Evaluation of Plant Capacity. To evaluate the capacity of an existing plant, the model is calibrated using wastewater characterization and plant performance data. Calibrations based only on comparing the model predictions to the plant effluent concentration are not necessarily valid. Low effluent concentrations normally exist for all soluble degradable components, and thus the ability of the model to predict the plant performance is clouded by analytical accuracy and practical considerations. Intermediate soluble substrate concentrations from aerobic stages and/or anoxic and anaerobic stages provide a more reliable indication of the ability to describe the kinetics for the site. Oxygen uptake rate data are more meaningful for model calibration, as the data reflect different factors in the model including kinetic rates for different reactions and stoichiometric ratios for cell yield and decay. Oxygen uptake rate data for staged systems are valuable for model calibration. Nitrification rates and sludge production rates are also important parameters for model calibration.

Use of Model Default Values. Default values for 45 kinetic parameters in ASM2d have been selected and are summarized in the model report (Henze et al., 1995). Using these values does not ensure that the model can be used to predict the performance of an activated sludge process accurately, as some of the coefficient values can be different at different sites. One of the parameters found to vary the most at different sites and often adjusted during model calibration is the maximum specific growth rate of nitrifying bacteria μ_{AUT}. Variations in nitrification kinetics may be due to differences in wastewater characteristics, population selection, and inhibitors on nitrification or may also reflect other kinetic changes for which μ_{AUT} adjustments improve the overall fit.

Evaluation of Different Process Configuration. Process design engineers can take advantage of the powerful tool provided by simulation models to study various design configurations and possible operating conditions on expected system performance. Because the selection of process reaction equations and coefficient values used in different commercial software packages varies, the design engineer must be familiar with all model assumptions and model structure. Simple desktop designs, as will be presented in the next three sections, can be used to obtain reactor sizing and configuration for use in the simulation models and to also gain a sense for the expected results as a function of SRT, number of stages, DO conditions, and recycle streams. At a minimum the designer should be comfortable with the oxygen demand rates and sludge production rates predicted by the simulation models relative to alternate calculation methods.

Recent Simulation Models. The model presented in this section is consistent with ASM2d, but the latest commercial computer simulation models apply additional process models that are not included in ASM2d or ASM3. For example, ammonium oxidation to nitrite and nitrite oxidation to nitrate is not separated in the activated sludge models discussed above. In most commercial computer simulation programs, these two reactions are treated separately to describe more accurately the nitrogen removal processes, and also allow a modeling of nitritation/denitritation. Models for deammonification have also been developed and used by computer modeling programs.

8–6 PROCESSES FOR BOD REMOVAL AND NITRIFICATION

Important considerations for the design of activated sludge processes were presented in Secs. 8–3, 8–4, and 8–5. The purpose of this section is to illustrate in detail the design procedure for three common but different activated sludge processes for BOD removal and nitrification. The objective of the three different activated sludge process design examples presented in this section is to demonstrate the application of the fundamental principles discussed previously for BOD removal and nitrification processes and to provide insight into their behavior along with key design features. The material in this section is organized into the following topics: (1) overview of BOD removal and nitrification processes, (2) general process design considerations, (3), (4), (5) process designs for three different activated sludge processes, and (6) a summary of alternative processes used for BOD removal and nitrification, typical process design parameters, and process selection considerations. Biological nitrogen and phosphorus removal can be incorporated into most of the processes used for BOD removal and nitrification, but because additional design factors must be considered, nitrogen and phosphorus removal processes are covered separately in Secs. 8–7 and 8–8, respectively. Details for the selection and design of physical facilities may be found in Secs. 8–9, 8–11, and 8–12.

Overview of BOD Removal and Nitrification Processes

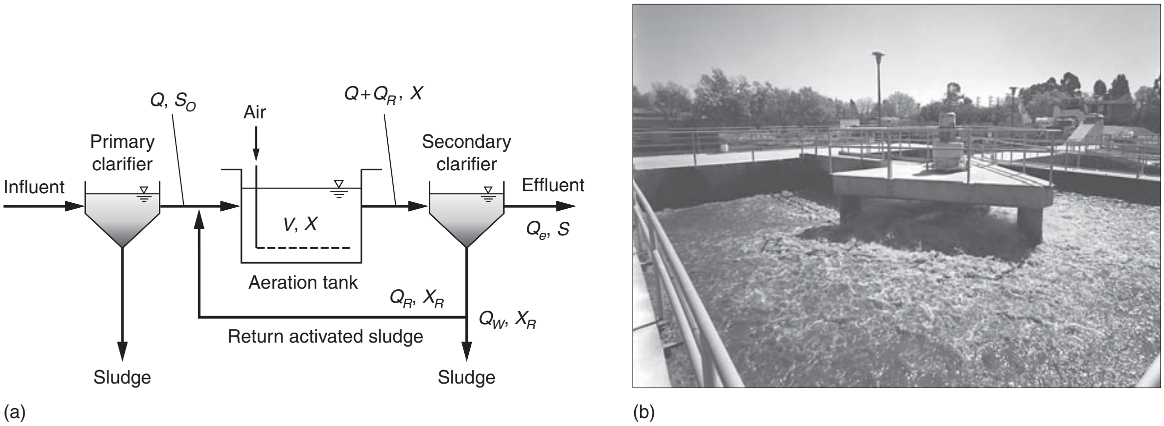
All of the considerations involved in BOD removal and nitrification process design can be applied to a BOD removal-only design by modifying the SRT and removing items that deal with nitrification. The design methodology presented is based fundamentally on using appropriate SRT values, and thus can be applied to the broad range of processes described at the end of this section. As an introduction to BOD removal and nitrification, descriptions of the following three process configurations that are used most commonly are presented below.

1. A complete-mix activated sludge process without and with nitrification
2. A sequencing batch reactor (SBR) with nitrification
3. A multi-staged nitrification process.

Each of these process configurations is considered in the following discussion.

Complete-Mix Activated Sludge Process. A typical complete-mix activated sludge (CMAS) process is shown on Fig. 8–19. Effluent from the primary sedimentation tank and recycled return activated sludge are introduced typically at several points in the reactor. Because the tank contents are mixed thoroughly, the organic load, oxygen demand, and substrate concentration are uniform throughout the entire aeration tank and the F/M ratio is low. Care should be taken to assure that the contents of CMAS reactor are well mixed and that influent feed and effluent withdrawal points are selected to prevent short-circuiting of untreated or partially treated wastewater. The complete-mix reactor is usually configured in square, rectangular, or round shapes. Tank dimensions depend mainly on the size, type, and mixing pattern of the aeration equipment.

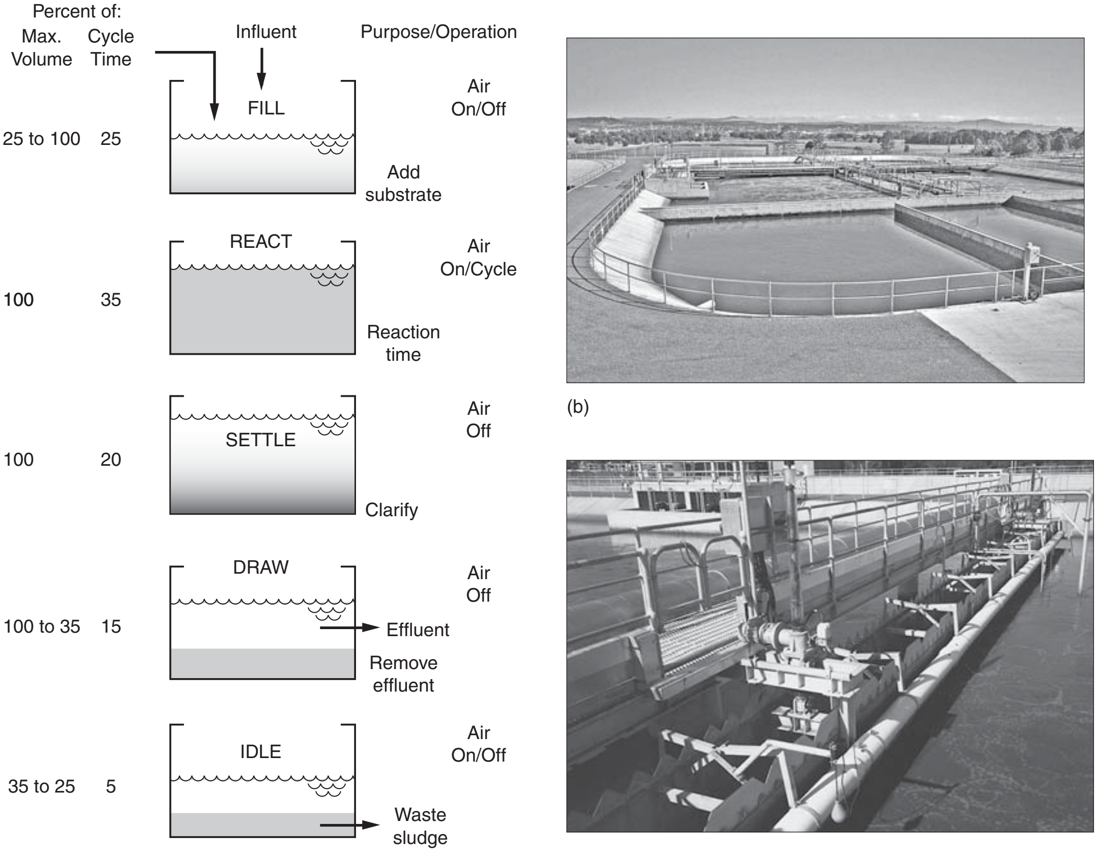
Sequencing Batch Reactor Process. The sequencing batch reactor (SBR) process utilizes a fill-and-draw reactor with complete mixing during the batch reaction step (after filling) and where the subsequent steps of aeration and clarification occur in the same tank. All SBR systems have five steps in common, carried out in following sequence: (1) fill, (2) react (aeration), (3) settle (sedimentation/clarification), (4) draw (decant), and (5) idle. Each of these steps is illustrated on Fig. 8–20 and described later in Table 8–16 on page 771. For continuous-flow applications, at least two SBR tanks must be provided so that one tank receives flow



(a) (b)

Figure 8–19

Complete-mix activated sludge process: (a) schematic diagram and (b) view of a typical complete-mix reactor.



(a) (b) (c)

Figure 8–20

Sequencing batch reactor (SBR) activated sludge process: (a) schematic diagram and (b) view of a typical SBR reactor and a view of movable weir used to decant supernatant after settling period in SBR reactor. Weir is located on the far side of the second dividing wall shown in (c). Photographs were taken in Australia.

while the other completes its treatment cycle. Several process modifications have been made in the times associated with each step to achieve nitrogen and phosphorus removal.

Staged Activated Sludge Process. Activated sludge processes can be designed with baffle walls to intentionally create a number of complete-mix activated sludge zones operating in series (see Fig. 8–22 on page 782). Long, narrow aeration tanks referred to as plug flow activated sludge systems may also have 3 to 4 effective stages depending on the tank layout and aeration mixing characteristics. For the same total reactor volume, a system with reactors in series can provide greater treatment efficiency than a single complete-mix reactor, or provide a greater treatment capacity. As a consequence, staged activated sludge process configurations are used for aerobic nitrification and anoxic zone designs at many full-scale installations.

General Process Design Considerations

The fundamental principles of wastewater characterization, biological treatment, and process analysis were presented in Chap. 7 and in Secs. 8–2 and 8–3. For wastewater characterization, bCOD, TKN, rbCOD and nbVSS are of greatest significance in process design. For BOD removal and nitrification processes, the wastewater bCOD and TKN concentration, and activated sludge temperature and aerobic SRT are important for determining the oxygen demand rate. The rbCOD, TKN, and NH_4-N concentrations are important for evaluating the oxygen demand profiles for plug-flow, staged, and batch-fed processes. The influent bCOD and nbVSS concentrations affect the process sludge production and aeration tank volume requirements. Design and operating issues specific to each of the three activated sludge process configurations considered in the overview are addressed separately.

Process Kinetics for BOD Removal. For general design purposes, kinetic expressions used for design are summarized in Table 8–10. Kinetic coefficients for the removal of carbonaceous material (based on bCOD) by heterotrophic bacteria and ammonia and nitrite oxidation by autotrophic bacteria are given in Table 8–14. Values for many of these coefficients vary widely in the literature. The values provided are those used most commonly and that also provide some degree of conservatism for the design. The values for the heterotrophic organism are essentially the same as the default values used in the IWA ASM2d model (Henze et al., 1995). Nitrification kinetics values are based, for the most part, on nitrification kinetics derived from a Water Environment Research Foundation study on parameters for activated sludge modeling (Melcer et al., 2003).

Process Kinetics for Nitrification. The nitrification kinetic values for K_{O_2}, K_{NH_4}, and μ_{max}, as discussed in Sec. 7–9 in Chap. 7, can vary with the nitrifying bacteria population selection due to the reactor configuration and operating conditions. The half-velocity coefficient for DO (K_{O_2}) is also site specific, as it is dependent on the activated sludge reactor MLSS concentration, mixing conditions, volumetric oxygen uptake rate, and floc size. Where industrial wastewater is present in the WWTP influent, the potential for nitrification inhibition must be considered. Sampling and bench scale testing should be considered in such cases to assure that expected nitrification rates can be obtained. The SRT and aeration tank volume requirements are related directly to nitrification μ_{max} values. Source control measures may be required to mitigate nitrification inhibition.

Complete-Mix Activated Sludge Process Design

In the computational approach used in the design of the activated sludge process, as outlined in Table 8–15, use is made of the design equations presented previously in Chap. 7

Table 8–14

Activated sludge design kinetic coefficients for BOD removal and nitrification at 20°C

Coefficient	Unit	COD oxidation[a]	NH_4 oxidation[b]	NO_2 oxidation[b]
μ_{max}	g VSS/g VSS·d	6.0	0.90	1.0
K_s, K_{NH_4}, K_{NO_2}	mg/L	8.0	0.50	0.20
Y	g VSS/g substrate oxidized	0.45	0.15	0.05
b	g VSS/g VSS·d	0.12	0.17	0.17
f_d	unitless	0.15	0.15	0.15
K_{o_2}	mg/L	0.20	0.50	0.90
θ Value				
μ_{max}	unitless	1.07	1.072	1.063
b	unitless	1.04	1.029	1.029
K_s, K_{NH4}, K_{NO2}	unitless	1.0	1.0	1.0

Table 8–15

Computation approach for the design of the activated sludge process

1. Obtain influent wastewater characterization data.
2. Determine the effluent requirements in terms of NH_4-N, TSS, and BOD concentrations.
3. Select an appropriate nitrification safety factor for the design SRT based on expected peak/average TKN loadings. Safety factors may vary from 1.3 to 2.0.
4. Select the minimum DO concentration for the aeration basin mixed liquor. A minimum DO concentration of 2.0 mg/L is recommended for nitrification.
5. Determine the nitrification maximum specific growth rate (μ_{max}) based on the aeration basin temperature and DO concentration, and determine K_n.
6. Determine the net specific growth rate μ and SRT at this growth rate, to meet the effluent NH_4-N concentration.
7. Obtain the design SRT by applying the safety factor to Step 6.
8. Determine the biomass production.
9. Perform a nitrogen balance to determine NO_X, the concentration of NH_4-N oxidized.
10. Calculate the VSS mass and TSS mass for the aeration basin.
11. Select a design MLSS concentration and determine the aeration basin volume and hydraulic residence time.
12. Determine the overall sludge production and observed yield.
13. Calculate the oxygen demand.
14. Design the aeration oxygen transfer system.
15. Determine if alkalinity addition is needed.
16. Design the secondary clarifier.
17. Summarize the final effluent quality.
18. Prepare a design summary table.

and in Secs. 8–2 and 8–3, as summarized in Table 8–10. The application of the design approach is presented in Example 8–3. The key elements of process analysis are selection of the design SRT, selection of kinetic and stoichiometric coefficients, and application of appropriate mass balances.

Example 8–3 **Complete-mix Activated Sludge Process Design for BOD Removal Only and for BOD Removal with Nitrification** Prepare a process design for a complete-mix activated sludge (CMAS) system to treat 22,700 m^3/d of primary effluent (including recycle flows) to (a) meet a BOD_e concentration less than 30 g/m^3 and (b) accomplish BOD removal and nitrification with an effluent NH_4-N concentration of 0.50 g/m^3 and BOD_e and $TSS_e \leq 15\ g/m^3$. Compare the two design conditions in a summary table. The aeration basin mixed-liquor temperature is 12°C.

The following wastewater characteristics and design conditions apply:

Wastewater characteristics:

Constituent	Concentration, mg/L
BOD	140
sBOD	70
COD	300
sCOD	132
rbCOD	80
TSS	70
VSS	60
TKN	35
NH_4-N	25
TP	6
Alkalinity	140 as $CaCO_3$
bCOD/BOD ratio	1.6

Note: g/m^3 = mg/L.

Design conditions and assumptions:

1. Fine bubble membrane diffusers with an aeration clean water O_2 transfer efficiency = 35%
2. Liquid depth for the aeration basin = 4.9 m
3. The point of air release for the ceramic diffusers is 0.5 m above the tank bottom
4. DO in aeration basin = 2.0 g/m^3
5. Site elevation is 500 m (pressure = 95.6 kPa)
6. Aeration α factor = 0.50 for BOD removal only and 0.65 for nitrification; β = 0.95 for both conditions, and diffuser fouling factor F = 0.90
7. Use kinetic coefficients given in Table 8–14
8. SRT for BOD removal = 5 d

9. Design MLSS X_{TSS} concentration = 3000 g/m^3; values of 2000 to 3000 g/m^3 can be considered
10. Peak to average TKN loading rate ratio = 1.5

Solution, Part A—BOD removal without nitrification

1. Develop the wastewater characteristics needed for design.
   a. Find bCOD.

$$\text{bCOD} = 1.6\ (\text{BOD}) = 1.6\ (140\ \text{g/m}^3) = 224\ \text{g/m}^3$$

   b. Find nbCOD using Eq. (8–12).

$$\text{nbCOD} = \text{COD} - \text{bCOD} = (300 - 224)\ \text{g/m}^3 = 76\ \text{g/m}^3$$

   c. Find effluent nonbiodegradable sCOD (nbsCOD_e).

$$\text{nbsCOD}_e = \text{sCOD} - 1.6\ \text{sBOD}$$
$$= (132\ \text{g/m}^3) - (1.6)(70\ \text{g/m}^3) = 20\ \text{g/m}^3$$

   d. Find nbVSS using Eq. (8–7, 8–8 and 8–9).

$$\text{nbpCOD} = \text{TCOD} - \text{bCOD} - \text{nbsCODe}$$

$$\text{nbpCOD} = (300 - 224 - 20)\ \text{g/m}^3 = 56\ \text{g/m}^3$$

$$\text{VSS}_{\text{COD}} = \frac{\text{TCOD} - \text{sCOD}}{\text{VSS}}$$

$$\text{VSS}_{\text{COD}} = \frac{(300 - 132)\text{g/m}^3}{60\ \text{g/m}^3} = 2.8\ \text{g COD/g VSS}$$

$$\text{nbVSS} = \frac{\text{nbpCOD}}{\text{VSS}_{\text{COD}}}$$

$$\text{nbVSS} = \frac{56\ \text{g COD/m}^3}{2.8\ \text{g COD/g VSS}} = 20.0\ \text{g nbVSS/m}^3$$

   e. Find the iTSS.

$$\text{iTSS} = \text{TSS} - \text{VSS}$$
$$= (70 - 60)\ \text{g/m}^3 = 10\ \text{g/m}^3$$

2. Design suspended growth system for BOD removal only.
   a. Determine biomass production using Eq. (8–20) in Table 8–10.

$$P_{X,\text{Bio}} = \frac{QY_H(S_o - S)}{1 + b_H(\text{SRT})} + \frac{(f_d)(b_H)QY_H(S_o - S)\text{SRT}}{1 + b_H(\text{SRT})}$$

Define input data for above equation.

Q = 22,500 m^3/d

S_o = 224 g bCOD/m^3 (see Step 1)

From Table 8–14.

