multi-staged nitrification system, and low dissolved oxygen concentration.

Matrix Model Format. A long list of complex equations would be needed to describe the various reactions in an activated sludge process involving numerous components such as organic substrates (soluble and particulate), inorganic substrates (ammonia, nitrate, and

Table 8–11

Key process components in ASM2d and types of reactions affecting their reactor concentration

		Reactions or input	
Model component	**Symbol**	**Production or input**	**Depletion**
Dissolved O_2	S_{O_2}	• Influent wastewater • Aeration	• Consumption by X_H, X_{AUT}, X_{PAO}
rbCOD	S_F	• Influent wastewater • Hydrolysis of X_S	• Biodegradation by X_H • Fermentation by X_H
Acetate	S_A	• Influent WWT • Fermentation of S_F	• Uptake by X_{PAO} • Biodegradation by X_H
Ammonia	S_{NH_4}	• Influent wastewater • Hydrolysis of organic N • Hydrolysis of cell decay products	• Oxidation by autotrophic bacteria (X_{AUT}) • Synthesis uptake by X_H, X_{AUT}, X_{PAO}
Nitrate	S_{NO_3}	• Oxidation of S_{NH_4} by X_{AUT}	• Synthesis
Phosphorus	S_{PO_4}	• Influent wastewater • Hydrolysis of organics	• Synthesis uptake by X_H, X_{AUT}, X_{PAO} • Anoxic and aerobic uptake by X_{PAO}
Alkalinity	S_{ALK}	• Influent wastewater • During biological reduction of S_{NO_3}	• During S_{NH4} oxidation by X_{AUT}
Biodegradable particulate COD	X_I	• Influent wastewater • Cell decay	
Slowly biodegradable COD	X_S	• Influent wastewater • Cell decay	• Hydrolysis by X_H
Ordinary heterotrophs	X_H	• Growth from S_F, S_A	• Cell decay
Phosphorus accumulating heterotrophs	X_{PAO}	• Growth from using X_{PHA}	• Cell decay
Stored PHA	X_{PHA}	• Production in anaerobic zone by X_{PAO} from S_A	• Biodegradation by X_{PAO} in aerobic and anoxic zones
Stored polyphosphate	X_{PP}	• During oxidation of X_{PHA}	• Release in anaerobic conditions by X_{PAO}
Ammonia oxidizing bacteria	X_{AUT}	• Growth during S_{NH_4} oxidation	• Cell decay

phosphorus), dissolved oxygen, and various heterotrophic and autotrophic bacteria. Instead of presenting the model in terms of numerous equations, a more general matrix model approach has been adopted. Process reactions and the stoichiometric factors that link the components to the various reactions are presented in a matrix model format. The advantage of the matrix format is that a relatively simple, concise format can be used to describe the process. The purpose of this section is to provide a basic introduction to the matrix model approach showing the components, reactions, and stoichiometric coefficients for the activated sludge process model and how the matrix format can be used to describe the process. In addition, the approach can also be used to illustrate how the matrix model can be interpreted to describe a complete set of equations for a given process component. For example, the Activated Sludge Model No. 2 (ASM2d) (Henze et al., 1995) is used to describe basic features of a comprehensive activated sludge model.

Model Matrix Format, Components, and Reactions

A convenient matrix format is used to describe the model without having to present the large number of equations involved. The ASM2d model includes 19 components and accounts for 21 process reactions. Some of the component and reaction terms are described here to illustrate the basic model format.

Process Reactions and Stoichiometric Coefficients. Fourteen key components related to the biological processes are described in Table 8–11. An example of some of the process reactions and the corresponding stoichiometric rate coefficients are given in Tables 8–12 and 8–13, respectively. The stoichiometric coefficients are used to relate

Simultaneous precipitation of phosphorus with ferric hydroxide.

changes in model components to the growth rate. The process reactions in ASM2d are divided into the following five groups dealing with:

- Hydrolysis processes
- Heterotrophic organisms (including aerobic oxidation, denitrification, fermentation, and cell lysis)
- Phosphorus accumulation organisms
- Ammonia oxidizing organisms
- Simultaneous precipitation of phosphorus with ferric hydroxide

For simplicity, the process equations related to enhanced biological phosphorus removal including a description of PHA and phosphorus storage under anaerobic, anoxic, and aerobic conditions; phosphorus accumulating organism (X_{PAO}) growth under anoxic and aerobic conditions; and X_{PAO} cell lysis and release of phosphorus and PHA are not shown in Table 8–12.