$Y_H = 0.45$ g VSS/g bCOD

$b_{H,20} = 0.12$ g/g·d

$f_d = 0.15$

Determine S from Eq. (7–46) in Table 8–10. Note: Yk = μ_{max}

$$S = \frac{K_s[1 + b_H(\text{SRT})]}{\text{SRT}(\mu_{max} - b_H) - 1}$$

Use μ_{max}, b, and K_s at 20°C from Table 8–14

$\mu_{m,T} = \mu_m \theta^{(T-20)}$ from Eq. (1–44) in Table 8–1

$\mu_{m,12°C} = 6.0\text{ g/g·d }(1.07)^{12-20} = 3.5\text{ g/g·d}$

$b_{H,T} = b_{H,20}\,\theta^{(T-20)}$ from Eq. (1–44)

$b_{H,12°C} = (0.12\text{ g/g·d})(1.04)^{12-20} = 0.088\text{ g/g·d}$

$$S = \frac{(8.0\text{ g/m}^3)[1 + (0.088\text{ g/g·d})(5\text{ d})]}{(5\text{ d})(3.5 - 0.088)\text{ g/g·d} - 1} = 0.7\text{ g bCOD/m}^3$$

b. Substitute the above values in the expression given above and solve for $P_{X,VSS}$.

$$P_{X,\text{Bio}} = \frac{(22{,}700\text{ m}^3/\text{d})(0.45\text{ g/g})[(224 - 0.7)\text{ g/m}^3](1\text{ kg}/10^3\text{ g})}{[1 + (0.088\text{ g/g·d})(5\text{ d})]}$$

$$+ \frac{(0.15\text{ g/g})(0.088\text{ g/g·d})(22{,}700\text{ m}^3/\text{d})(0.45\text{ g/g})[(224 - 0.7)\text{ g/m}^3](5\text{ d})(1\text{ kg}/10^3\text{ g})}{[1 + (0.088\text{ g/g·d})(5\text{ d})]}$$

$P_{X,\text{Bio}} = (1584.0 + 104.5)\text{ kg/d} = 1688.5\text{ kg VSS/d}$

3. Determine the mass in terms of VSS and TSS in the aeration basin. The mass of VSS and TSS can be determined using Eqs. (8–20), (8–21) and (7–57) given in Table 8–10.

Mass = P_X(SRT)

a. Determine $P_{X,VSS}$ and $P_{X,TSS}$ using Eqs. (8–20) including parts A, B, and D. Part C = 0 because there is no nitrification.

$P_{X,VSS} = P_{X,\text{bio}} + Q(\text{nbVSS})$

$$\begin{aligned} P_{X,VSS} &= 1688.5\text{ kg/d} + Q(\text{nbVSS}) \\ &= 1688.5\text{ kg/d} + (22{,}700\text{ m}^3/\text{d})(20\text{ g/m}^3)(1\text{ kg}/10^3\text{ g}) \\ &= (1688.5 + 454.0)\text{ kg/d} = 2142.5\text{ kg/d} \end{aligned}$$

From Eq. (8–21), $P_{X,TSS}$ is

$$\begin{aligned} P_{X,TSS} &= [(1688.5\text{ kg/d})/0.85] + (454.0\text{ kg/d}) + Q(\text{TSS}_o - \text{VSS}_o) \\ &= 1986.5\text{ kg/d} + 454.0\text{ kg/d} + (22{,}700\text{ m}^3/\text{d})(10\text{ g/m}^3)(1\text{ kg}/10^3\text{ g}) \\ &= 2667.5\text{ kg/d} \end{aligned}$$

b. Calculate the mass of VSS and TSS in the aeration basin.
   i. Mass of MLVSS using Eq. (7–57) in Table 8–10

$$\begin{aligned}(X_{\text{VSS}})(V) &= (P_{X,\text{VSS}})\,\text{SRT}\\ &= (2142.5\,\text{kg/d})(5\text{ d}) = 10{,}712\,\text{kg}\end{aligned}$$

   ii. Mass of MLSS using Eq. (7–57) in Table 8–10

$$\begin{aligned}(X_{\text{TSS}})(V) &= (P_{\text{X,TSS}})\,\text{SRT}\\ &= (2667.5\,\text{kg/d})(5\text{ d}) = 13{,}337\,\text{kg}\end{aligned}$$

4. Select a design MLSS mass concentration and determine the aeration tank volume and detention time using the TSS mass computed in Step 3b.
   a. Determine the aeration tank volume using the relationship from Step 3b.

$$(X_{\text{TSS}})(V) = 13{,}337\,\text{kg}$$

At $X_{\text{TSS}} = 3000\text{ g/m}^3$

$$V = \frac{(13{,}337\,\text{kg})(10^3\text{ g/1 kg})}{(3000\,\text{g/m}^3)} = 4445.7\,\text{m}^3$$

   b. Determine the aeration tank detention time.
   Use 3 basins at 1480 m^3 each so that one of the basins can be taken offline for a short period of time when maintenance of the aeration system is necessary.

$$\tau = \frac{V}{Q} = \frac{(4445.7\,\text{m}^3)(24\text{ h/d})}{(22{,}700\,\text{m}^3\text{/d})} = 4.7\,\text{h}$$

   c. Determine MLVSS.

$$\text{Fraction VSS} = \frac{10{,}712\,\text{kg VSS}}{13{,}337\,\text{kg TSS}} = 0.80$$

$$\text{MLVSS} = 0.80(3000\text{ g/m}^3) = 2400\text{ g/m}^3$$

5. Determine F/M and BOD volumetric loading.
   a. Determine F/M using Eq. (7–62) in Table 8–10.

$$\begin{aligned}\text{F/M} &= \frac{QS_o}{XV} = \frac{\text{kg BOD}}{\text{kg MLVSS}\cdot\text{d}}\\ &= \frac{(22{,}700\,\text{m}^3\text{/d})(140\,\text{g/m}^3)}{(2400\,\text{g/m}^3)(4446\text{ m}^3)} = 0.30\,\text{g/g}\cdot\text{d} = 0.30\,\text{kg/kg}\cdot\text{d}\end{aligned}$$

   b. Determine volumetric BOD loading using Eq. (7–69) in Table 8–10.

$$\begin{aligned}\text{BOD loading} &= \frac{QS_o}{V} = \frac{\text{kg BOD}}{\text{m}^3\cdot\text{d}}\\ &= \frac{(22{,}700\,\text{m}^3\text{/d})(140\,\text{g/m}^3)}{(4446\,\text{m}^3)(10^3\,\text{g/1 kg})} = 0.71\text{ kg/m}^3\cdot\text{d}\end{aligned}$$

6. Determine the observed yield based on TSS and VSS.
   a. Observed yield based on TSS.

Observed yield = g TSS/g bCOD = kg TSS/kg bCOD

$P_{X,\,\mathrm{TSS}} = 2667.6\ \mathrm{kg/d}$

$$\begin{aligned}\text{bCOD removed} &= Q(S_o - S)\\ &= (22{,}700\ \mathrm{m^3/d})[(224 - 0.7)\ \mathrm{g/m^3}](1\ \mathrm{kg}/10^3\ \mathrm{g})\\ &= 5068.9\ \mathrm{kg/d}\end{aligned}$$

$$\begin{aligned}Y_{\mathrm{obs,TSS}} &= \frac{(2667.6\ \mathrm{kg/d})}{(5068.9\ \mathrm{kg/d})} = \frac{0.53\ \mathrm{kg\ TSS}}{\mathrm{kg\ bCOD}} = \frac{0.53\ \mathrm{g\ TSS}}{\mathrm{g\ bCOD}}\\ &= \left(\frac{0.53\ \mathrm{g\ TSS}}{\mathrm{g\ bCOD}}\right)\left(\frac{1.6\ \mathrm{g\ bCOD}}{\mathrm{g\ BOD}}\right) = 0.84\ \mathrm{g\ TSS/g\ BOD}\end{aligned}$$

b. Observed yield based on VSS.

$Y_{\mathrm{obs,VSS}}$: VSS/TSS = 0.80 (see Step 4c)

$$\begin{aligned}&= \left(\frac{0.53\ \mathrm{g\ TSS}}{\mathrm{g\ bCOD}}\right)\left(\frac{0.8\ \mathrm{g\ VSS}}{\mathrm{g\ TSS}}\right)\\ &= 0.42\ \mathrm{g\ VSS/g\ bCOD}\\ &= \left(\frac{0.42\ \mathrm{g\ VSS}}{\mathrm{g\ bCOD}}\right)\left(\frac{1.6\ \mathrm{g\ bCOD}}{\mathrm{g\ BOD}}\right)\\ &= 0.64\ \mathrm{g\ VSS/g\ BOD}\end{aligned}$$

7. Calculate the O_2 demand using Eq. (8–23) in Table 8–10.

$$\begin{aligned}R_o &= Q(S_o - S) - 1.42\,P_{X,\mathrm{bio}} + 4.57(Q)\mathrm{NO}_x\\ &= (22{,}700\ \mathrm{m^3/d})[(224 - 0.7)\ \mathrm{g/m^3}](1\ \mathrm{kg}/10^3\ \mathrm{g}) - 1.42(1688.5\ \mathrm{kg/d})\end{aligned}$$

$$\begin{aligned}R_o &= 5068.9\ \mathrm{kg/d} - 2397.7\ \mathrm{kg/d}\\ &= 2671.2\ \mathrm{kg/d} = 111.3\ \mathrm{kg\ O_2/h}\end{aligned}$$

8. Fine bubble aeration design – determine air flowrate at average design flowrate. Based on Eq. (5–55) the aeration oxygen transfer rate under actual conditions in the aeration tank is related to the oxygen transfer rate at standard conditions.

$$\mathrm{SOTR} = \left(\frac{\mathrm{OTR}_f}{\alpha F}\right)\left[\frac{C^*_{\infty 20}}{\beta(C_{\mathrm{st}}/C^*_{\mathrm{s20}})(P_b/P_s)(C^*_{\infty 20}) - C}\right][(1.024)^{20-T}]$$

Where SOTR = standard oxygen transfer rate at site, kg/h
OTR_f = actual oxygen transfer rate at site, kg/h
α = relative transfer rate to clean water
β = relative DO saturation to clean water (0.95 to 0.98)
F = diffuser fouling factor
$\mathrm{C}^*_{\mathrm{st}}$ = saturated DO at sea level and operating temperature, mg/L
$\mathrm{C}^*_{\mathrm{s20}}$ = saturated DO value at sea level and 20°C, mg/L
$\mathrm{C}^*_{\infty,20}$ = saturated DO value at sea level and 20°C for diffused aeration, mg/L. It is higher than C_{st} as it is affected by oxygen transfer from bubbles under pressure in water column.

$C^*_{\infty,20}$ can be estimated by the following equation (U.S. EPA, 1989):

$$C^*_{\infty,20} = C^*_{S20}\left[1 + d_e\left(\frac{D_f}{P_a}\right)\right]$$

P_a = standard pressure at sea level, (760 mm) (10.33 m)
P_b = pressure at the plant site based on elevation, m
D_f = depth of diffusers in basin, m or ft
C = operating DO in basin, mg/L
T = aeration basin temperature, °C
d_e = mid-depth correction factor; may vary from 0.25–0.45 (0.40)

i. From Table E–1 (Appendix E), $C_{s,20} = 9.09$ mg/L and $C_{12} = 10.78$ mg/L
ii. Determine the relative pressure at elevation 500 m to correct the DO concentration for altitude.
From Appendix B

$$\frac{P_b}{P_a} = \exp\left[-\frac{gM(z_b - z_a)}{RT}\right]$$

$$= \exp\left\{-\frac{(9.81\ \text{m/s}^2)(28.97\ \text{kg/kg-mole})[(500 - 0)\ \text{m}]}{(8314\ \text{kg}\cdot\text{m}^2/\text{s}^2\cdot\text{kg-mole}\cdot\text{K})[(273.15 + 12)\ K]}\right\} = 0.94$$

a. Determine the oxygen concentration at 20°C ($C_{sat,20}$) accounting for the gas release at the diffuser depth.
Tank liquid depth = 4.9 m
Diffuser depth, D_f = 4.9 m − 0.5 m = 4.4 m

$$C^*_{\infty 20} = C^*_{s20}\left[1 + d_e\left(\frac{D_f}{P_a}\right)\right]$$

$$C^*_{\infty 20} = 9.09\left[1 + 0.40\left(\frac{4.4\ \text{m}}{10.33\ \text{m}}\right)\right] = 10.64$$

b. Determine the SOTR using $\alpha = 0.50$, $\beta = 0.95$, and diffuser fouling factor $F = 0.9$.

$$\text{SOTR} = \left(\frac{\text{OTR}_f}{\alpha F}\right)\left\{\frac{C^*_{\infty 20}}{\left[\beta\frac{C^*_{\text{st}}}{C^*_{\text{s20}}}\left(\frac{P_b}{P_a}\right)(C^*_{\infty 20}) - \text{C}_\text{L}\right]}\right\}(1.024^{20-T})$$

$$\text{SOTR} = \left(\frac{111.3\ \text{kg/h}}{0.50(0.90)}\right)\left\{\frac{10.64}{\left[0.95\left(\frac{10.78}{9.09}\right)(0.94)(10.64) - 2.0\right]}\right\}(1.024^{20-12})$$

$$= 343.3\ \text{kg/h}$$

c. Determine the air flowrate.

$$\text{Air flowrate, m}^3/\text{min} = \frac{(\text{SOTR kg/h})}{[(E)(60\ \text{min/h})(\text{kg O}_2/\text{m}^3\ \text{air})]}$$

Using the data given in Appendix B, the density of air at 12°C and a pressure of 95.2 kPa (0.94 × 101.325 kPa) is 1.1633 kg/m^3. The corresponding amount of oxygen by weight is 0.270 (0.2318 × 1.1633 kg/m^3). Thus, the required air flowrate is

$$\text{Air flowrate, m}^3/\text{min} = \frac{(343.3\ \text{kg/h})}{[(0.35)(60\ \text{min/h})(0.270\ \text{kg O}_2/\text{m}^3\ \text{air})]}$$
$$= 60.5\ \text{m}^3/\text{min}$$

Note: To continue the facilities design for secondary clarifiers for the BOD removal process, move to Part C, Step 21. For nitrification design, continue to Step 9.

Solution, Part B—BOD removal and nitrification

9. Perform the nitrification design following the same steps as for BOD removal except the design SRT must first be determined. Determine the specific growth rate μ_n for the ammonia oxidizing bacteria using Eq. (7–94) in Table 8–10. The nitrification rate will control the design because the nitrifying organisms grow more slowly than the heterotrophic organisms that remove organic carbon.

$$\mu_{\text{AOB}} = \mu_{\text{max,AOB}}\left[\frac{S_{\text{NH}_4}}{S_{\text{NH}_4} + K_{\text{NH}_4}}\right]\left[\frac{S_o}{S_o + K_{o,\text{AOB}}}\right] - b_{\text{AOB}}$$

Select values for $\mu_{\text{max,AOB}}$, b_{AOB}, K_{NH_4} and $K_{o,\text{AOB}}$ from Table 8–14 at 20°C. These are 0.90 g/g·d, 0.17 g/g·d, 0.50 g/m^3, and 0.50 g/m^3, respectively. Use temperature correction, θ values, from Table 8–14.

a. Find $\mu_{\text{max,AOB}}$ at T = 12°C.

$$\mu_{\text{max,AOB,12°C}} = (0.90\ \text{g/g·d})(1.072)^{12-20} = 0.516\ \text{g/g·d}$$

b. Find b_{AOB}, at T = 12°C.

$$b_{\text{AOB,12°C}} = (0.17\ \text{g/g·d})(1.029)^{12-20} = 0.135\ \text{g/g·d}$$

c. Substitute the above and given values in Eq. (7–94) and solve for μ_{AOB}.
$S_{\text{NH}_4} = 0.50$ g/m^3, DO = 2.0 g/m^3, $K_{o,\text{AOB}} = 0.50$ g/m^3

$$\mu_{\text{AOB}} = \left\{\frac{(0.516\ \text{g/g·d})(0.50\ \text{g/m}^3)}{[(0.50 + 0.50)\ \text{g/m}^3]}\right\}\left\{\frac{(2.0\ \text{g/m}^3)}{[(2.0 + 0.50)\ \text{g/m}^3]}\right\} - (0.135\ \text{g/g·d})$$
$$= 0.0714\ \text{g/g·d}$$

10. Determine the theoretical and design SRT.

a. Find theoretical SRT using Eq. (7–98) in Table 8–10.

$$\text{SRT} = \frac{1}{\mu_{\text{AOB}}} = \frac{1}{(0.0714\ \text{g/g·d})} = 14.0\ \text{d}$$

b. Determine the design SRT using Eq. (7–73).

Design SRT = (SF)(theoretical SRT)

SF = Peak to average TKN load = 1.5

Design SRT = 1.5 (14.0 d) = 21.0 d

11. Determine biomass production using Eq. (8–20) with parts A, B, and C in Table 8–10.

$$P_{X,\text{bio,VSS}} = \frac{QY_{\text{H}}(S_o - S)}{1 + b_{\text{H}}(\text{SRT})} + \frac{(f_d)(b_{\text{H}})QY_{\text{H}}(S_o - S)\text{SRT}}{1 + b_{\text{H}}(\text{SRT})} + \frac{QY_n(\text{NO}_X)}{1 + b_{\text{AOB}}(\text{SRT})}$$

a. Define input data for the above equation.

$Q = 22{,}700\ \text{m}^3/\text{d}$

$Y_\text{H} = 0.45\ \text{VSS/g bCOD}$

$S_o = 224\ \text{g bCOD/m}^3$ (Step 1)

$b_\text{H} = 0.088\ \text{g/g·d}$ (Step 2a)

$\mu_m = 3.5\ \text{g/g·d}$ (Step 2a)

Determine S from Eq. (7–46) in Table 8–10.

$$S = \frac{K_s[1 + b_\text{H}(\text{SRT})]}{[\text{SRT}(\mu_m - b_\text{H}) - 1]}$$

$$S = \frac{(8\ \text{g/m}^3)[1 + (0.088\ \text{g/g·d})(21.0\ \text{d})]}{(21.0\ \text{d})(3.5 - 0.088\ \text{g/g·d}) - 1} = 0.32\ \text{g bCOD/m}^3$$

$Y_n = 0.15\ \text{g VSS/g NO}_x$ (Table 8–14)

$b_{\text{AOB},12°\text{C}} = 0.135\ \text{g/g·d}$ (Step 9b)

A value for NO_x is needed in part C of Eq. (8–20). As NO_x is contained in Eq. (8–20) to obtain $P_{X,\text{Bio}}$, one solution approach is to assume the NO_x concentration in Eq. (8–20) as a certain percentage of the influent TKN. An iterative solution can then be used to solve for NO_x, after calculating $P_{X,\text{Bio}}$. A value for $\text{NO}_x = 80\%$ (TKN) is a reasonable approximation for the BOD to TKN ratio for this problem. The error would be small as the nitrifier VSS yield is a normally a small fraction of total MLVSS concentration.

$\text{NO}_x = 0.80(35\ \text{g/m}^3) = 28\ \text{g/m}^3$

b. Substitute the above values in the expression given above and solve for $P_{X,\text{bio,VSS}}$.

$$P_{X,\text{bio,VSS}} = \frac{(22{,}700\ \text{m}^3/\text{d})(0.45\ \text{g/g})[(224 - 0.32)\ \text{g/m}^3](1\ \text{kg}/10^3\ \text{g})}{[1 + (0.088\ \text{g/g·d})(21.0\ \text{d})]}$$
$$+ \frac{(0.15\ \text{g/g})(0.088\ \text{g/g·d})(0.45\ \text{g/g})(22{,}700\ \text{m}^3/\text{d})[(224 - 0.32)\ \text{g/m}^3](21.0\ \text{d})(1\ \text{kg}/10^3\ \text{g})}{[1 + (0.088\ \text{g/g·d})\ (21.0\ \text{d})]}$$
$$+ \frac{(22{,}700\ \text{m}^3/\text{d})(0.15\ \text{g/g})(28\ \text{g/m}^3)(1\ \text{kg}/10^3\ \text{g})}{[1 + (0.135\ \text{g/g·d})(21.0\ \text{d})]}$$

$$\begin{aligned} P_{X,\text{bio,VSS}} &= 802.3\ \text{kg/d} + 222.4\ \text{kg/d} + 24.9\ \text{kg/d} \\ &= 1049.6\ \text{kg VSS/d} \end{aligned}$$

12. Determine the amount of nitrogen oxidized to nitrate (NO_x). The amount of nitrogen oxidized to nitrate can be found by performing a nitrogen balance using Eq. (8–24) in Table 8–10.

$$\begin{aligned} \text{NO}_x &= \text{TKN} - N_e - 0.12 P_{X,\text{bio}}/Q \\ &= 35.0\ \text{g/m}^3 - 0.50\ \text{g/m}^3 \\ &\quad - (0.12\ \text{g N/g VSS})(1049.6\ \text{kg VSS/d})(10^3\ \text{g/kg})/(22{,}700\ \text{m}^3/\text{d}) \\ &= (35.0 - 0.50 - 5.6)\ \text{g/m}^3 = 28.9\ \text{g/m}^3 \end{aligned}$$

The computed value is close to the 28.0 g/m^3 assumed. Substituting 28.9 for NO_x in the above calculation yields a NO_x value of 28.9 g/m^3 again, so one iteration was satisfactory. The increase in $P_{X,\text{bio,VSS}}$ for Part C in Eq. (8–20) is from 24.9 kg/d to 25.7 kg/d, so $P_{X,\text{bio,VSS}}$ is now 1050.4 kg VSS/d

13. Determine the concentration and mass of VSS and TSS in the aeration basin. The mass of VSS and TSS can be determined using Eqs. (8–20), (8–21) and (7–57) given in Table 8–10.

$$\text{Mass} = P_X(\text{SRT})$$

a. Determine $P_{X,\text{VSS}}$ using Eq. (8–20) including parts A, B, C and D by adding the contribution from nbVSS to the above.

$$P_{X,\text{VSS}} = P_{x,\text{bio}} + Q(\text{nbVSS})$$

$$\begin{aligned} P_{X,\text{VSS}} &= 1050.4\,\text{kg/d} + Q(\text{nbVSS}) \\ &= 1050.4\,kg/\text{d} + (22{,}700\,\text{m}^3/\text{d})(20\,\text{g/m}^3)(1\,\text{kg}/10^3\,\text{g}) \\ &= (1050.4 + 454.0)\,\text{kg/d} = 1504.4\,\text{kg/d} \end{aligned}$$

From Eq. (8–21), $P_{X,\text{TSS}}$ is

$$\begin{aligned} P_{X,\text{TSS}} &= [(1050.4\,\text{kg/d})/0.85] + (454.0\,\text{kg/d}) + Q(\text{TSS}_o - VSS_o) \\ &= 1235.8\,\text{kg/d} + 454.0\,\text{kg/d} + (22{,}700\,\text{m}^3/\text{d})(10\,g/\text{m}^3)(1\,\text{kg}/10^3\,\text{g}) \\ &= 1916.8\,\text{kg/d} \end{aligned}$$

b. Calculate the mass of VSS and TSS in the aeration basin.
   i. Mass of MLVSS using Eq. (7–57) in Table 8–10

$$\begin{aligned} (X_{\text{VSS}})(V) &= (P_{X,\text{VSS}})\,\text{SRT} \\ &= (1504.4\,\text{kg/d})(21.0\,\text{d}) = 31{,}592.4\,\text{kg} \end{aligned}$$

   ii. Mass of MLSS using Eq. (7–57) in Table 8–10

$$\begin{aligned} (X_{\text{TSS}})(V) &= (P_{X,\text{TSS}})\,\text{SRT} \\ &= (1916.8\,\text{kg/d})(21.0\,\text{d}) = 40{,}252.8\,\text{kg} \end{aligned}$$

14. Select a design MLSS mass concentration and determine the aeration tank volume and detention time using the TSS mass computed in Step 13b.
a. Determine the aeration tank volume using the relationship from Step 13b.

$$(X_{\text{TSS}})(V) = 40{,}252.8\,\text{kg}$$

At $X_{\text{TSS}} = 3000\ \text{g/m}^3$

$$V = \frac{(40{,}252.8\,\text{kg})(10^3\,\text{g}/1\,\text{kg})}{(3000\,\text{g/m}^3)} = 13{,}418\,\text{m}^3$$

b. Determine the aeration tank detention time.
Use 3 basins at 4470 m^3 each so that one of the basins can be taken offline for a short period of time when maintenance of the aeration system is necessary.

$$\tau = \frac{V}{Q} = \frac{(13{,}410\,\text{m}^3)(24\ \text{h/d})}{(22{,}700\,\text{m}^3/\text{d})} = 14.2\,\text{h}$$

c. Determine MLVSS.

$$\text{Fraction VSS} = \frac{31{,}592 \text{ kg VSS}}{40{,}253 \text{ kg TSS}} = 0.79$$

$$\text{MLVSS} = (0.79)\ 3000 \text{ g/m}^3 = 2370 \text{ g/m}^3$$

15. Determine F/M and BOD volumetric loading.

a. Determine F/M using Eq. (7–62) in Table 8–10.

$$\text{F/M} = \frac{QS_o}{XV} = \frac{\text{kg BOD}}{\text{kg MLVSS·d}}$$

$$= \frac{(22{,}700 \text{ m}^3\text{/d})(140 \text{ g/m}^3)}{(2370 \text{ g/m}^3)(13{,}410 \text{ m}^3)} = 0.10 \text{ g/g·d} = 0.10 \text{ kg/kg·d}$$

b. Determine volumetric BOD loading using Eq. (7–69) in Table 8–10.

$$\text{BOD loading} = \frac{QS_o}{V} = \frac{\text{kg BOD}}{\text{m}^3\text{·d}}$$

$$= \frac{(22{,}700 \text{ m}^3\text{/d})(140 \text{ g/m}^3)}{(13{,}410 \text{ m}^3)(10^3 \text{ g/1 kg})} = 0.24 \text{ kg/m}^3\text{·d}$$

16. Determine the observed yield based on TSS and VSS.

a. Observed yield or net yield based on TSS.

Observed yield = g TSS/g bCOD = kg TSS/kg bCOD

$P_{\text{X,TSS}} = 1917$ kg/d

$$\text{bCOD removed} = Q(S_o - S)$$

$$= (22{,}700 \text{ m}^3\text{/d})[(224 - 0.32) \text{ g/m}^3](1 \text{ kg}/10^3 \text{ g})$$

$$= 5078 \text{ kg/d}$$

$$Y_{\text{obs,TSS}} = \frac{(1917 \text{ kg/d})}{(5078 \text{ kg/d})} = \frac{0.38 \text{ kg TSS}}{\text{kg bCOD}} = \frac{0.38 \text{ g TSS}}{\text{g bCOD}}$$

$$= \left(\frac{0.38 \text{ g TSS}}{\text{g bCOD}}\right)\left(\frac{1.6 \text{ g bCOD}}{\text{g BOD}}\right) = 0.61 \text{ g TSS/g BOD}$$

b. Observed yield based on VSS.

$Y_{\text{obs,VSS}}$:VSS/TSS = 0.79(see Step 14c)

$$= \left(\frac{0.38 \text{ g TSS}}{\text{g bCOD}}\right)\left(\frac{0.79 \text{ g VSS}}{\text{g TSS}}\right)$$

$$= 0.30 \text{ g VSS/g bCOD}$$

$$= \left(\frac{0.30 \text{ g VSS}}{\text{g bCOD}}\right)\left(\frac{1.6 \text{ g bCOD}}{\text{g BOD}}\right)$$

$$= 0.48 \text{ g VSS/g BOD}$$

17. Calculate the O_2 demand using Eq. (8–23) in Table 8–10.

$$R_o = Q(S_o - S) - 1.42\,P_{X,\text{bio}} + 4.57(Q)\text{NO}_x$$

$$P_{X,\text{bio,VSS}} = 802.3\text{ kg/d} + 222.4\text{ kg/d (Step 11} - \text{does not include nitrifying bacteria)}$$

$$= 1024.7\text{ kg VSS/d}$$

$$R_o = (22{,}700\text{ m}^3\text{/d})[(224 - 0.32)\text{ g/m}^3](1\text{ kg/}10^3\text{ g}) - 1.42(1024.7\text{ kg/d})$$

$$+\,4.57(22{,}700\text{ m}^3\text{/d})(28.9\text{ g/m}^3)(1\text{ kg/}10^3\text{ g})$$

$$R_o = 5077.5 - 1455.1 + 2998.1 = 6620\text{ kg O}_2\text{/d} = 275.9\text{ kg O}_2\text{/h}$$

18. Fine bubble aeration design—determine air flowrate at average design flowrate (see procedure for Step 8).
   a. Determine the SOTR using the values given in the problem statement: $\alpha = 0.65$, $\beta = 0.95$, and $F = 0.9$.

$$\text{SOTR} = \left(\frac{\text{OTR}_\text{f}}{\alpha F}\right)\left\{\frac{\text{C}^*_{\infty 20}}{\left[\beta\dfrac{\text{C}^*_{\text{st}}}{\text{C}^*_{\text{s}20}}\left(\dfrac{P_b}{P_b}\right)(\text{C}^*_{\infty 20}) - \text{C}\right]}\right\}(1.024^{20-T})$$

$$\text{SOTR} = \left(\frac{275.9\text{ kg/h}}{0.65(0.90)}\right)\left\{\frac{10.64}{\left[0.95\left(\dfrac{10.78}{9.09}\right)(0.94)(10.64) - 2.0\right]}\right\}(1.024^{20-12}) = 654.6\text{ kg/h}$$

   b. Determine the air flowrate.

$$\text{Air flowrate, m}^3\text{/min} = \frac{(654.6\text{ kg/h})}{[(0.35)(60\text{ min/h})(0.270\text{kg O}_2\text{/m}^3\text{ air})]}$$

$$= 115.5\text{ m}^3\text{/min}$$

19. Check alkalinity.
   a. Prepare an alkalinity (Alk) balance:

Alkalinity to maintain pH ~ 7 = Influent Alk −Alk used + Alk to be added
Influent alkalinity: 140 g/m^3 as $CaCO_3$
Amount of nitrogen converted to nitrate: NO_x = 28.9 g/m^3 (see Step 12)
Alkalinity used for nitrification = (7.14 g $CaCO_3$/g NH_4-N)(28.9 g/m^3)
= 206.3 g/m^3 used as $CaCO_3$

   b. Substitute known values and solve for alkalinity needed.
   Residual alkalinity concentration needed to maintain pH in the range of 6.8–7.0 ≅ 70 g/m^{3}as $CaCO_3$

$$70\text{ g/m}^3 = \text{Influent alk} - \text{alk used} + \text{alk to be added}$$

$$70\text{ g/m}^3 = 140\text{ g/m}^3 - 206.3\text{ g/m}^3 + \text{alk to be added}$$

$$\text{Alkalinity added} = 136.3\text{ g/m}^3\text{ as CaCO}_3$$

$$= (22{,}700\text{ m}^3\text{/d})(136.3\text{ g/m}^3)(1\text{ kg/}10^3\text{ g})$$

$$= 3094\text{ kg/d as CaCO}_3$$

c. Determine the alkalinity needed as sodium bicarbonate.
Sodium bicarbonate may be preferred over lime for alkalinity addition due to ease of handling and fewer scaling problems as compared to lime. The amount of $NaHCO_3$ needed is as follows:

Equivalent weight of $NaHCO_3 = 84$ g/equivalent

$$NaHCO_3 \text{ added} = \frac{(3094\,\text{kg/d CaCO}_3)(84\,\text{g NaHCO}_3/\text{eq})}{(50\,\text{g CaCO}_3/\text{equivalent})}$$
$$= 5197\,\text{kg/d NaHCO}_3$$

20. Estimate effluent BOD using Eq. (8–26).

$$\text{BOD} = \text{sBOD}_e + \left(\frac{0.85\,\text{g BOD}}{1.42\,\text{g VSS}}\right)\left(\frac{0.85\,\text{g VSS}}{\text{g TSS}}\right)(\text{TSS, g/m}^3)$$

Assume $\text{sBOD}_e = 3.0\ \text{g/m}^3$
$\text{TSS} = 10\ \text{g/m}^3$

$$\text{BOD} = 3.0\,\text{g/m}^3 + (0.85)(0.85)(10\,\text{g/m}^3)$$
$$= 10.2\,\text{g/m}^3$$

Solution, Part C—Secondary clarifier sizing

21. Secondary clarifier design (for both BOD removal and BOD removal and nitrification).
a. Define return sludge recycle ratio [see Fig. 8–11(b)]:

$Q_R X_R = (Q + Q_R)X$ (assume waste sludge mass is insignificant)

$Q_R = RAS$ flowrate, m^3/d

X_R = return sludge mass concentration, g/m^3

RAS recycle ratio $= Q_R/Q = R$

$RX_R = (1 + R)X$

$$R = \frac{X}{X_r - X}$$

b. Determine size of clarifier.
Assume $X_R = 8000\ \text{g/m}^3$ (moderate settling/thickening sludge; per Sec. 8–3 range is 4000 to 12,000 mg/L).

$$R = \frac{(3000\,\text{g/m}^3)}{[(8000 - 3000)\,\text{g/m}^3]} = 0.60$$

Assume a hydraulic application rate of 24 $m^3/m^2{\cdot}d$ at average flowrate for the secondary clarifier (see Table 8–34); the range is 16 to 28 $m^3/m^2{\cdot}d$

$$\text{Area} = \frac{(22{,}700\,\text{m}^3/\text{d})}{(24\,\text{m}^3/\text{m}^2\cdot\text{d})} = 946\,\text{m}^2$$

Use 3 clarifiers (1 for each aeration tank)

Area/clarifier = 315 m^2

Clarifier diameter = 20 m

c. Check solids loading.

$$\text{Solids loading} = \frac{(Q + Q_r)(\text{MLSS})}{A} = \frac{(1 + R)Q(\text{MLSS})}{A}$$

where A = area of clarifier, $m^2 = (\pi/4)(20\text{ m})^2 \times 3 = 942\text{ m}^2$

$$\text{Solids loading} = \frac{(1 + 0.6)(22{,}700\text{ m}^3/\text{d})(3000\text{ g/m}^3)(1\text{ kg}/10^3\text{ g})}{(942\text{ m}^2)(24\text{ h/d})}$$

$$= 4.9\text{ kg MLSS/m}^2\cdot\text{h}$$

(within acceptable range of solids loading of 4 to 6 kg/m^2·d given in Table 8–34 on page 890)

22. Prepare design summary.

Design parameter	Unit	BOD removal only (Part A)	BOD removal and nitrification (Part B)
Average flow	m^3/d	22,700	22,700
Average BOD load	kg/d	3178	3178
Average TKN load	kg/d	795	795
Aerobic SRT	d	5.0	21.0
Aeration tanks	number	3	3
Aeration tank volume, ea	m^3	1480	4470
Hydraulic detention time,	h	4.7	14.2
MLSS	g/m^3 (mg/L)	3000	3000
MLVSS	g/m^3 (mg/L)	2400	2370
F/M	g/g·d	0.30	0.10
BOD loading	kg BOD/m^3·d	0.71	0.24
Sludge production	kg/d	2667	1917
Observed yield	kg VSS/kg BOD	0.64	0.48
	kg TSS/kg BOD	0.84	0.61
Oxygen required	kg/h	111.3	275.9
Air flowrate at average wastewater flowrate	m^3/min	60.5	115.5
RAS ratio	Unitless	0.60	0.60
Clarifier hydraulic application rate	m^3/m^2·d	24	24
Clarifiers	number	3	3

(continued)

(*Continued*)

Design parameter	Unit	BOD removal only (Part A)	BOD removal and nitrification (Part B)
	Diameter, m	20	20
Alkalinity addition as $Na(HCO_3)$	kg/d	—	5197
Effluent BOD	g/m^3 (mg/L)	<30	10.2
TSSe	g/m^3 (mg/L)	<30	10
Effluent NH_4-N	g/m^3 (mg/L)	—	≤0.5

Comment The effluent NH_4-N concentration for the BOD removal only design would be a little less than the 28.9 mg/L of NH_4-N oxidized in the nitrification system due to the shorter SRT. In this example, the design procedure is described for an average wastewater flowrate. In actual design, computations must also be made for peak flow and load conditions.

In Example 8–3 the NH_4-N oxidation was assumed to be oxidized completely to NO_3-N and the presence of NO_2-N due to the two step nitrification process of NH_4-N oxidation by AOB and NO_2-N oxidation to NO_3-N by NOB was ignored. The NO_2-N concentration is generally less than 0.30 mg/L in systems operated at typical DO concentrations at or near 2.0 mg/L and temperatures below 25°C, so that ignoring the NO_2-N concentration does not pose a significant error in calculating the oxygen demand or effluent total nitrogen concentration for most applications. However, if the activated sludge system designed in Example 8–3 is operated at a much lower DO concentration, an elevated NO_2-N concentration is possible. The effect of a lower DO concentration on the activated sludge NO_2-N and NH_4-N concentrations is illustrated in Example 8–4.

EXAMPLE 8–4 **Effect of DO Concentration on NO_2-N and NH_4-N Concentrations for the Complete-mix Activated Sludge System Designed in Example 8–3** Using the information from Example 8–3 determine: (a) the NO_2-N effluent concentration and (b) the effluent NO_2-N and NH_4-N concentrations for the complete-mix activated sludge system, if the DO concentration is 0.40 mg/L instead of 2.0 mg/L?

Design conditions and assumptions
1. SRT = 20.6 d
2. Temperature = 12°C

Solution, Part A—NO_2-N effluent concentration

1. Use Eq. (7–46) in Table 8–10 to determine the effluent NO_2-N concentration at DO = 2.0 mg/L. Note: $Yk = \mu$

$$NO_2\text{-N} = \frac{K_{NO_2}[1 + b_{NOB}(SRT)]}{SRT(\mu_{NOB} - b_{NOB}) - 1}$$

2. Determine the effective μ_{NOB} accounting for $\mu_{\mathrm{max,NOB}}$ and the effect of DO.

$$\mu_{\mathrm{NOB}} = \mu_{\mathrm{max,NOB}}\left(\frac{S_{O_2}}{S_{O_2} + K_{O_2,\mathrm{NOB}}}\right)$$

select values for $\mu_{\mathrm{max,NOB}}$, $K_{\mathrm{NO_2}}$, $K_{O_2,\mathrm{NOB}}$, and b_{NOB} from Table 8–14. The selected values are: 1.0 g/g·d, 0.20 g/m^3, 0.90 g/m^3, and 0.17 g/g·d, respectively. Use the temperature correction values from Table 8–14 to correct the coefficients for 12°C. Find $\mu_{\mathrm{max,NOB}}$ at T = 12°C

$$\mu_{\mathrm{max,NOB,12}} = (\mu_{\mathrm{max,NOB,20}})\theta^{(\mathrm{T}-20)}$$

$$\mu_{\mathrm{max,NOB,12}} = (1.0\ \mathrm{g/g{\cdot}d})1.963^{12-20} = 0.61\ \mathrm{g/g{\cdot}d}$$

$$\mu_{\mathrm{NOB,12}} = (0.61\ \mathrm{g/g{\cdot}d})\left[\frac{(2.0\ \mathrm{g/m^3})}{(2.0\ \mathrm{g/m^3} + 0.90\ \mathrm{g/m^3})}\right] = 0.42\ \mathrm{g/g{\cdot}d}$$

3. Find b_{NOB} at T = 12°C.

$$b_{\mathrm{NOB,12}} = (\mathrm{b}_{20})\theta^{(\mathrm{T}-20)}$$
$$b_{\mathrm{NOB,12}} = (0.17\ \mathrm{g/g{\cdot}d})1.029^{(12-20)} = 0.135\ \mathrm{g/g{\cdot}d}$$

4. Substitute the above coefficients in Eq. (7–46) and solve for the effluent NO_2-N concentration.

$$\mathrm{NO_2\text{-}N} = \frac{(0.20\ \mathrm{g/m^3})[1 + (0.135\ \mathrm{g/g{\cdot}d})(20.6\ \mathrm{d})]}{[(20.6\ \mathrm{d})(0.42\ \mathrm{g/g{\cdot}d} - 0.135\ \mathrm{g/g{\cdot}d})] - 1} = 0.16\ \mathrm{mg/L}$$

Solution, Part B—NO_2-N and NH_4-N effluent concentrations

1. Solve for the NO_2-N concentration at DO = 0.40 g/m^3
   a. Determine the effective μ_{NOB} at DO = 0.40 g/m^3 and T=12°C and substitute value into Eq. (7–46).

$$\mu_{\mathrm{NOB,12}} = (0.61\ \mathrm{g/g{\cdot}d})\left[\frac{(0.40\ \mathrm{g/m^3})}{(0.40\ \mathrm{g/m^3} + 0.90\ \mathrm{g/m^3})}\right] = 0.188\ \mathrm{g/g{\cdot}d}$$

$$\mathrm{NO_2\text{-}N} = \frac{(0.20\ \mathrm{g/m^3})[1 + (0.135\ \mathrm{g/g{\cdot}d})(20.6\ \mathrm{d})]}{[(20.6\ \mathrm{d})(0.188\ \mathrm{g/g{\cdot}d} - 0.135\ \mathrm{g/g{\cdot}d})] - 1} = 8.20\ \mathrm{g/m^3}$$

2. Solve for the NH_4-N concentration at DO = 0.40 g/m^3.
   a. Determine μ_{AOB} at DO = 0.40 g/m^3 and T = 12°C and substitute this value and other coefficient values from Example 8–3 into Eq. (7–46) to obtain the effluent NH_4-N concentration. From Example Problem 8–3, $b_{\mathrm{AOB,12}}$ = 0.135 g/gal and $K_{\mathrm{NH_4}}$ = 0.50 g/m^3. From Table 8–14, K_{O_2} = 0.50 g/m^3. The effective μ_{AOB} accounting for $\mu_{\mathrm{max,AOB}}$ and the effect of DO:

$$\mu_{\mathrm{AOB,12}} = \mu_{\mathrm{max,AOB,12}}\left(\frac{S_{O_2}}{S_{O_2} + K_{O_2,\mathrm{AOB}}}\right)$$

$$\mu_{\mathrm{AOB,12}} = (0.52\ \mathrm{g/g{\cdot}d})\left[\frac{(0.40\ \mathrm{g/m^3})}{(0.40\ \mathrm{g/m^3} + 0.50\ \mathrm{g/m^3})}\right] = 0.231\ \mathrm{g/g{\cdot}d}$$

$$\mathrm{NH_4\text{-}N} = \frac{0.50\ \mathrm{g/m^3}[1 + (0.135\ \mathrm{g/g{\cdot}d})(20.6\ \mathrm{d})]}{20.6\ \mathrm{d}(0.231\ \mathrm{g/g{\cdot}d} - 0.135\ \mathrm{g/g{\cdot}d}) - 1} = 1.90\ \mathrm{g/m^3}$$

Summary for effluent NH_4-N and NO_2-N concentrations at a DO of 2.0 mg/L and 0.40 g/m^3 at a 20.6-d SRT:

	DO concentration, mg/L	
Parameter	2.00	0.40
NH_4-N	0.50	1.90
NO_2-N	0.16	8.20

Comment At a low DO concentration, a much higher NO_2-N concentration is predicted, and thus the oxidation of NH_4-N to NO_3-N is incomplete. Note that it is likely that at the low DO concentration some denitrification of NO_2-N would occur within the heterotrophic floc, so that its concentration in the activated sludge reactor would be lower than predicted by assuming only an aerobic condition.