For example, as given in Table 8–12, the change in the heterotrophic bacteria (X_H) concentration is related to process reactions 4, 5, 6, 7, and 9. The term η represents the fraction of heterotrophic bacteria that can use nitrate in place of dissolved oxygen.

The corresponding stoichiometric rate coefficients for these biomass growth reactions are 1, 1, 1, 1 as given in Table 8–13. For cell decay, the death-lysis model is used, which is given by process reactions 9 and 19 for heterotrophic and autotrophic bacteria, respectively (see Table 8–12). The cell debris material produced during biomass decay is indicated by X_I and the production of degradable particulate substrate (X_s) is indicated by a stoichiometric coefficient ($1 - f_{XI}$). The hydrolysis of the particulate organic substrates under either aerobic or anoxic conditions is described by processes 1 and 2, respectively.

Rate Expressions. The rate expression for each component for a specific reaction is the product of the stoichiometric coefficient given in Table 8–13 and the corresponding process reaction given in Table 8–12. An equation for each component (e.g., S_F, S_A, etc.) can be written by summing the product of the stoichiometric coefficients given in Table 8–13 for that term times the corresponding rate expressions given in Table 8–12. The summation rate equation is:,

$$R_C = \sum_{i=1}^{n} C_i(j_i) \tag{8–44}$$

where R_C = rate of change for the process component C (e.g., S_F, S_A, X_I, X_S, etc.)
C_i = stoichiometric coefficient for component C, reaction i
j_i = rate reaction i

For example, for component S_A under aerobic growth (reaction 5, Table 8–12), the stoichiometric coefficient from Table 8–13 is $-(1/Y_H)$. Thus, under aerobic conditions, the rate of change of S_A is given by the following expression:

$$R_{S_A} = -\frac{1}{Y_H}\mu_H\left(\frac{S_{O_2}}{K_{O_2} + S_{O_2}}\right)\left(\frac{S_A}{K_A + S_A}\right)\left(\frac{S_A}{S_A + S_F}\right)(\text{Growth}_{\text{Lim}})(X_H) \tag{8–45}$$

$$\text{where Growth}_{\text{Lim}} = \left(\frac{S_{NH_4}}{K_{NH_4} + S_{NH_4}}\right)\left(\frac{S_{PO_4}}{K_{PO_4} + S_{PO_4}}\right)\left(\frac{S_{ALK}}{K_{ALK} + S_{ALK}}\right)$$

The stoichiometric coefficients for oxygen consumption are described as follows: for heterotrophic growth, the term $(1 - Y_H)$ is the g O_2 used/g COD removed. The term $(1 - Y_H)$ is divided by Y_H (g cell COD/g COD used) to obtain the stoichiometric coefficient as g O_2/g cell COD produced to fit to the matrix format. The stoichiometric term for autotrophic growth contains the factor 4.57. The term is required because ammonia, the substrate for the nitrifying bacteria, is expressed as nitrogen in the matrix S_{NH}, and oxygen is expressed as COD. The oxygen equivalent for ammonia is 4.57 g O_2/g NH_4-N. The amount in the numerator is lower by Y_A, which accounts for the ammonia used in cell synthesis. Application of Eqs. (8–44) and (8–45) is demonstrated in Example 8–2. It is intended to illustrate how the model matrix is interpreted to describe the rate of concentration change of a model component.

Example 8–2 **Apply ASM2d Model Matrix** Use the ASM2d model matrix to describe the concentration of the readily biodegradable COD component, S_F, due to nonphosphorus accumulating heterotrophic bacteria in reactor number 2 of the staged reactor shown on Fig 8-8(b). Substitute $S_F + S_A$ for S_s in figure for the rbCOD components. For simplicity in demonstrating the use of the matrix information the PAO reactions are not included here.

Solution

1. Develop mass balance equation for S_F and S_A for reactor 2.
   a. The general word statement is

      Rate of change = rate in − rate out + rate of production + rate of depletion

   b. Write the symbolic representation.
      i. The incoming and outgoing mass of S_F with the flow is $(Q + Q_R)\,S_{F,1}$, and $(Q + Q_R)\,S_{F,2}$ expressed in g/d, respectively.
      ii. The rate of production of S_F due to aerobic and anoxic hydrolysis, given by reactions 1 and 2 in Table 8–12, can be represented as R_1 and R_2, respectively.
      iii. The rate of depletion of S_F due to aerobic and anoxic growth, given by reactions 4 and 6 in Table 8–12, can be represented as R_4 and R_6, respectively.
      iv. Substituting the terms given above in the mass balance equation yields the following expression

$$V_2\frac{dS_{F2}}{dt} = (Q + Q_R)S_{F,1} - (Q + Q_R)S_{F,2} + R_1V_2 + R_2V_2 + R_6V_2$$