Sequencing Batch Reactor Process Design

Treatment in an SBR system is accomplished over a series of time steps in a single reactor compared to what is done spatially in a flow-through activated sludge system. A unique feature of the SBR system is that there is no need for a return activated sludge (RAS) system, because both aeration and settling occur in the same tank. The SBR process can

Table 8–16

Description of operational steps for the sequencing batch reactor (SBR)

Operational step	Description
Fill	During the fill period, raw wastewater or primary effluent is added to the reactor. In the fill step the liquid level in the reactor typically rises from 75 percent (at the end of the idle period) to 100 percent of the maximum liquid volume. When two tanks are used, the time for the fill process may last about 50 percent of the full cycle time. During fill, the reactor may be mixed only or mixed and aerated to promote biological reactions with the influent wastewater. A mix only of at least 50 percent promotes filamentous growth control and improved settling and thickening.
React	During the react period, the biomass consumes the substrate under controlled environmental conditions, which can be aeration only or cyclic aeration and mixing to promote biological nitrification and denitrification for nitrogen removal.
Settle	Solids are allowed to separate from the liquid under quiescent conditions, resulting in a clarified supernatant that can be discharged as effluent.
Decant	Clarified effluent is removed during settled supernatant removal during the decant period. Many types of decanting mechanisms can be used with the most popular being floating or adjustable weirs.
Idle	An idle period is used in a multi-tank system to provide time for one reactor to complete its fill phase before switching to another unit. It also provides capacity for handling higher flows that may occur as a function of wet weather or seasonal loadings.

also be modified to operate in a continuous-flow mode, as discussed later in this chapter. Issues specific to the SBR process include (1) sludge wasting, (2) the application of process kinetics, and (3) selection of key operating conditions including the fraction of the tank contents to be removed during decanting and the settle, decant, and aeration times.

Sludge Wasting in SBRs. Sludge wasting is another important step in the SBR operation that is needed for SRT control and greatly affects performance. Wasting is not included as one of the five basic process steps because there is no set time period within the cycle dedicated to wasting. The amount and frequency of sludge wasting is determined by performance requirements, as with a conventional continuous-flow system. In an SBR operation, sludge wasting usually occurs during the react phase so that a uniform discharge of solids (including fine material and large floc particles) occurs. SBR tanks should be designed with the ability for surface wasting of mixed liquor as discussed in Sec. 8–3 as an effective means for foam control by suppressing the growth of *M. Parvicella* and bacteria causing nocardioform foam.

Application of Process Kinetics. During the react period, batch kinetics apply. The substrate concentration is much higher initially than would be present in a CMAS system, and the substrate concentration decreases with time as it is consumed by the biomass. The change in substrate concentration with time can be determined by starting with the substrate mass balance in Chap. 7 [Eq. (7–43)] for a continuous-flow complete-mix reactor:

$$\frac{dS}{dt}V = QS_o - QS - r_{su}V \tag{7–43}$$

where $$r_{su} = \frac{\mu_m XS}{Y(K_s + S)} \tag{7–15}$$

Other terms as defined previously.

Because $Q = 0$ for the batch reaction, the substrate concentration is

$$\frac{dS}{dt} = -\frac{\mu_m XS}{Y(K_s + S)} \tag{8–46}$$

Integration of Eq. (8–59) with respect to time yields.

$$K_s \ln\frac{S_o}{S_t} + (S_o - S_t) = X\left(\frac{\mu_m}{Y}\right)t \tag{8–47}$$

where S_o = initial substrate concentration at $t = 0$, mg/L
t = time, *d*
S_t = substrate concentration at time t, mg/L

The same kinetic expression applies for nitrification where $X = X_n$, the nitrifying bacteria concentration, $S = N$, the NH_4-N concentration, and the Monod model kinetic coefficients are substituted:

$$K_{NH_4} \ln\frac{N_o}{N_t} + (N_o - N_t) = X_n\left(\frac{\mu_{\max,AOB}}{Y_n}\right)t \tag{8–48}$$

where N_o = NH_4-N concentration at $t = 0$, mg/L
N_t = NH_4-N concentration at time t, mg/L
X_n = nitrifying bacteria concentration, mg/L

The maximum specific growth rate for nitrifying bacteria is affected by the DO concentration [Eq. (7–94)], so this effect is included in Eq. (8–49) as follows:

$$K_{\mathrm{NH_4}} \ln\frac{N_o}{N_t} + (N_o - N_t) = X_n\left(\frac{\mu_{\mathrm{max,AOB}}}{Y_{\mathrm{AOB}}}\right)\left(\frac{S_o}{K_{\mathrm{O,AOB}} + S_o}\right)t \qquad (8\text{–}49)$$

The above batch kinetic equations can be used to determine if the react period aeration time selected for SBR design is sufficient to provide the desired amount of degradation. An overall mass balance can be done first, assuming a certain amount of substrate is removed, to determine the heterotrophic and nitrifier biomass concentrations (X and X_n) for use in the equations. The time needed for dissolved BOD removal is relatively short (less than 1 h) due to the batch kinetics for treating domestic wastewater, resulting in a relatively low initial dissolved BOD concentration. For nitrification, SBR aerobic react times may range from 2.0 to 4.0 h. It should be noted that the SRTs for the SBR and continuous-flow activated sludge processes are not comparable. At the same SRT, the SBR may be expected to be more efficient because of its batch kinetics, but the biomass is only under aeration for a fraction of time, due to the time needed for settling, decanting, and filling without aeration so that the effective aerobic SRT is lower.

Because the substrate concentration changes with time, the substrate utilization and oxygen demand rates change, progressing from high to low levels. The aeration system should be designed to reflect the changing requirements in oxygen demand. Additional descriptive material for the SBR process is provided in a later part of this section.

Key Operating Conditions. Because of the many design variables involved in an SBR design, an iterative approach is necessary in which key reactor operating conditions are first assumed. A set of different operating conditions can be evaluated by use of a spreadsheet analysis to determine the most optimal choice. The key operating conditions that must be selected are (1) the fraction of the tank contents removed during decanting and (2) the settle, decant, and aeration times. Because the fill volume equals the decant volume, the fraction of decant volume equals the fraction of the SBR tank volume used for the fill volume per cycle and is defined as the *fill fraction* or fill volume to total volume ratio. The fill volume fraction is a key SBR design parameter that is used to determine the required liquid volume of an SBR tank. The allowable fraction is based on having a sufficient supernatant liquid above the settled solids during decanting. The fill fraction must be lower for operations with higher MLSS concentration and higher SVI values as a greater depth would be needed to contain the settled solids. The fraction of the total tank depth needed to contain the settled volume can be estimated as follows:

$$F(V_T) = (\mathrm{MLSS,\ mg/L})\left(\frac{\mathrm{SVI,\ mL/g}}{10^6}\right) \qquad (8\text{–}50)$$

where $F(V_T)$ = fraction of SBR full tank volume occupied by settled solids

Allowable fill volume fractions are shown on Fig. 8–21 as a function of SVI and MLSS concentration at the full tank volume. The fill fractions are based on having 0.2 to 0.5 m of supernatant depth below the decanter. Depending on the decanter design and the expected fluid disturbances during decant, a more conservative lower fill volume fraction value than that shown for a given MLSS concentration and SVI would be used. The fill volume

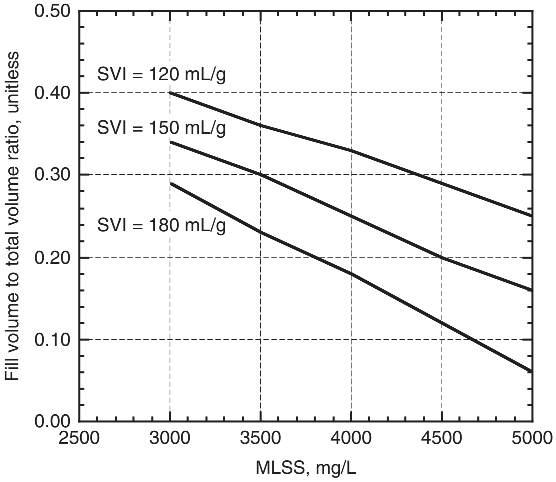

Figure 8–21

Recommended fill/decant fraction for sequencing batch reactor tank as a function of design MLSS concentration at full volume and SVI.

fraction is normally 0.25 or less to allow for a supernatant with low suspended solids after settling. The fill volume per cycle, based on the number of cycles per day and daily flowrate, is used in combination with the fill volume fraction to determine the volume of the SBR tank. The design procedure for the SBR system is presented in Table 8–17 and illustrated in Example 8–5.

Table 8–17

Computation approach for the design of a sequencing batch reactor

Item	Description
1.	Obtain influent wastewater characterization data, define effluent requirements, and define safety factors.
2.	Select the number of SBR tanks.
3.	Select the react/aeration, settling, and decant times. Determine the fill time and total time per cycle. Determine the number of cycles per day.
4.	From the total number of cycles per day, determine the fill volume per cycle
5.	Select the MLSS concentration and determine the fill volume fraction relative to the total tank volume. Determine the decant depth. Using the computed depths, determine the SBR tank volume.
6.	Determine the SRT for the SBR process design developed.
7.	Determine the amount of TKN added that is nitrified.
8.	Calculate the nitrifier biomass concentration and determine if the aeration time selected is sufficient for the nitrification efficiency needed.
9.	Adjust the design as needed–additional iterations may be done.
10.	Determine the decant pumping rate.
11.	Determine the oxygen required and average transfer rate.
12.	Determine the amount of sludge production.
13.	Calculate the F/M and BOD volumetric loading.
14.	Evaluate alkalinity needs.
15.	Prepare design summary.

EXAMPLE 8–5 **Sequencing Batch Reactor Process Design** Prepare a process design for a sequencing batch reactor process to treat a domestic wastewater with a flowrate of 7570 m^3/d with the following wastewater characteristics. The reactor mixed-liquor concentration at full volume is 3500 g/m^3 and the temperature is 12°C. The required effluent NH_4-N concentration = 1.0 g/m^3. Primary treatment is not used.

Wastewater characteristics:

Constituent	Concentration, mg/L
BOD	220
sBOD	80
COD	485
sCOD	160
rbCOD	80
TSS	240
VSS	220
TKN	35
NH_4-N	25
TP	6
Alkalinity	200 as $CaCO_3$
bCOD/BOD ratio	1.6

Note: g/m^3 = mg/L.

Design conditions and assumptions:
1. Use 2 tanks
2. Total liquid depth when full = 6 m
3. Decant depth = 20 percent of tank depth
4. SVI = 150 mL/g
5. Ammonia oxidized (NO_X) = 80 percent of TKN
6. Use kinetic coefficients in Table 8–14
7. bCOD = 1.6(BOD)

Solution

1. Develop wastewater characteristics needed for process design.
   a. Determine bCOD.

$$\text{bCOD} = 1.6(220\ g/m^3) = 352\ g/m^3$$

   b. Determine nbVSS concentration using Eq. (8–7), (8–8), (8–9).

$$\text{bsCOD} = 1.6(\text{sBOD})$$

$$\text{bsCOD} = 1.6(80\ g/m^3) = 128\ g/m^3$$

$$\text{nbsCOD}_e = \text{sCOD} - \text{bsCOD} = (160 - 128)\ g/m^3 = 32\ g/m^3$$

$$\text{nbpCOD} = \text{COD} - \text{bCOD} - \text{nbsCOD} = (485 - 352 - 32)\ g/m^3 = 101\ g/m^3$$

$$\text{VSS}_{\text{COD}} = \frac{\text{TCOD} - \text{sCOD}}{\text{VSS}}$$

$$\text{VSS}_{\text{COD}} = \frac{(485 - 160)\ \text{g/m}^3}{220\ \text{g/m}^3} = 1.48\ \text{g COD/g VSS}$$

$$\text{nbVSS} = \frac{\text{nbpCOD}}{\text{VSS}_{\text{COD}}} = \frac{101\ \text{g/m}^3}{1.48\ \text{g COD/g VSS}} = 68.2\ \text{g/m}^3$$

c. Determine iTSS.

$$\begin{aligned}\text{iTSS} &= \text{TSS}_o - \text{VSS}_o\\ &= (240 - 220)\ \text{g/m}^3 = 20\ \text{g/m}^3\end{aligned}$$

2. Determine SBR operating cycle.
The total cycle time (T_c) consists of fill (t_F), react/aerate (t_A), settle (t_S), and decant (t_D). An idle time (t_I) can also be added. Thus, the total cycle time $T_C = t_f + t_A + t_S + t_D + t_I$. At least 2 tanks are needed so that when one tank is in the fill period (t_F), the following periods are occurring in the other tank: aeration t_A, settling t_S, and decant t_D cycles. No idle time is included in this example.

$t_F = t_A + t_S + t_D$

Select period times:

Assume: $t_A = 2.0$ h
$t_S = 0.50$ h
$t_D = 0.50$ h
$t_I = 0$

Then $t_F = 2.0 + 0.50 + 0.50 = 3.0$ h for each tank (Note: Some aeration may also be done in the fill period, but if aeration occurs over more than 50% of the fill time, filamentous bulking may be encouraged.)

Total cycle time $T_C = t_f + t_A + t_S + t_D = 6.0$ h

$$\text{Number of cycles/tank}\cdot\text{d} = \frac{(24\ \text{h/d})}{(6\ \text{h/cycle})} = 4$$

$$\begin{aligned}\text{Total number of cycles/d} &= (2\ \text{tanks})\left[\frac{(4\ \text{cycles/d})}{\text{tank}}\right]\\ &= 8\ \text{cycles/d}\end{aligned}$$

$$\text{Fill volume/cycle} = \frac{(7570\ \text{m}^3/\text{d})}{(8\ \text{cycles/d})} = 946.3\ \text{m}^3/\text{fill}$$

3. Determine the tank volume and overall hydraulic retention time τ.
Full liquid depth = 6.0 m
Decant depth = 0.2 (6.0 m) = 1.2 m

$$\text{V}_\text{T} = \frac{\text{V}_\text{F}/\text{tank}}{0.2} = \frac{(946.3\ \text{m}^3/\text{tank})}{0.2} = 4732\ \text{m}^3/\text{tank}$$

$$\text{Overall}\ \tau = \frac{2\ \text{tanks}(4732\ \text{m}^3/\text{tank})(24\ \text{h/d})}{(7570\ \text{m}^3/\text{d})} = 30.0\ \text{h}$$

4. Determine the SRT.

a. Use Eqs. (8–20), (8–21), and (7–57) in Table 8–10 to obtain a relationship that can be used to solve for ($P_{X,\,\text{TSS}}$) SRT.

$$(P_{X,\text{TSS}})\text{SRT} = \frac{QY_\text{H}(S_o - S)SRT}{[1 + b_\text{H}(\text{SRT})](0.85)}$$

$$+ Q(\text{nbVSS})\text{SRT} + \frac{QY_n(\text{NO}_x)\text{SRT}}{[1 + b_n(\text{SRT})](0.85)}$$

$$+ \frac{(f_d)(b_\text{H})Q(Y_\text{H})(S_o - S)\text{SRT}^2}{[1 + b_\text{H}(S\text{RT})](0.85)} + Q(\text{TSS}_o - \text{VSS}_o)\text{SRT}$$

$$\begin{aligned}(P_{X,\text{TSS}})\text{SRT} &= (V)(X_\text{MLSS}) = (4732\text{ m}^3)(3500\text{ g/m}^3)\\ &= 16{,}562{,}000\text{ g}\end{aligned}$$

b. Develop input data to solve the above relationship for SRT:

nbVSS = 68.2 g/m^3 (from Step 1b)

Assume $S_o \approx S_o - S$

S_o = bCOD = 352 g/m^3 (Step 1a)
Q = (7570 m^3/d)/2 tanks = 3785 m^3/tank·d
iTSS$_o$ = TSS$_o$ − VSS$_o$ = 20 g/m^3 (Step 1c)
NO$_x$ = (0.80)(35 g TKN/m^3) = 28 g/m^3

Kinetic coefficients from Table 8–14,

Y = 0.45 g VSS/g bCOD
$b_{12°\text{C}} = 0.12\text{ g/g·d}(1.04)^{12-20} = 0.088\text{ g/g·d}$
Y_n = 0.15 g VSS/g NO$_x$

The nitrifier endogenous decay rate is higher during aeration (0.17 g/g·d at 20°C) and reduced during non-aerobic periods (0.07 at 20°C per Chap. 7, Sec. 7–9). Thus, a weighted average endogenous decay rate is determined.
Aerobic:
$b_{n,12°\text{C}} = 0.17\text{ g/g·d}(1.029)^{12-20} = 0.135\text{ g/g·d}$
Anoxic:
$b_{n,12°\text{C}} = 0.07\text{ (g/g·d)}(1.029)^{12-20} = 0.056\text{ g/g·d}$
Average:
$b_{n,12°\text{C}} = 0.135\text{ g/g·}(t_A/T_C) + 0.056\,(1 - t_A/T_C)\text{ g/g·d}$

$$\frac{t_A}{T_C} = \frac{2}{6} = 0.33$$

Average $b_{n,12°\text{C}}$ = (0.135 g/g·d)(0.33) + (0.056 g/g·d)(0.67) = 0.082 g/g·d

f_d = 0.15 g/g

Substituting values and calculations for above equation yields

$$16{,}562{,}000\text{ g} = \frac{(3785\text{ m}^3\text{/d})(0.45\text{ g VSS/g bCOD})(352\text{ g/m}^3)(\text{SRT})}{[1 + (0.088\text{ g/g·d})(\text{SRT})](0.85)}$$

$$+ (3785\text{ m}^3\text{/d})(68\text{ g/m}^3)(\text{SRT})$$

$$+ \frac{(3785\text{ m}^3\text{/d})(0.15\text{ g/g·d})(28\text{ g/m}^3)(\text{SRT})}{[1 + (0.082\text{ g/g·d})(\text{SRT})](0.85)}$$

$$+ \frac{(0.15\text{ g/g})(0.088\text{ g/g·d})(0.45\text{ g VSS/g bCOD})(3785\text{ m}^3\text{/d})(352\text{ g/m}^3)\text{SRT}^2}{[1 + (0.088\text{ g/g·d})(\text{SRT})](0.85)}$$

$$+ (3785\text{ m}^3\text{/d})(20\text{ g/m}^3)(\text{SRT})$$

Solve for SRT (use spreadsheet with solver or solve by successive trials)
SRT = 26.5 d

5. Determine MLVSS concentration.
   a. Solve Eq. (7–56) in Table 8–10 (SRT = 26.5 d) ($S_o \approx S_o - S$).

$$(P_{X,\mathrm{VSS}})\mathrm{SRT} = V_T(X_{\mathrm{MLVSS}})$$

$$(P_{X,\mathrm{VSS}})\mathrm{SRT} = \frac{Q(Y_{\mathrm{H}})(S_o - S)\mathrm{SRT}}{1 + b_{\mathrm{H}}(\mathrm{SRT})} + Q(\mathrm{nbVSS})\mathrm{SRT}$$

$$+ \frac{QY_n(\mathrm{NO}_x)\mathrm{SRT}}{1 + b_n(\mathrm{SRT})} + \frac{(f_d)(b_{\mathrm{H}})(Q)(Y_{\mathrm{H}})(S_o - S)\mathrm{SRT}^2}{1 + b_{\mathrm{H}}(\mathrm{SRT})}$$

$$= \frac{(3785\ \mathrm{m^3/d})(0.45\ \mathrm{g\ VSS/g\ bCOD})(352\ \mathrm{g/m^3})(26.5\ \mathrm{d})}{[1 + (0.088\ \mathrm{g/g{\cdot}d})(26.5\ \mathrm{d})]}$$

$$+ (3785\ \mathrm{m^3/d})(68\ \mathrm{g/m^3})(26.5\ \mathrm{d})$$

$$+ \frac{(3785\ \mathrm{m^3/d})(0.15\ \mathrm{g\ VSS/g\ NO}_x)(28\ \mathrm{g/m^3})(26.5\ \mathrm{d})}{[1 + (0.082\ \mathrm{g/g{\cdot}d})(26.5\ \mathrm{d})]}$$

$$+ \frac{(0.15\ \mathrm{g/g})(0.088\ \mathrm{g/g{\cdot}d})(0.45\ \mathrm{g\ VSS/g\ COD})(3785\ \mathrm{m^3/d})(352\ \mathrm{g/m^3})(26.5\ \mathrm{d})^2}{[1 + (0.088\ \mathrm{g/g{\cdot}d})(26.5\ \mathrm{d})]}$$

$$= 13{,}399{,}320\ \mathrm{m^3{\cdot}g/m^3} = V_T(X_{\mathrm{MLVSS}})$$

$$\mathrm{V_T} = 4732\ \mathrm{m^3}\ \text{(Step 3)}$$

$$\mathrm{V_T(X_{MLVSS})} = (4732\ \mathrm{m^3})(\mathrm{X_{MLVSS}})$$

$$13{,}399{,}320\ (\mathrm{m^3{\cdot}g/m^3}) = (4732\ \mathrm{m^3})(X_{\mathrm{MLVSS}})$$

$$\mathrm{X_{MLVSS}} = 2832\ \mathrm{g/m^3}$$

   b. Determine the fraction of MLVSS.

$$\frac{X_{\mathrm{MLVSS}}}{X_{\mathrm{MLSS}}} = \frac{(2832\ \mathrm{g/m^3})}{(3500\ \mathrm{g/m^3})} = 0.81$$

6. Determine amount of $\mathrm{NH_4}$-N oxidized (NO_x).
   Nitrogen balance (Eq. 8–24) in Table 8–10

$$\mathrm{NO}_x = \mathrm{TKN}_o - \mathrm{N}_e - 0.12\,P_{X,\mathrm{bio}}/Q$$

$$P_{X,\mathrm{bio}} = [\text{Items } A + B + C \text{ in Eq. } (8\text{–}20)]$$

$$P_{X,\mathrm{bio}} = \frac{QY_{\mathrm{H}}(S_o - S)}{1 + b_{\mathrm{H}}(\mathrm{SRT})} + \frac{QY_n(NO_x)}{1 + b_n(\mathrm{SRT})} + \frac{(f_d)(b_{\mathrm{H}})QY_{\mathrm{H}}(S_o - S)\mathrm{SRT}}{1 + b_{\mathrm{H}}(\mathrm{SRT})}$$

$$= \frac{(3785\ \mathrm{m^3/d})(0.45\ \mathrm{g\ VSS/g\ bCOD})(352\ \mathrm{g/m^3})}{[1 + (0.088\ \mathrm{g/g{\cdot}d})(26.5\ \mathrm{d})]}$$

$$+ \frac{(3785\ m^3/\mathrm{d})(0.15\ \mathrm{g\ VSS/g\ NO_x})(28\ \mathrm{g/m^3})}{[1 + (0.082\ \mathrm{g/g{\cdot}d})(26.5\ \mathrm{d})]}$$

$$+ \frac{(0.15\ \mathrm{g/g})(0.088\ \mathrm{g/g{\cdot}d})(3785\ \mathrm{m^3/d})(0.45\ \mathrm{g\ VSS/g\ COD})(352\ \mathrm{g/m^3})(26.5\ \mathrm{d})}{[1 + (0.088\ \mathrm{g/g{\cdot}d})(26.5\ \mathrm{d})]}$$

$$= 247{,}995\ \mathrm{g/d} = 248.0\ \mathrm{kg/d}$$

$$\mathrm{NO}_x = 35.0 - 1.0 - \frac{(0.12)(248.0\ \mathrm{kg/d})(10^3\ \mathrm{g/1\ kg})}{(3785\ \mathrm{m^3/d})}$$

$$= (35.0 - 1.0 - 7.9)\ \mathrm{g/m^3}$$

$\mathrm{NO}_x = 26.1\ \mathrm{g/m^3}$ Note: iteration by substituting 26.1 in place of the assumed 28 $\mathrm{g/m^3}$ for NO_x in item B above results in $\mathrm{NO}_x = 26.1\ \mathrm{g/m^3}$.

7. Check the degree of nitrification to determine whether NH_4-N will be removed to a level of 1.0 g/m^3 in a 2-h aeration period.
   a. Determine the amount of oxidizable N available. (Assumes all organic nitrogen is converted to NH_4-N)

$$NO_x = 26.1\ g/m^3 = NH_4\text{-N in feed flow that can be oxidized}$$

Oxidizable NH_4-N added/cycle:

$$\begin{aligned} V_F(NO_x) &= 946.3\ m^3/\text{cycle}\ (26.1\ g/m^3) \\ &= 24{,}698\ g/\text{fill} \end{aligned}$$

NH_4-N remaining before fill $= V_s(N_e)$

$$N_e = 1.0\ g/m^3\ NH_4\text{-N}$$

$$\begin{aligned} V_s(N_e) &= N_e(V - V_F) \\ &= (1.0\ g/m^3)[(4732 - 946.3)\ m^3] \\ &= 3785.7\ g \end{aligned}$$

Total oxidizable N at beginning of cycle = (24,698 + 3785.7) g = 28,483.7 g

$$\text{Initial concentration} = N_o = \frac{28{,}483.7\ g}{V_T} = \frac{28{,}483.7\ g}{4732\ m^3} = 6.0\ g/m^3$$

   b. Determine the reaction time.
   Using Eq. (8–53), the react time (aeration) after fill to achieve the desired NH_4-N concentration can be calculated. First, the nitrifier concentration must be determined.

$$K_{NH_4} \ln\left(\frac{N_o}{N_t}\right) + (N_o - N_t) = X_n\left(\frac{\mu_{\max,AOB}}{Y_n}\right)\left(\frac{S_o}{K_{o,AOB} + S_o}\right)t$$

      i. Nitrifier concentration.

$$\begin{aligned} X_n &= \frac{Q(Y_n)(NO_x)SRT}{[1 + b_n(SRT)]V} \\ &= \frac{(3785\ m^3/d)(0.15\ g\ VSS/g\ NH_4\text{-N})(26.1\ g/m^3)(26.5\ d)}{[1 + (0.082\ g/g\cdot d)(26.5\ d)](4732\ m^3)} \\ &= 26.1\ g/m^3 \end{aligned}$$

Use kinetic coefficients from Table 8–14.

$$\mu_{m,12°C} = 0.90\ g/g\cdot d\,(1.072)^{12-20} = 0.52\ g/g\cdot d$$

$$K_{NH_4,12°C} = 0.50\ g/m^3$$

$$K_o = 0.50\ g/m^3$$

      ii. Determine the time for reaction.

Solve for t for $N_o = 6.0\ g/m^3$, $N_e = 1.0\ g/m^3$

$$0.50\ln\left[\frac{(6.0\,\text{g/m}^3)}{(1.0\,\text{g/m}^3)}\right] + [(6.0 - 1.0)\,\text{g/m}^3] = (26.1\,\text{g/m}^3)\left[\frac{(0.52\,\text{g/g·d})}{(0.15\,\text{g/g})}\right]\left(\frac{2.0}{0.5 + 2.0}\right)t$$

$$t = 0.08\,\text{d} = 1.95\,\text{h}$$

c. Determine the aeration time.
Required aeration time = 1.95 h
Aeration time selected was 2.0 h; therefore, aeration time is satisfactory.

8. Determine the decant pumping rate.
Decant volume = fill volume

$$V_F = 946.3\,\text{m}^3$$

Decant time = 30 min

$$\text{Pumping rate} = \frac{946.3\,\text{m}^3}{30\,\text{min}} = 31.5\ \text{m}^3/\text{min}$$

9. Determine total oxygen required/tank using Eq. (8–23).

$$\begin{aligned} R_o &= Q(S_o - S) - 1.42P_{X,\text{bio}} + 4.57Q(\text{NO}_x) \\ &= (3785\,\text{m}^3/\text{d})(352\,\text{g/m}^3)(1\,\text{kg}/10^3\,\text{g}) - 1.42(248.0\,\text{kg/d}) \\ &\quad + 4.57(26.1\,\text{g/m}^3)(3785\,\text{m}^3/\text{d})(1\,\text{kg}/10^3\,\text{g}) \end{aligned}$$

$$R_o = (1332 - 352.1 + 451.5)\,\text{kg/d} = 2136\,\text{kg/d}$$

Number of cycles/d = 4
Oxygen required per cycle

$$= \frac{(2136\ \text{kg/d})}{(4\ \text{cycles/d})} = 534\ \text{kg O}_2/\text{cycle}$$

Aeration time/cycle = 2 h

$$\text{Average oxygen transfer rate} = \frac{(534\,\text{kg O}_2/\text{cycle})}{(2\ \text{h/cycle})} = 267\ \text{kg O}_2/\text{h}$$

Note: The oxygen demand will be much higher at the beginning of the aeration period, so the aeration system oxygen transfer capacity must be higher than the average oxygen transfer rate. The oxygen transfer rate should be multiplied by a factor of 2.0 to 3.0 to provide sufficient oxygen transfer at the beginning of the cycle and to handle peak loads.

10. Determine sludge production using Eq. (7–57). (MLSS = X_{TSS})

$$\begin{aligned} P_{X,\text{TSS}} &= \frac{(V)(\text{MLSS})}{\text{SRT}} \\ &= \frac{(2\,\text{tanks})(4732\,\text{m}^3/\text{tank})(3500\,\text{g/m}^3)(1\,\text{kg}/10^3\,\text{g})}{26.5\,\text{d}} \\ &= 1250\,\text{kg/d} \end{aligned}$$

$$\begin{aligned}\text{bCOD removed} &= (7570\,\text{m}^3/\text{d})(352\,\text{g/m}^3)(1\,\text{kg}/10^3\,\text{g})\\ &= 2664\,\text{kg/d}\end{aligned}$$

$$\text{BOD removed} = \frac{(2664\,\text{kg bCOD/d})}{(1.6\,\text{kg bCOD/kg BOD})} = 1665\,\text{kg/d}$$

$$\text{Observed yield, g TSS/g BOD} = \frac{(1250\text{ kg TSS/d})}{(1665\text{ kg BOD/d})} = \frac{0.75\,\text{g TSS}}{\text{g BOD}}$$

$$\begin{aligned}\text{Observed yield, g VSS/g BOD} &= \left(\frac{0.75\,\text{g TSS}}{\text{g BOD}}\right)\left(\frac{0.81\,\text{g VSS}}{\text{g TSS}}\right)\\ &= \frac{0.61\,\text{g VSS}}{\text{g BOD}}\end{aligned}$$

thus a higher yield results.

Design parameter	Unit	Value
Average flowrate	m^3/d	7570
Average BOD load	kg/d	1665
Average TKN load	kg/d	265
Number of tanks	Number	2
Fill time	h	3.0
React time	h	2.0
Total aeration time	h	2.0
Settle time	h	0.5
Cycle time	h	6.0
Total SRT	d	26.5
Tank volume	m^3	4732

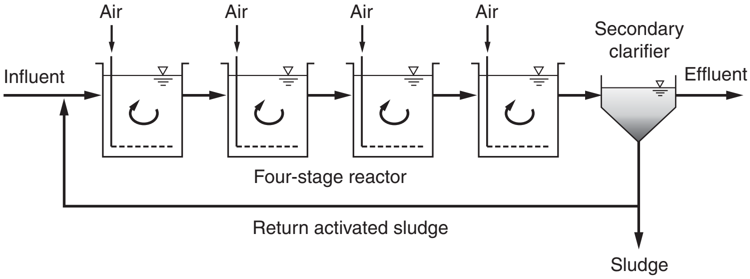
Average O_2 transfer rate	kg/h	267

Figure 8–22

Schematic diagram of a staged activated sludge process.



Staged Activated Sludge Process Design

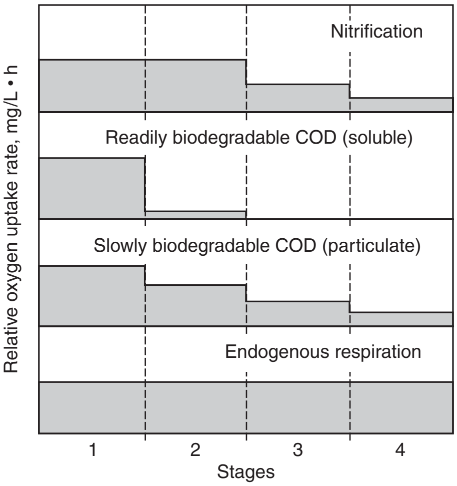
Important process variables specific to the staged activated sludge process design are the (1) oxygen demand, (2) oxygen demand distribution, and (3) NH_4-N concentration.

Oxygen Demand in Staged Processes. The oxygen demand varies in staged complete-mix reactor designs and can be high enough in the first stage to challenge the volumetric oxygen transfer capability of aeration equipment. With high-density fine bubble aeration diffusers, such as membrane aeration panels described in Sec. 5–12 in Chap. 5, oxygen transfer rates of 100 to 150 mg/L·h are possible, with some manufacturers claiming higher rates. The changes in oxygen uptake rates (OURs) in each stage of a four-stage activated sludge process (defined as a function of oxygen needed for nitrification, rbCOD removal, particulate degradable COD, and endogenous respiration) are depicted on Fig. 8–23. Most of the rbCOD will be consumed in the first stage, and the OUR for pCOD degradation will decrease from stage to stage as a function of the degradation kinetics. The nitrification rate could be at a maximum zero-order kinetic rate in the first and second stages, due to higher NH_4-N concentrations in the early stages. Oxygen demand for endogenous respiration will be relatively constant from stage to stage.

Oxygen Demand Distribution. The oxygen demand distribution may be estimated to determine the aeration design for staged processes. The percent of the total oxygen consumption may range from 40, 30, 20, and 10 percent, respectively, for a four-stage system. One design approach that can be used to obtain an estimate of the oxygen

Figure 8–23

Changes in oxygen uptake rates for a staged activated sludge process.



demand in a staged system is to calculate the total oxygen demand as would be done for a CMAS process, and then estimate the oxygen demand distribution with consideration to the various components described above. With proper selection of the type and placement of the diffusers and by providing an air supply system with DO control in each portion of the system, the air can be provided where needed. Generally, the approach outlined above is satisfactory because during the life of the process, the oxygen demand will vary across the tank as the load changes. The effect of using a staged system as compared to a single CMAS tank for nitrification is illustrated in Example 8–6.

EXAMPLE 8–6 **Evaluation of Staged Reactors for Nitrification** Compare the steady-state nitrification performance of a four-stage activated sludge system with equal volumes per stage to that for a single-stage CMAS system with the same total volume. The hydraulic retention time is 8 h for both systems, and the same SRT is used. The CMAS system SRT is calculated for an effluent NH_4-N concentration of 0.50 g/m^3 and the amount of ammonia oxidized (NO_x) is assumed at 30.0 g/m^3. Use the kinetic coefficients given in Table 8–14, along with the following conditions:

Design conditions and assumptions:

Item	Unit	Value
Temperature	°C	16
$\mu_{max,16}$	g/g·d	0.681
K_{NH_4}	g/m^3	0.50
Y_n	g VSS/g NH_4-N	0.15
$b_{n,16}$	g/g·d	0.151
Amount of NH_4-N oxidized (NO_x)	g/m^3	30.0
Effluent NH_4-N	g/m^3	0.50
DO	g/m^3	2.0
K_o	g/m^3	0.5
RAS recycle ratio	Unitless	0.5

Note: g/m^3 = mg/L.

Solution

1. Determine the SRT value and the concentration of the nitrifying bacteria for a single-stage system, $\tau = 8\text{ h} = 0.33\text{ d}$, $N = 0.50\text{ g/m}^3$.
   a. Solve for the specific growth rate using Eq. (7–94) in Table 8–10.

$$\mu_{AOB} = \mu_{max,AOB,16}\left(\frac{S_{NH}}{S_{NH} + K_{NH}}\right)\left(\frac{S_o}{S_o + K_{o,AOB}}\right) - b_{AOB}$$

$$\mu_{AOB} = \left\{\frac{(0.681\text{ g/g·d})(0.50\text{ g/m}^3)}{[(0.50 + 0.50)\text{ g/m}^3]}\right\}\left\{\frac{(2.0\text{ g/m}^3)}{[(0.50 + 2.0)\text{ g/m}^3]}\right\} - 0.151 = 0.121\text{ g/g·d}$$

b. Solve for SRT using Eq. (7–98) in Table 8–10.

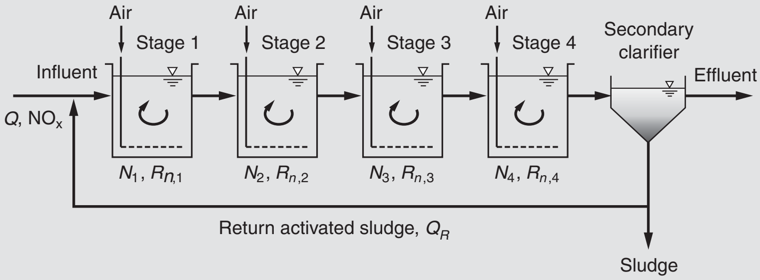
$$\text{SRT} = \frac{1}{\mu_{\text{AOB}}} = \frac{1}{0.121\ \text{g/g}\cdot\text{d}} = 8.24\ \text{d}$$

c. Solve for the concentration of nitrifying bacteria using a modified form of Eq. (7–42).

$$X_n = \frac{(\text{SRT})Y_n(\text{NO}_x)}{\tau[1 + b_n(\text{SRT})]}$$

$$= \frac{(8.24\ \text{d})(0.15\ \text{g/g})(30\ \text{g/m}^3)}{(0.33\ \text{d})[1 + (0.151\ \text{g/g}\cdot\text{d})(8.24\ \text{d})]} = 50.1\ \text{g/m}^3$$

2. Perform nitrogen mass balances for a four-stage system shown on the following figure using equal volumes per stage. The total volume of the four-stage system is equal to the volume of the CMAS system, τ/stage = 0.333 d/4 = 0.0833 d/stage.



a. For Stage 1

Accumulation = in − out + generation

$$\frac{dN_1}{dt}V = Q(\text{NO}_x) + Q_R N_4 - (Q + Q_R)N_1 - R_{n,1}V$$

The rate expression for nitrification, derived from Eq. (7–101) in Table 8–10 includes a correction for the DO concentration, and is given by

$$r_{\text{NH}_4} = \left(\frac{\mu_{\text{max,AOB}}}{Y_{\text{AOB}}}\right)\left(\frac{S_{\text{NH}_4}}{S_{\text{NH}_4} + K_{\text{NH}_4}}\right)\left(\frac{S_o}{S_o + K_{o,\text{AOB}}}\right)X_{\text{AOB}}$$

where Q = wastewater flowrate, m^3/d

NO_x = amount of available influent NH_4-N oxidized, 30 g/m^3

Q_R = recycle flowrate from stage 4, m^3/d

Q_R/Q = 0.50

N_1 = NH_4-N concentration for stage 1, g/m^3

N_4 = NH_4-N concentration for stage 4, g/m^3

$R_{n,1}$ = nitrification rate for stage 1, $\text{g/m}^3\cdot\text{d}$

X_n = nitrifying bacteria concentration, g/m^3

The nitrifying bacteria concentration is the same as that calculated for the CMAS system assuming that the same amount of NH_4-N is removed and the systems are at the same SRT.