2. Write the mass balance equation with the appropriate rate expressions including the process reactions from Table 8–12 and the corresponding stoichiometric coefficients from Table 8–13. For example, the rate expression for aerobic hydrolysis, R_1, for component S_F (rbCOD) is:

$$R_1 = 1 \times K_h\left(\frac{S_{\mathrm{O_2}}}{K_{\mathrm{O_2}} + S_{\mathrm{O_2}}}\right)\left[\frac{X_{\mathrm{S},2}/X_{\mathrm{H},2}}{K_X + (X_{\mathrm{S},2}/X_{\mathrm{H},2})}\right]X_{\mathrm{H},2}$$

   Thus, the mass balance S_A for the reactor 2 can be expressed as:

$$\begin{aligned}
V_2\frac{dS_{\mathrm{F},2}}{dt} &= (Q + Q_R)S_{\mathrm{F},1} - (Q + Q_R)S_{\mathrm{F},2} \\
&\quad + K_h\left(\frac{S_{\mathrm{O_2},2}}{K_{\mathrm{O_2}} + S_{\mathrm{O_2},2}}\right)\left[\frac{X_{\mathrm{S},2}/X_{\mathrm{H},2}}{K_X + (X_{\mathrm{S},2}/X_{\mathrm{H},2})}\right]X_{\mathrm{H},2}(V_2) \\
&\quad + K_h\left(\frac{K'_{\mathrm{O_2}}}{K'_{\mathrm{O_2}} + S_{\mathrm{O_2}}}\right)\left(\frac{S_{\mathrm{NO_3}}}{K_{\mathrm{NO_3}} + S_{\mathrm{NO_3}}}\right)\left[\frac{X_{\mathrm{S},2}/X_{\mathrm{H},2}}{K_X + (X_{\mathrm{S},2}/X_{\mathrm{H},2})}\right](\eta_{\mathrm{NO_3}})X_{\mathrm{H},2}(V_2) \\
&\quad + \left(\frac{-1}{Y_H}\right)\mu_H\left(\frac{S_{\mathrm{O_2},2}}{K_{\mathrm{O_2}} + S_{\mathrm{O_2},2}}\right)\left(\frac{S_{\mathrm{F},2}}{K_{\mathrm{F}} + S_{\mathrm{F},2}}\right)\left(\frac{S_{\mathrm{F},2}}{S_{\mathrm{A},2} + S_{\mathrm{F},2}}\right)(\mathrm{Growth}_{\mathrm{Lim},2})(X_{\mathrm{H},2})(V_2) \\
&\quad + \left(\frac{-1}{Y_{\mathrm{H}}}\right)\mu_H(\eta_{\mathrm{NO_3}})\left(\frac{K'_{\mathrm{O_2}}}{K'_{\mathrm{O_2}} + S_{\mathrm{O_2},2}}\right)\left(\frac{S_{\mathrm{NO_2},2}}{K_{\mathrm{NO_3}} + S_{\mathrm{NO_3},2}}\right)\left(\frac{S_{\mathrm{F},2}}{K_{\mathrm{F}} + S_{\mathrm{F},2}}\right)\left(\frac{S_{\mathrm{F},2}}{S_{\mathrm{A},2} + S_{\mathrm{F},2}}\right) \\
&\quad (\mathrm{Growth}_{\mathrm{Lim},2})(X_{\mathrm{H},2})(V_2)
\end{aligned}$$

Comment The solution for S_{F} depends on the concentrations of (1) non-PAO heterotrophic bacteria, (2) slowly biodegradable COD, $\mathrm{X_s}$, (3) dissolved oxygen, (4) nitrate-nitrogen, (5) acetate COD, S_{A}, (6) ammonia-nitrogen, (7) phosphate, and (8) alkalinity. Similar sets of equations can be provided for these components using the matrix information shown in Table 8–13.

Other Simulation Model Applications

In addition to process design and analysis, models may be used as (1) a research tool to evaluate biological processes and to better understand important parameters that affect a certain type of performance, and (2) as a means to evaluate the treatment capacity of a given facility. For item 2, the availability of accurate and representative wastewater characterization data is critical where dynamic simulations are used assess the effect of variable flow and concentrations with time.