At steady state $dN_1/dt = 0$, and

$$\text{NO}_x + Q_R/QN_4 - (1 + Q_R/Q)/N_1 - R_{n,1}V/Q = 0$$

$$\text{NO}_x + 0.5N_4 = 1.5N_1 + R_{n,1}(\tau)$$

where $\tau = 0.0833$ d, detention time of stage 1
$NO_x = 30\ g/m^3$

b. For Stage 2, use the same procedure as Stage 1.

$$V\frac{dN_2}{dt} = (Q + Q_R)N_1 - (Q + Q_R)N_2 - R_{n,2}V$$

$$1.5N_1 = 1.5N_2 + R_{n,2}(\tau)$$

c. For Stage 3

$$1.5N_2 = 1.5N_3 + R_{n,3}(\tau)$$

d. For Stage 4

$$1.5N_3 = 1.5N_4 + R_{n,4}(\tau)$$

3. $R_{n,i(i=1\text{–}4)}$ is a function of the NH_4-N concentration (N) in each stage:
For stage 1,

$$R_{n,i} = \left[\frac{(0.681\ \text{g/g·d})}{(0.15\ \text{g VSS/g NH}_4\text{-}N)}\right]\left\{\frac{N_i}{[(0.50 + N_i)\text{g/m}^3]}\right\}\left\{\frac{2.0\ \text{g/m}^3}{[(0.5 + 2.0)\ \text{g/m}^3]}\right\}(50.1\ \text{g/m}^3)$$

$$R_{n,i} = 181.96\left\{\frac{N_i}{[(0.50 + N_i)\ \text{g/m}^3]}\right\},\ \text{Where } i = 1, 2, 3, \text{or } 4 \text{ for stages } 1\text{–}4$$

4. The above equations for the four stages are solved with a spreadsheet program starting with Stage 1 either by using Solver in the Excel software or by an iterative technique. In the iterative technique the value for N_4 is assumed and N_1 is calculated. Subsequently N_2, N_3 and N_4 are calculated. Using Solver, the following effluent NH_4-N concentrations are computed for each stage for a return sludge recycle ratio of 0.50. In addition a solution is also shown for a return sludge recycle ratio of 6.0 as would be typical for an MBR system:

	NH_4-N concentration, g/m^3	
Stage	Recycle ratio = 0.50	Recycle ratio = 6.0
1	10.64	2.89
2	2.30	1.34
3	0.15	0.39
4	0.01	0.08

Comment Based on the above results, the same amount of nitrification can be achieved theoretically with the use of 4 stages for the aerobic nitrification step in a little less than 75 percent of the aeration tank volume required for a CMAS design. Thus, a staged nitrification reactor is more efficient than a CMAS reactor design and compared to the CMAS the staged system can have a lower SRT and thus lower total volume. Or for the same SRT and volume, the staged system would produce a lower average effluent NH_4-N concentration under diurnal varying ammonia loads. The above solution is also illustrative of the importance of the return activated sludge recycle ratio. The effluent NH_4-N concentration would be higher for an MBR system, which has a higher recycle ratio. The effect of the higher recycle ratio is to dilute the influent NH_4-N concentration more so that the NH_4-N concentration is lower in the first stage. Because the nitrification rate is related to the NH_4-N concentration, the rate is lower and thus the effluent concentration is higher for the same reactor volume.

Alternative Processes for BOD Removal and Nitrification

Over the past 30 years numerous activated sludge processes have been developed for the removal of organic material (BOD) and for nitrification. Some of the processes are modifications or variations of basic processes that have evolved to meet different performance objectives. Descriptions and flowsheets are presented in Table 8–18 for representative processes used for BOD removal and nitrification. The processes are grouped according to the basic reactor configuration: plug-flow, complete-mix, and sequentially operated systems. A view of a large wastewater treatment plant using plug-flow reactors is shown on Fig. 8–24 on page 792.

High Rate Processes. The high rate processes identified in Table 8–18 [(a) through (f)] differ in terms of their aeration configuration, aeration equipment design, solids retention time, operating mode, and ability to remove nitrogen, and some are proprietary. The contact stabilization and high-purity oxygen processes are used primarily for BOD removal only, are designed for relatively short SRTs, and require less space than other processes. These processes are particularly attractive for large municipalities where space is limited and nitrification is not needed. The conventional plug-flow, step-feed, and complete-mix processes are used for both BOD removal and nitrification and are applied over a wide range of SRTs, depending on the wastewater temperature and treatment needs. The primary motivation for using the two-sludge AB process is to reduce the amount of energy imported to the WWTP. Removal of BOD at the low SRT in the high rate first step requires less aeration energy and moves a larger amount of the influent organic material to anaerobic digestion for increased methane production.

Low Rate Processes. In contrast to the high-rate processes described above, the remaining processes in Table 8–18 [(g) through (n)] are generally operated with longer aeration times and higher SRTs, though the oxidation ditch has also been applied at lower SRTs to provide a mixing and aeration alternative to the CMAS processes using diffused aeration. Conventional extended aeration, oxidation ditch, Orbal™, and CCAS™, processes are used commonly in smaller WWTPs and employ a simpler treatment scheme by eliminating primary treatment and anaerobic digestion. An oxidation ditch and a Biolac® process are shown on Fig. 8–25 (a) and (b) respectively (on page 792) and described in Table 8–18 (h) and (k), respectively. Larger aeration tanks with longer SRTs, usually exceeding 20 d, are used.

The process approach is attractive for smaller communities where space is not an issue and less complex operation is preferred. The large aeration tank volume provides good equalization at high flow and loading occurrences, and a high-quality effluent is produced. With the exception of the conventional extended aeration process, the systems are often operated to promote denitrification in addition to nitrification. The aeration and mixing of the channel-flow processes (oxidation ditch, Orbal™, and CCAS™) require much less energy for mixing than needed for aeration so that aeration equipment design is based on meeting oxygen requirements instead of tank mixing. Less energy is required in comparison to conventional extended aeration processes in which mixing energy controls. In the past, the oxidation ditch and extended aeration processes were thought to need long SRTs to provide well-stabilized biosolids for reuse. However, with stricter regulations governing biosolids stabilization (see Chap. 14), separate aerobic digestion facilities are used to meet the requirements for reuse.

Table 8–18

Description of activated sludge processes for BOD removal and nitrification

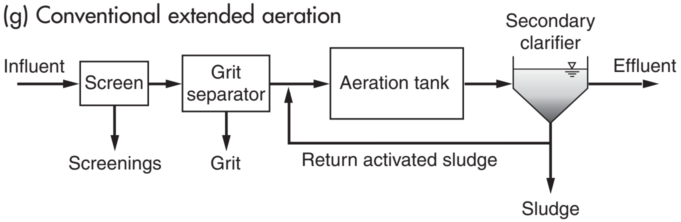
Process	Description
(a) Complete mix activated sludge (CMAS) 	The CMAS process is an application of the flow regime of a continuous-flow stirred tank reactor. Settled wastewater and recycled activated sludge are introduced typically at several points in the aeration tank. The organic load on the aeration tank, MLSS concentration, and oxygen demand are uniform throughout the tank. An advantage of the CMAS process is the dilution of shock loads that occur in the treatment of industrial wastewaters. The CMAS process is relatively simple to operate but tends to have low organic substrate concentrations (i.e., low F/M ratios) that encourage the growth of filamentous bacteria, causing sludge bulking problems.
(b) Conventional plug flow 	Conventional *plug flow* activated sludge originated from the use of narrow aeration tank widths (typically 8 to 10 m) as a result of using sidewall, coarse bubble aeration for mixing and aeration. The area provided by the limited width and the use of liquid depths in the range of 5 to 6 m (16 to 20 ft) required tank lengths typically >100 m (330 ft). Settled wastewater and return activated sludge (RAS) enter the front end of the aeration tank and typically travel through 3 to 4 channels (passes) before flow to the secondary clarifier. The oxygen demand is very high at the front of the tank and decreases with increasing tank length. The aeration system must be designed to meet the changing oxygen demand, and has been referred to as tapered aeration to reflect the change from higher aeration rates at the front of the plug flow tanks to lower aeration rates at the end. True plug flow does not exist due to back mixing caused by the aeration system. Baffle walls may be added at appropriate locations in plug flow tanks to select for a number of reactors in series with the appropriate desired volumes.
(c) Step feed 	Step feed is a modification of the conventional plug flow process in which the settled wastewater is introduced at 3 to 4 feed points in the aeration tank to equalize the F/M ratio, thus lowering peak oxygen demand. Generally, three or more parallel channels are used. Flexibility of operation is one of the important features of this process because the apportionment of the wastewater feed can be changed to suit operating conditions. The concentration of MLSS may be as high as 5000 to 9000 mg/L in the first pass, with lower concentrations in subsequent passes as more influent feed is added. The step feed process has the capability of carrying a higher solids inventory, and, thus, a higher SRT for the same volume as a conventional plug flow process. The step feed process can also be operated in the contact-stabilization mode by feeding only the last pass, and high wet weather flows can be bypassed to the last pass so that the solids load to the secondary clarifier can be minimized.

(*continued*)

Table 8–18 (*Continued*)

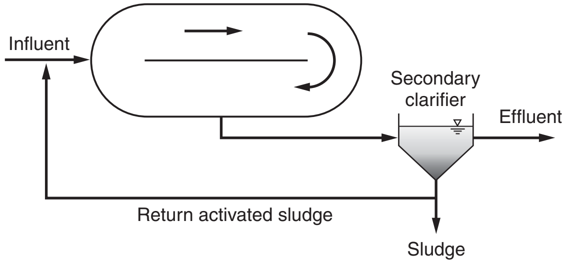
Process	Description
(d) Contact stabilization 	Contact stabilization uses two separate tanks or compartments for the treatment of the wastewater and stabilization of the activated sludge. The stabilized activated sludge is mixed with the influent (either raw or settled) wastewater in a contact zone. The contact zone detention time is relatively short (30 to 60 min), and the MLSS concentration in the contact zone is lower than that in the stabilization zone. Rapid removal of soluble BOD occurs in the contact zone and colloidal and particulate organics are captured in the activated sludge floc for degradation later in the stabilization zone. In the stabilization zone, return activated sludge (RAS) is aerated and the detention time is in the order of 1 to 2 h to maintain a sufficient SRT for sludge stabilization. Because the MLSS concentration is so much higher in the stabilization zone, the contact-stabilization process requires much less aeration volume than complete mix or conventional plug flow processes for the same SRT. The process was developed for BOD removal, and the short contact time limits the amount of soluble BOD degraded and NH_4-N oxidation. Nitrification can occur in the stabilization zone if there is sufficient volume to maintain the aerobic SRT needed for the nitrifying bacteria.
(e) Two-sludge AB Process 	The two sludge process is a two stage system using high rate activated sludge for BOD removal followed by a second stage for nitrification, which is operated at a longer SRT. A portion of the wastewater influent may be bypassed around the stage to provide BOD and suspended solids for the nitrification process to promote flocculation and solids capture in secondary clarification. Separation of the BOD removal stage from the nitrification stage reduces the aeration energy demands of the activated sludge process and directs more organic material to anaerobic digestion for increased methane production (Boehnke et al., 1997). The two stage approach also allows for removal of toxic substances in the first stage to protect the more sensitive nitrifying bacteria, but this problem is normally prevented by enforcing industrial pretreatment programs.
(f) High purity oxygen 	A staged enclosed reactor is used in the high purity oxygen activated sludge process (McWhirter, 1978). Three or four stages are generally used and the influent wastewater, RAS, and high-purity oxygen are added to the first stage. The headspace gas and mixed liquor flow concurrently from stage to stage. The oxygen partial pressure in the headspace may range from 40 to 60 percent in the first stage to 20 percent in the last stage. At high oxygen partial pressure, higher volumetric oxygen transfer rates are possible so that pure oxygen systems can have a higher MLSS concentration and operate at a shorter τ and higher volumetric organic loadings than conventional processes. The rate of oxygen addition is about 2 to 3 times greater than that by conventional aeration systems. Onsite oxygen generation equipment is needed to provide the pure oxygen gas for the process, making the process operation more complex than conventional activated sludge processes. Nitrification ability is limited with the high purity oxygen processes due to the accumulation of carbon dioxide in the gas headspace, which causes low pH in the mixed liquor (less than 6.5). Major advantages for pure oxygen systems are the reduced space requirement and greatly reduced quantities of off-gas if odor control and VOC control are required.

(g) Conventional extended aeration



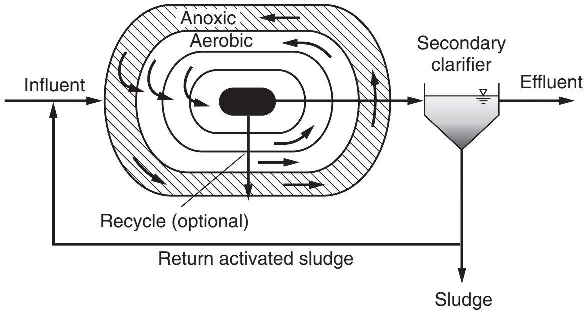
The extended aeration activated sludge process is designed with a very high SRT (20 to 30 d) and hydraulic retention times of 24 h or more. Because of the large volume needed and relatively low volumetric oxygen demand rate, the aeration equipment design is controlled by mixing needs and not oxygen demand. The process is used extensively for pre-engineered plants for small communities. Generally, primary clarification is not used. Secondary clarifiers are designed at lower hydraulic loading rates than conventional activated sludge clarifiers to better handle large flowrate variations typical of small communities. Although the biosolids are well stabilized, additional biosolids stabilization is required to permit beneficial reuse (see Chap. 14).

(h) Oxidation ditch



The oxidation ditch consists of a ring- or racetrack-shaped channel equipped with mechanical aeration and mixing devices. Screened and degritted wastewater enters the channel and is combined with the return activated sludge. The tank configuration and aeration and mixing devices promote unidirectional channel flow, so that the energy used for aeration is sufficient to provide mixing in a system with a relatively long hydraulic retention time. The aeration/mixing method used creates a velocity from 0.25 to 0.30 m/s (0.8 to 1.0 ft/s) in the channel, which is sufficient to keep the activated sludge in suspension. At these channel velocities, the mixed liquor completes a tank circulation in 5 to 15 min, and the magnitude of the channel flow is such that it can dilute the influent wastewater flowrate by a factor of 20 to 30. As a result, the process kinetics approach that of a complete mix reactor, but with plug flow along the channels. As the wastewater leaves the aeration zone, the DO concentration decreases and denitrification may occur downstream from the aeration zone. Brush-type or surface-type mechanical aerators are used for mixing and aeration (see Sec. 5–12 in Chap. 5).

(i) Orbal®



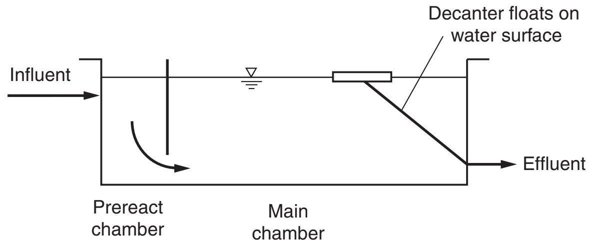
The Orbal® process is a variation of the oxidation ditch and uses a series of concentric channels within the same structure. Wastewater enters the larger outer channel and mixed liquor flows typically toward the center of the structure through at least two more channels before entering an internal clarifier or a distribution box. Disk aerators mounted on a horizontal shaft provide aeration. Channel depths range up to 4.3 m (14 ft). One version of the Orbal design (Bionutre™) limits the aeration rate in the first channel so that both nitrification and denitrification (anoxic condition) occur.

(*continued*)

Table 8–18 (*Continued*)

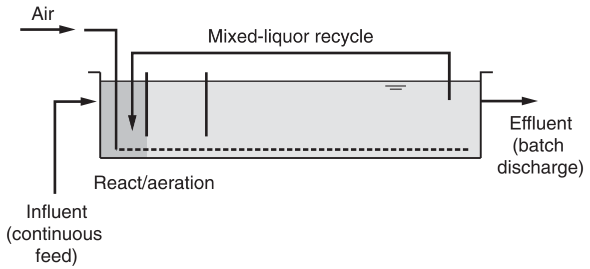
Process	Description
(j) Counter current aeration system (CCAS™)  	In the CCAS process, a unique aeration system is employed in which air diffusers are mounted at the bottom of a revolving bridge in a circular aeration tank. Because of the circulating motion of the bridge, which is moving faster than the aeration tank contents, fine bubbles are dispersed in a sweeping motion behind the traveling bridge. When the air is turned off, the movement of the diffusers creates enough mixing energy to keep the tank contents in suspension. The process is operated at a DO ranging from 0.7 to 1.0 mg/L. The low DO concentration is sufficient for nitrification at the long SRT, while allowing anoxic conditions to develop to promote denitrification. The system is normally designed with extended aeration SRTs.
(k) Biolac™ process  	Biolac is a proprietary process that combines long solids retention times with submerged aeration in earthen basins. Fine bubble membrane diffusers are attached to floating aeration chains that are moved across the basin by the air released from the diffusers. Aeration basins are typically 2.4 to 4.6 m (8 to 15 ft) deep. The process can be designed for nitrification since the SRT ranges from 40 to 70 d. The F/M ratio ranges from 0.04 to 0.1 and the MLSS range is from 1500 to 5000 g/m^3. A variation of the standard process, known as the "wave oxidation modification" allows biological nitrification and denitrification to occur simultaneously by using timers to cycle the air flowrate to each aeration chain. Either an internal or external clarifier can be used.
(l) Sequencing batch reactor (SBR)  	The SBR is a fill and draw type reactor system involving a single complete mix reactor in which all steps of the activated sludge process occur. For municipal wastewater treatment with continuous flow, at least 2 basins are used so that one basin is in the fill mode while the other goes through react, solids settling, and effluent withdrawal. An SBR goes through a number of cycles per day; a typical cycle may consist of 3-h fill, 2-h aeration, 0.5-h settle, and 0.5-h for withdrawal of supernatant. An idle step may also be included to provide flexibility at high flows. Mixed liquor remains in the reactor during all cycles, thereby eliminating the need for separate secondary sedimentation tanks. Decanting of supernatant is accomplished by either fixed or floating decanter mechanisms. SBR hydraulic retention times generally range from 18 to 30 h, based on influent flowrate and tank volume used. Aeration may be accomplished by jet aerators or coarse or fine bubble diffusers with submerged mixers (see Sec. 5–12 in Chap. 5). Separate mixing provides operating flexibility and is useful for contacting influent and mixed liquor during the fill period for anoxic or anaerobic operation period. Sludge wasting occurs normally during the aeration period.

(m) Intermittent cycle extended aeration system, ICEAS™)



The ICEAS process, developed in Australia, is another type of SBR process used for treating flowrates up to 500,000 m^3/d (130 Mgal/d). Influent wastewater is fed continuously through the same cycles of react, settle, and decant as in an SBR. The influent is fed into one side of a baffled chamber (a prereact zone) so the flow does not disturb the mixed liquor during the settling and decant period. Wastewater flows through openings at the bottom of the baffle wall and into the main react zone where BOD and nitrification occur. After aeration and settling, separated liquid is removed by an automated, time-controlled decant mechanism. Sludge wasting is also accomplished during this phase.

(n) Cyclic activated sludge system (CAAS™)



The CAAS process uses three baffled zones in an approximate volumetric proportion of 1/2/20, and mixed liquor is recycled from Zone 3 to Zone 1. Nitrification occurs because of the long SRTs used. Nitrate reduction is claimed to occur at significant levels in the sludge blanket during the settle and decant periods, as well as in the aeration period by operation at low DO concentrations. As in the ICEAS process, the influent wastewater is fed continuously while the effluent is removed on a batch basis.

Sequential Processes. Sequentially operated activated sludge processes that do not use separate tanks for liquid-solids separation are also described in Table 8–18 [(l) through (n)]. The processes include the sequencing batch reactor, batch decant reactor, and the cyclic activated sludge system. Operation is based usually on long τ and SRT values. The processes are attractive to small communities because of the simplicity of operation and relatively low cost. Sequentially operated processes are also adaptable to nitrogen removal, as discussed in Sec. 8–7.

Process Design Parameters. Typical parameters used for the design and operation of various activated sludge processes are presented in Table 8–19. Reactor configurations

Table 8–19

Typical design parameters for commonly used activated sludge processes

Process name	Type of reactor	SRT, d	F/M, kg BOD/kg MLVSS·d	Volumetric loading: lb BOD/1000 ft^3·d	Volumetric loading: kg BOD/m^3·d	MLSS, mg/L	Total τ, h
High-rate aeration (first step in AB Process)	CMAS or plug flow	0.5–2	1.5–2.0	75–150	1.2–2.4	500–1500	1–2
Contact stabilization	CMAS or plug flow	5–10	0.2–0.6	60–75	1.0–1.3	1000–3000[a] 6000–10,000[b]	0.5–1[a] 2–4[b]
High-purity oxygen	Staged	1–4	0.5–1.0	80–200	1.3–3.2	2000–4000	1–3
Conventional plug flow	Plug flow	3–15	0.2–0.4	20–40	0.3–0.7	1000–3000	4–8
Step feed	Plug flow or staged	3–15	0.2–0.4	40–60	0.7–1.0	1500–4000	3–5
Complete mix	CMAS	3–15	0.2–0.6	20–100	0.3–1.6	1500–4000	3–6
Extended aeration	CMAS or plug flow	20–40	0.04–0.1	5–15	0.1–0.3	2000–4000	20–30
Oxidation ditch	CMAS + plug flow	15–30	0.04–0.1	5–15	0.1–0.3	3000–5000	15–30
Batch decant (ICEAS, CAAS)	Plug flow	12–30	0.04–0.1	5–15	0.1–0.3	2000–5000	20–40
Sequencing batch reactor	Batch	15–30	0.04–0.1	5–15	0.1–0.3	2000–5000	15–40
Counter current aeration system (CCAS™)	Plug flow	15–30	0.04–0.1	5–10	0.1–0.3	2000–4000	15–40

[b] MLSS and detention time in stabilization basin.

may be completely mixed, staged, or plug flow. The oxidation ditch is a combination of complete mix and plug flow. The recirculation flowrate in the ditch provides a flowrate that is typically 20–30 times the influent flowrate so the dilution factor approaches a complete mix substrate condition. In addition, plug flow kinetics conditions are approached as the flow moves down the ditch channels away from the mixed aeration zone.

Process Selection Considerations. Selection of an activated sludge process for BOD removal and nitrification is a function of many considerations including specific site constraints, compatibility with the existing process, compatibility with existing equipment, present and future treatment needs, level of capability of the operating staff, capital costs, and operating costs. Significant features and limitations of the various activated sludge process alternatives that affect process selection in certain applications are summarized in Table 8–20.

Table 8–20

Advantages and limitations of activated sludge processes for BOD removal and nitrification

Process	Advantages	Limitations
Complete mix	Common, proven process	Susceptible to filamentous sludge bulking
	Adaptable to many types of wastewater	
	Large dilution capacity for shock and toxic loads	
	Uniform oxygen demand	
	Design is relatively uncomplicated	
	Suitable for all types of aeration equipment	
Conventional plug flow	Proven process	Design and operation for tapered aeration is more complex
	Adaptable to many operating schemes including step feed, selector design, and anoxic/aerobic processes	May be difficult to match oxygen supply to oxygen demand in first pass
		More complex operation
Step feed	Distributes load to provide more uniform oxygen demand	Flow split is not usually measured or known accurately
	Peak wet weather flows can be bypassed to the last pass to minimize high clarifier solids loading	More complicated design for process and aeration system
	Flexible operation	
	Adaptable to many operating schemes including anoxic/aerobic processes	
Contact stabilization	Requires smaller aeration volume	Has little or no nitrification capability
	Handles wet weather flows without loss of MLSS	Operation somewhat more complex
Two-sludge AB process	Requires less aeration tank volume than conventional plug flow	Requires process control to assure sufficient solids in nitrification step
	Uses less aeration energy	Requires two clarifiers
	Provides for more methane production with anaerobic digestion	Less resilient for high peak flows and loads
High purity oxygen	Requires relatively small aeration tank volume	Limited capability for nitrification
	Uses more energy than air aeration	More complex equipment to install, operate, and maintain
	Generally produces good settling sludge	*Nocardioform* foaming
	Operation and DO control are relatively uncomplicated	High peak flows can disrupt operation by washing out MLSS
Extended aeration	High quality effluent possible	Aeration energy use is high
	Relatively uncomplicated design and operation	Relatively large aeration tanks
	Capable of treating highly variable loads and intermittent toxic loads	Adaptable mostly to small plants
	Well stabilized sludge; low biosolids production	Filamentous sludge bulking is possible

(*continued*)

Table 8–20 (*Continued*)

Process	Advantages	Limitations
Oxidation ditch	Highly reliable process; simple operation	Large structure, greater space requirement
	Capable of treating shock/toxic loads without affecting effluent quality	Low F/M bulking is possible
	Economical process for small plants	Requires more aeration energy than conventional CMAS and plug flow treatment
	Uses less energy than extended aeration	Plant capacity expansion is more difficult
	Adaptable to nutrient removal	
	High quality effluent possible	
	Well stabilized sludge; low biosolids production	
Sequencing Batch Reactor	Process is simplified; final clarifiers and RAS pumping are not required	Process design and control more complicated
	Modular construction possible	High peak flows can disrupt operation
	Operation is flexible; nutrient removal can be accomplished by operational changes	Batch discharge may require equalization prior to filtration and disinfection
	Can be operated as a selector process to minimize sludge bulking potential	Higher maintenance skills required for instruments, monitoring devices, and automatic valves
	Quiescent settling enhances solids separation (low effluent TSS)	Some designs use less efficient aeration devices
	Economical for small plants	Volumetric tankage requirements can be high
Counter current aeration	High quality effluent possible	Fine screening is required to prevent diffuser fouling
	Oxygen transfer efficiencies are higher than convention aeration systems	Process is proprietary
	Well stabilized sludge; low biosolids production	Significant down-time of aeration unit for maintenance will affect plant performance
	Process design can be modified to accommodate nutrient removal	Good operator skills required

8–7 PROCESSES FOR BIOLOGICAL NITROGEN REMOVAL

Nitrogen removal is often required before discharging treated wastewater to sensitive water bodies (to prevent eutrophication), or for groundwater recharge or other reuse applications. Processes for BOD removal and nitrification, presented previously in Sec. 8–6, were based on the fundamental principles presented in Chap. 7 and Secs. 8–2 and 8–3. In this section, an additional treatment step, *biological denitrification*, is considered and information is presented that is specific to the nitrogen removal process. Nitrogen removal can be either an integral part of the biological treatment system or an add-on process to an existing treatment plant.

The purpose of this section, as in the previous section, is to illustrate in detail the design procedure for biological processes used to remove nitrogen from wastewater. The material on nitrogen removal presented in this section is organized into the following topics: (1) process development, (2) overview of biological nitrogen removal processes, (3) general process design consideration, (4), (5), (6) process designs for three different types of biological nitrogen removal processes, (7) external carbon addition, (8) summary of alternative processes used for biological nitrogen removal, and (9) process control and performance.

Process Development

The antecedents of biological nitrogen removal date back to observations in the 1940s in studies on rising sludge in secondary clarifiers due to nitrification and denitrification (Sawyer and Bradney, 1945). The first WWTP process scheme for biological nitrogen removal involved the addition of a tank whose contents were mixed, but unaerated, (post-anoxic) following an aerobic nitrification tank. This arrangement was first proposed, implemented, and discussed by Wuhrman in a series of conference proceedings from 1960 to 1962 (Wuhrman, 1964; Bishop et al., 1976). Wuhrman noted that denitrifying bacteria were abundant in activated sludge and was the first to recognize *simultaneous nitrification and denitrification* in activated sludge. He also noted that denitrification occurred as a result of a low mixed liquor DO, which was insufficient to penetrate the interior of floc particles, where nitrate reduction could occur.

Building on Wuhrman's observations on denitrification at low DO concentrations, Ludzack and Ettinger studied the effect of recycling mixed liquor from a nitrifying aerobic zone upstream to a mixed nonaerated zone so that influent BOD could be used for denitrification. This was the first preanoxic nitrogen removal process (Ludzack and Ettinger, 1962). Later Balakrishnan and Eckenfelder (1970) provided recycle of nitrate in secondary clarifier effluent to an upstream unaerated, mixed stabilization zone of a contact-stabilization process prior to the aerobic contact zone and secondary clarifier. A disadvantage of this approach was the higher hydraulic load to the secondary clarifier because of the nitrate recycle flow. Barnard (1974) provided both preanoxic and postanoxic denitrification zones in his development of the Bardenpho Process. Although the Bardenpho process could produce effluent total nitrogen concentrations below 3.0 mg/L, such low levels of nitrogen were not deemed necessary in the 1970s; thus, the post anoxic zone was not necessary and it was more common to just use the preanoxic/aerobic steps. This anoxic/aerobic sequence with recycle from the aeration zone to the preanoxic zone was termed the Modified Ludzack Ettinger process or MLE process.

In addition to this work with distinctive anoxic and aerobic zones, others investigated cyclic aerobic/mixing modes for nitrogen removal by nitrification and denitrification in single or staged reactors (Bishop et al., 1976). During this same time period, the ability to achieve high nitrogen removal in a single-tank oxidation ditch system was documented by Matsche from full-scale plant results at the Vienna Blumental wastewater treatment facility (Matsche, 1972). All of the above nitrogen removal processes were applied in single-sludge activated sludge systems, which means that only one solids-liquid separation step (secondary clarification) is used in the process. However, in the late 1960s a three sludge system was tested on a lab scale (Barth et al., 1968) and then demonstrated in a pilot plant (Heidman et al., 1975) to achieve high nitrogen removal efficiency with effluent total nitrogen concentrations of less than 3.0 mg/L. The system consisted of (1) high rate BOD removal activated sludge process with clarifier, (2) nitrification activated sludge process with clarifier, and (3) denitrification activated sludge process with clarifier. Methanol was added to the third step to provide an electron donor for denitrification. In the late 1990s and early 2000s this system was tested and installed at full scale, but only in a two-sludge system, with the nitrification and post denitrification processes with methanol addition combined in the second sludge system (Bailey et al., 1998 and Sadick et al., 2000).

Following these innovative applications for nitrogen removal in the 1960s and 1970s, a greater understanding of the nitrification and denitrification process kinetics was gained and applied in these and other design modifications in the 1980s and beyond. These processes are discussed in the following sections.

Overview of Types of Biological Nitrogen Removal Processes

All of the biological nitrogen removal processes include an aerobic zone in which biological nitrification coverts NH_4-N to NO_2-N and NO_3-N. Anoxic volume or time must also be included to provide biological denitrification to complete the objective of total nitrogen removal by both NH_4-N oxidation and NO_3-N and NO_2-N reduction to nitrogen gas. As discussed in Sec. 7–10 in Chap. 7, nitrate/nitrite reduction requires an electron donor, which can be supplied in the form of influent wastewater BOD, by endogenous respiration, or an external carbon source. The type of biological nitrogen removal process is classified in this section according to the location of the anoxic reactor relative to the nitrification step as follows:

1. Preanoxic denitrification processes
2. Postanoxic denitrification processes
3. Low DO and cyclic nitrification/denitrification processes

In addition to differences in reactor configuration for each of these process types, the primary substrate source and nitrate reduction kinetics vary. It should be noted that design and operating conditions of SBR systems can be selected to provide any of these types of denitrification processes or in various combinations including: (1) a preanoxic and postanoxic process, (2) a preanoxic and low DO process, or (3) a preanoxic and cyclic nitrification/denitrification process. The simultaneous removal of phosphorus is introduced here, but the subject of enhanced biological phosphorus removal is discussed in detail in Sec. 8–8.

Preanoxic Denitrification Processes. In the preanoxic configuration [see Fig. 8–26(a)], nitrate produced in the aerobic zone is recycled to the mixed preanoxic zone. Denitrifying bacteria in the preanoxic zone consume influent BOD to reduce the nitrate to nitrogen gas. The rate of denitrification in the preanoxic zone is affected by the rbCOD concentration in the influent wastewater, the MLSS concentration, and temperature. Typical views of the anoxic section of different activated sludge processes are shown on Fig. 8–27.

There are many advantages for using a preanoxic zone upstream of a nitrification zone. These include (1) the relative ease of retrofit to existing plants, (2) the benefits of the anoxic selector operation for control of filamentous sludge, (3) the production of alkalinity before the nitrification step, (4) the energy savings due to the use of nitrate for oxidation of the influent BOD, and (5) the ability to convert an existing biological treatment system to nitrogen removal with relatively short to moderate basin detention times. Because of these advantages a preanoxic zone should be used with activated sludge systems that are designed for nitrification, even if nitrogen removal is not required. In addition to the improved SVI and energy savings, the use of a nitrification/denitrification process has been shown to be a more economical choice as compared to nitrification alone (Rosso and Stenstrom, 2005a). Although the longer SRT values associated with nitrification and denitrification processes require increased tank volume as compared to systems designed only for BOD removal, there is only a small increase in the overall WWTP energy requirements results based on improved alpha values and aeration efficiencies and a decrease in the amount of waste sludge to handle (Leu et al., 2012).

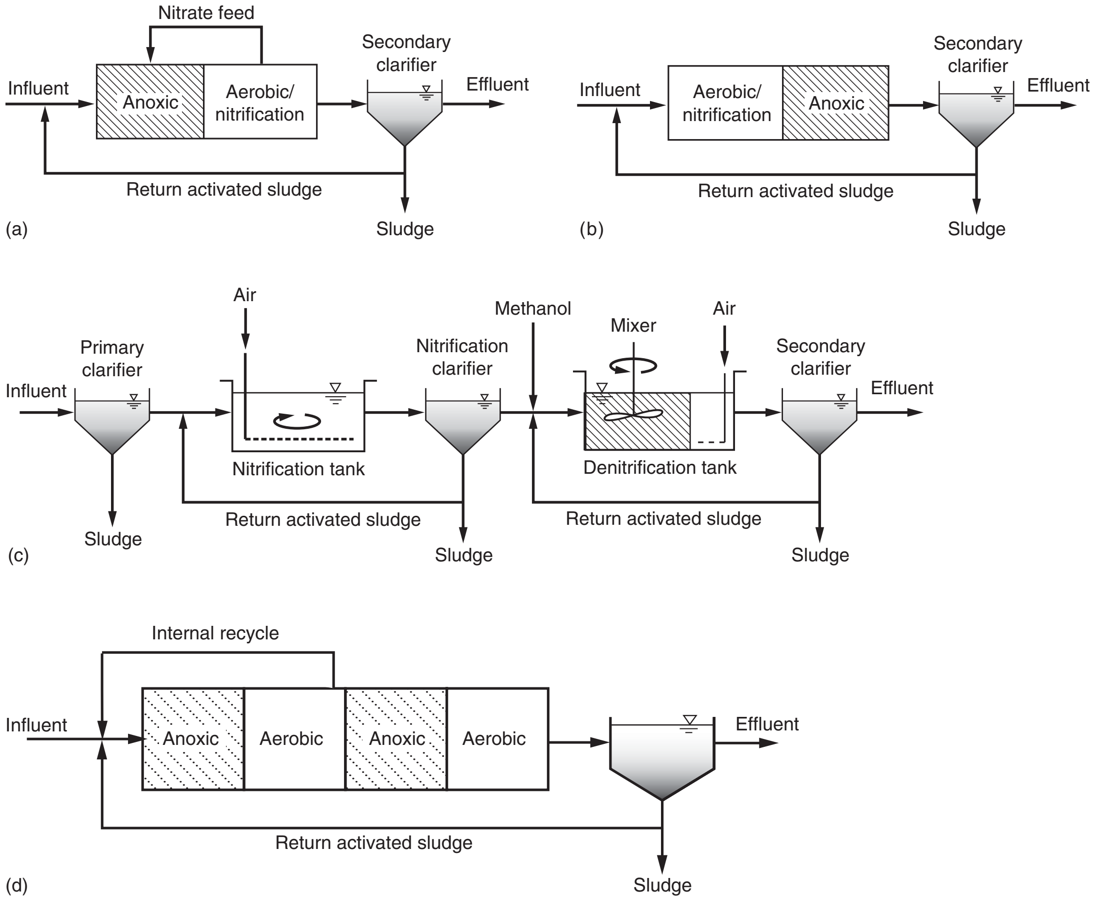

Figure 8–26

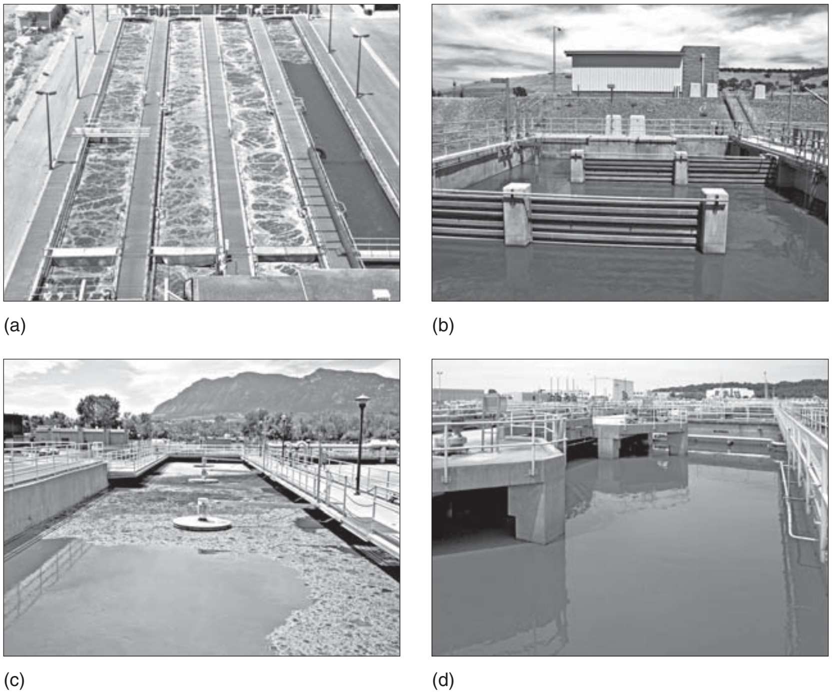
Schematic diagram of four basic biological nitrogen removal process configurations: (a) preanoxic, (b) postanoxic, (c) two-sludge nitrification-denitrification, and (d) Bardenpho process.

Postanoxic Denitrification Processes. Postanoxic designs [see Fig. 8–26(b), (c), and (d)] are commonly used as a polishing denitrification step to remove nitrate to a minimal effluent concentration. For example, in the Bardenpho process [see Fig. 8–26(d)] more than 75 percent of the nitrate is typically removed in the preanoxic zone with the reminder removed in the postanoxic zone. The postanoxic zone may be operated with or without an exogenous carbon source. Without an exogenous source, postanoxic processes depend on the endogenous respiration of the activated sludge to provide electron donor for nitrate consumption in lieu of oxygen. The denitrification rate is much slower, by a factor of 3 to 6, compared to preanoxic applications that use influent wastewater BOD for the electron donor.

Postanoxic denitrification have also been done in a two sludge system design as shown on Fig. 8–26(c) in which BOD and nitrification occurs in the first sludge system. Because of the cost of chemical addition for all of the nitrate removal and the need for a second clarifier, single-sludge systems with preanoxic zones are preferred over this suspended growth alternative for nitrogen removal. Where a two step process is used it is now more common to use fixed film denitrification processes with an exogenous carbon source for nitrate removal. Fixed film processes are considered in Chap. 9.

Figure 8–27

Views of anoxic reactors: (a) reactor used for nitrogen removal (the righthand channel without aeration is the preanoxic section, (b) baffled anoxic section of small plug-flow activated sludge reactor, (c) baffled (submerged) anoxic section with surface mixers of large plug-flow activated sludge reactor (coordinates 34.1825 N, 118.4793 W, view at altitude 250 m), and (d) postanoxic denitrification in nitrification reactors with methanol addition in deep tanks with invent mixers.

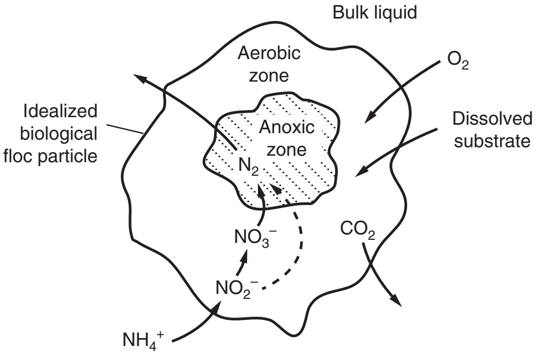


Low DO and Cyclic Nitrification/Denitrification Processes. Denitrification can be accomplished in single-reactor activated sludge systems without permanent and distinct nitrification and anoxic zones by two methods: (1) simultaneous nitrification-denitrification (SNdN) and (2) cyclic nitrification-denitrification (Cyclic NdN). These single reactor nitrification/denitrification processes rely on operational methods for aeration and mixing to accomplish nitrogen removal, instead of having distinct aerobic and anoxic zones as in the preanoxic and postanoxic processes.

Simultaneous NdN. SNdN is accomplished by operation at a low DO concentration so that the activated sludge floc contains both aerobic and anoxic zones, as illustrated in a simplified view of a biological floc on Fig. 8–28. Dissolved oxygen and dissolved substrates outside of the floc diffuse into the aerobic zone, and depending on the DO concentration and concentrations of ammonia and bCOD, oxygen may be depleted at significant rates within the floc so that the DO cannot penetrate the entire floc depth and anoxic zones occur

Figure 8–28

Diagram of an activated sludge floc showing aerobic and anoxic zones.



in the inner floc volume. Nitrite and nitrate produced by nitrification in the aerobic zone can diffuse into the inner anoxic zone along with substrate so that denitrification occurs within the floc depth. The major pathway for nitrogen removal may be NH_4-N to NO_2-N to N_2 instead of via NO_3-N to N_2 as indicated by observations of ammonia oxidizing microorganisms in limited DO aerated systems with archaea ammonia-oxidizing archaea (AOA) dominating in a low DO MBR system (Giraldo et al., 2011a and 2011b) and ammonia-oxidizing bacteria (AOB) in a lab reactor treating domestic wastewater (Peng et al., 2012).

Nitrification and denitrification rates are at less than optimal levels in simultaneous nitrification/denitrification (SNdN) processes. Only a portion of the biomass is used for each of these reactions. In addition, the nitrification rate is lower due to the low DO concentration, and the denitrification rate is lower due to substrate consumption in the aerobic portion of the floc. The impact of anoxic zones within the biological floc on decreasing nitrification rates was observed by Stenstrom and Song (1991) who reported that nitrification rates were related not only to bulk liquid DO concentration, but also to the amount of BOD present. At higher soluble BOD concentrations, higher oxygen uptake rates occurred, and lower nitrification rates were observed for the same bulk liquid DO concentration, most likely due to the fact that the aerobic zone of the activated sludge floc was decreased.

Cyclic NdN Processes. Cyclic NdN processes involve aeration and unaerated mixing process steps, either spatially or with time. An aeration step with elevated DO for nitrification is followed by an unaerated, mixed time for denitrification. Process control methods must be provided and implemented for successful nitrogen removal in cyclic NdN processes. Cyclic NdN processes have been demonstrated in: (1) oxidation ditches, (2) series compartments with alternating aerobic/anoxic operation, and (3) phased operation with tanks in series.

Reported plant effluent NO_3-N performance data for cyclic NdN processes range from 3.0 to 4.8 mg/L, with effluent total nitrogen (TN) concentrations below 8.0 mg/L (U.S. EPA, 1993). The relatively long τ values used provide sufficient dilution to minimize the effluent NH_4-N concentrations during the OFF period. A sufficiently long SRT is also needed to provide enough nitrification capacity to allow the aeration system to be operated intermittently.

Oxidation Ditch Processes. To accomplish cyclic NdN in an oxidation ditch, aerobic and anoxic zones are created along the ditch channel length with the mixed liquor recirculating. An elevated DO concentration occurs in the aeration zone of the oxidation ditch and in a portion of the volume downstream from the aeration zone so that nitrification occurs. DO is continually depleted as the flow moves down the channel until it is at or near zero and anoxic conditions then prevail for denitrification. The channel flow circulates around the ditch with circulation times typically ranging from 5 to 15 minutes with the activated sludge mixed liquor cycling through aerobic and anoxic conditions. The oxidation ditch aerator submergence or motor speed can be varied to control the size of the aerobic and anoxic zones for nitrification and denitrification.

Oxidation ditches can also employ intermittent aeration by having a directional mixer installed to maintain channel flow when the aerator is turned off. During the aeration-off period, the aeration tank operates essentially as an anoxic reactor as nitrate is used in lieu of DO for BOD removal. The operation of an oxidation ditch using intermittent aeration is shown on Fig. 8–29. Intermittent aeration systems typically are operated with SRT values in the range of 18 to 40 d and hydraulic detention times in excess of 16 h. During the anoxic reaction period [see Fig. 8–29(b)], aeration is stopped, a submerged mixer is turned on, and nitrate is used as the electron acceptor. The reactor (ditch) is operated as a complete-mix activated sludge anoxic process. During the anoxic period, DO and nitrate

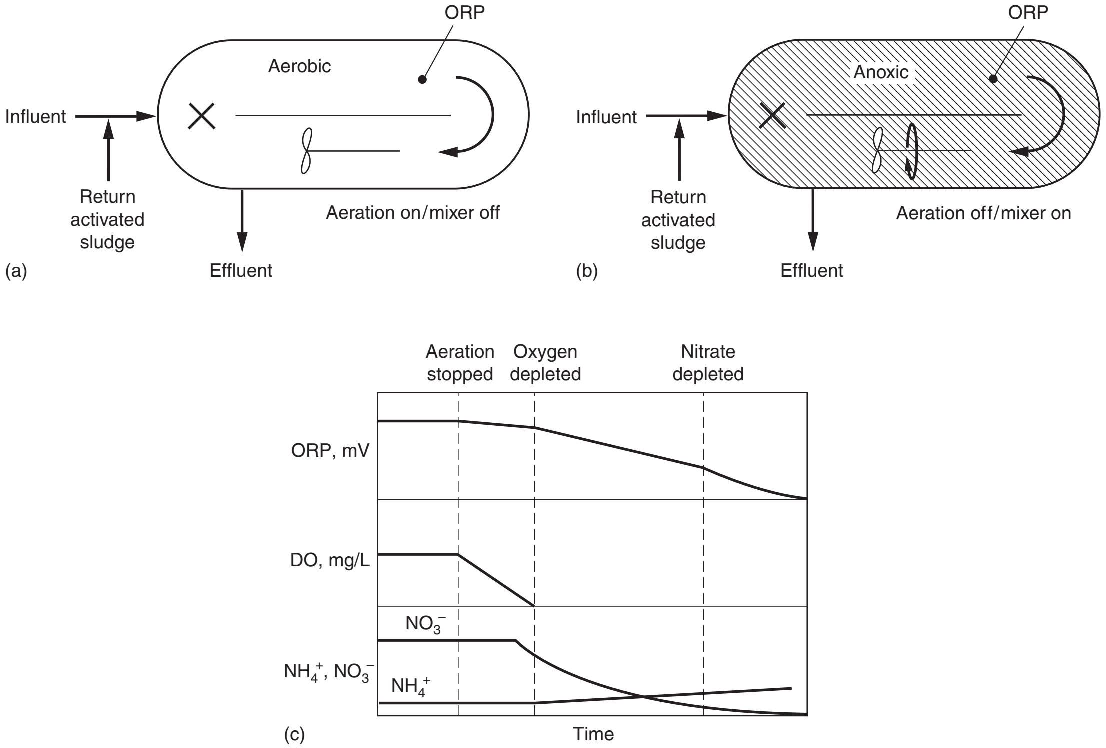


Figure 8–29

Operation of a oxidation ditch process using intermittent aeration: (a) aerobic conditions, (b) anoxic conditions, and (c) variations in ORP, DO, ammonia, and nitrate.

are depleted and the ammonia concentration increases [see Fig. 8–29(c)]. The time for the anoxic and aerobic periods is important in determining the system's treatment performance. A control method for the intermittent aeration using an oxidation-reduction probe (ORP) measurement is presented under the Process Control and Performance topic at the end of this nitrogen removal section.

Alternating Aerobic/Anoxic Processes. An alternating aerobic/anoxic operation involves the use of two compartments in series, with the influent going to the first compartment [see Fig. 8–30(a)]. At select times the first compartment is aerated and the second mixed and then it is switched with the first compartment mixed and the second aerated. Basically, the operation cycles between preanoxic and postanoxic denitrification.

Phased Operation Processes. For a phased operation, two compartments or tanks are also used but the influent feed is always fed to a mixed anoxic zone [see Fig. 8–30(b)]. In one phase tank A is fed influent and mixed and its effluent flow is to tank B which is aerated. The mixed liquor flow from tank B goes to the secondary clarifier. At selected times the flow and aeration/mixing is reversed between tank A and B. Tank B receives the influent flow and is a mixed anoxic tank due to the nitrate produced in its previous aerobic phase. In this phase the mixed liquor flow from tank B goes to tank A which is now aerated, and the effluent flow from tank A goes to the secondary clarifier. In the phased operation denitrification is done in a preanoxic denitrification process. An example of nitrogen

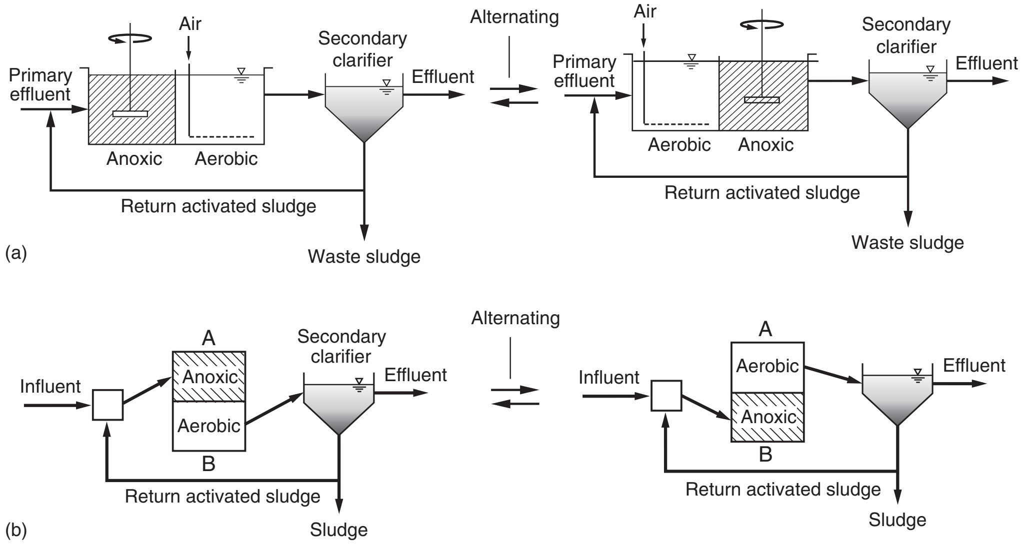

Figure 8–30

Schematic of Cyclic NdN Processes: (a) alternating or cycling process and (b) phase operation.

removal by phased operation is the BioDenitro process, which uses two oxidation ditches for the alternating anoxic and aerobic tanks (Stensel and Coleman, 2000).

Simultaneous Removal of Phosphorus. Enhanced biological phosphorus removal occurs in biological nitrogen removal processes when (1) there is excess rbCOD during the anoxic contact so that substrate is available for uptake by PAOs and (2) there is sufficient downstream aerobic time for stored carbon oxidation by the PAOs.

General Process Design Considerations

Design issues and design examples for commonly used biological nitrogen removal processes are presented below. The fundamental design concepts that are exemplified can be of use in evaluating other types of suspended growth biological nitrogen removal processes.

The main goal of the denitrification design is to determine the volume or time required for the particular type of anoxic zone. Each of the denitrification processes has unique design considerations and denitrification rates specific to that process type that are addressed in the process design for each denitrification process. Common issues related to all three types of denitrification processes discussed in this section are (1) system SRT, (2) specific denitrification rate (SDNR), (3) MLSS concentration, (4) temperature, (5) influent wastewater characteristics, (6) alkalinity, and (7) anoxic tank mixing requirements.

System SRT. The starting point for all the nitrogen removal designs is providing an adequate aerobic SRT for nitrification. The required aerobic SRT for nitrification, as discussed in Sec. 8–6, will depend on a number of factors, including the effluent NH_4-N concentration goal, flow and loading variability, DO concentration, and temperature. The required aerobic SRT is used to compute the aerobic volume and the total system SRT is approximately equal to the total volume (aerobic plus anoxic volume) to aerobic volume ratio times the aerobic SRT. Longer SRTs result in lower specific denitrification rates for postanoxic denitrification and cyclic NdN processes.

Specific Denitrification Rate (SDNR). Values of the SDNR have been used to characterize denitrification rates in different anoxic systems as well as to evaluate the effect of different external carbon sources. The SDNR in an anoxic tank is related to the amount of nitrate removed per unit time, normalized to the MLVSS concentration:

$$\text{SDNR} = \frac{\text{NO}_r}{(\text{MLVSS})(V_{\text{nox}})} \tag{8–51}$$

where SDNR = specific denitrification rate, g NO_3-N/g MLVSS·d
NO_r = nitrate-nitrogen removal rate, g/d
V_{nox} = anoxic tank volume, m^3
MLVSS = mixed liquor volatile suspended solids concentration, mg/L

The desktop design approach is based on using a specific denitrification rate (SDNR) to determine the NO_3-N removal rate in an anoxic tank volume.

$$\text{NO}_r = (V_{\text{nox}})(\text{SDNR})(\text{MLVSS}) \tag{8–52}$$

Values of SDNR observed for preanoxic tanks in full-scale installations have ranged from 0.04 to 0.42 g NO_3-N/g MLVSS·d (Burdick et al., 1982; Henze, 1991; Bradstreet and Johnson, 1994; Reardon et al., 1996; Hong et al., 1997; and Murakami and Babcock, 1998). For postanoxic denitrification without an exogenous carbon source, observed SDNRs have ranged from 0.01 to 0.03 g NO_3-N/g MLVSS·d.

MLSS Concentration. The required anoxic zone volume is less for higher MLSS concentrations. As will be shown in Sec. 8–10, the MLSS concentration that can be used is related to the activated sludge settling and thickening properties. Because the preanoxic denitrification process also serves as a selector for good settling mixed liquor, operation at higher MLSS concentrations is possible.

Temperature. As shown for nitrification, denitrification rates will also be lower for operation at lower temperatures. The lowest sustained temperature is normally selected as the worst case for the anoxic zone design. For some retrofit applications to biological nitrogen removal, it is possible that there may not be enough tankage available to provide the volume needed for both nitrification and denitrification. In that case the volume needed for nitrification is provided, and external carbon can be added to the denitrification zone to provide a faster nitrate reduction rate in the limited anoxic volume at colder temperatures. External carbon addition is addressed at the end of this section.

Influent Wastewater Characteristics. The influent wastewater characteristics are important in affecting biological denitrification rates in preanoxic, SNdN, and Cyclic NdN processes. Nitrate reduction is dependent on having sufficient electron donor so there must be a sufficient amount of influent BOD relative to the amount of nitrogen to be removed. As a rule of thumb, an influent BOD to TKN ratio of 4/1 is necessary to provide a sufficient amount of electron donor (Randall et al., 1992).

Alkalinity. Denitrifying bacteria have a wider range of pH tolerance than nitrifying bacteria so that influent alkalinity is not as critical for the denitrification design. However, it is useful to determine the amount of nitrate removal and its associated alkalinity production to determine if it can help to maintain a satisfactory alkalinity concentration and pH in the aerobic nitrification zone.

Anoxic Tank Mixing. For preanoxic, postanoxic, and some cyclic NdN systems the anoxic zones are designed as single-stage or a series of complete-mix tanks. Typical power requirements for mechanical mixing in the anoxic zone depends on the mixer design and tank geometry and can be as low as 3 kW/10^3 m^3 for slow speed mixers to 8 kW/10^3 m^3 for higher speed mixers (0.1 to 0.3 hp/10^3 ft^3).

Preanoxic Denitrification Processes

Design considerations for three biological nitrogen removal processes are discussed in this section. Following a presentation of some general background material that is specific to each of the three nitrogen removal processes, design examples for each are presented. The three design examples are: (1) preanoxic denitrification process design for the MLE process, (2) step feed nitrification and preanoxic denitrification process design, and (3) preanoxic denitrification process design for an SBR process. Similar discussion and analyses are provided for postanoxic denitrification and low DO and cyclic nitrification/denitrification processes in subsequent parts.

Preanoxic Denitrification Process Design for MLE Process. The design approach for the MLE process is summarized in Table 8–21 and in general proceeds with the following major steps: (1) determine the aerobic nitrification design, (2) determine the internal recycle rates and the amount of nitrogen to remove in the preanoxic zone, and (3) determine the anoxic tank volume and SDNR. The first step was described in Sec. 8–6. The same steps can be followed for an anoxic/aerobic design in an MBR process with necessary modifications with regard to the MLSS concentration, aeration tank configuration, and aeration design. The anoxic/aerobic design steps for an MBR system are summarized in Table 8–23 on page 807. The methods to obtain the SDNR and mass balance needed to obtain the internal recycle rate are discussed here. An example of a preanoxic denitrification process design for an MLE process with secondary clarifier and MBR system is presented following the presentation of the background material given below.

Relationship of SDNR to BOD F/M Ratio. Based on observed denitrification rates in pilot-plant and full-scale plants, empirical relationships have been developed that relate SDNR to the BOD or COD F/M ratio for the preanoxic tank (Burdick et al., 1982; U.S. EPA, 2010):

$$\mathrm{SDNR}_{20} = (\mathrm{F/M})(F_b/0.30)(\mathrm{F/M}) + 0.029 \tag{8–53}$$

$$F_b = \frac{(Y_\mathrm{H})/1 + b_\mathrm{H}(\mathrm{SRT})}{[(Y_\mathrm{H}/1) + b_\mathrm{H}(\mathrm{SRT}) + Y_\mathrm{I}]} \tag{8–54}$$

$$\frac{\mathrm{F}}{\mathrm{M}} = \frac{QS_o}{XV_\mathrm{nox}} \tag{8–55}$$

where F/M = g BOD applied/g MLVSS·d in the anoxic tank
SDNR_{20} = specific denitrification rate at 20°C, gNO_3-N/g MLVSS·d
Q = influent flowrate, m^3/d
S_o = influent BOD concentration, mg/L
X = MLVSS concentration in anoxic tank, mg/L
V_nox = anoxic tank volume, m^3
F_b = active biomass fraction of MLVSS
Y_H = heterotrophic biomass synthesis yield, 0.67 g VSS/g BOD removed
b_H = endogenous decay rate, g VSS/g VSS·d
Y_I = influent wastewater inert VSS fraction, g nbVSS/g BOD

Table 8–21

Computation approach for anoxic/aerobic process design with secondary clarification

Item	Description
1.	Establish wastewater flowrates and characteristics, including the rbCOD concentration, and effluent requirements.
2.	Follow the procedure outlined in Table 8–15 for the aerobic zone for a nitrification process with the exception that steps 13–18 are done after the anoxic reactor design.
3.	Determine the biomass concentration in the mixed liquor from the nitrification design.
4.	Determine the internal recycle (IR) ratio, using the NO_x value determined in step 9 of the nitrification design and desired effluent NO_3-N concentration.
5.	Calculate the amount of nitrate fed to the anoxic tank. The design is based on the assumption that essentially all of the nitrate fed to the anoxic zone will be reduced. A low nitrate concentration of 0.1 to 0.3 mg/L may remain, depending on the design, because the nitrate limits the denitrification reaction rate at only very low concentrations.
6.	Select the anoxic volume and configuration; single stage or multiple-staged reactors.
7.	Calculate the F/M_b based on the biomass concentration determined for the mixed liquor in the nitrification design.
8.	Use Eq. (8–57) or (8–58) and appropriate corrections for temperature and IR ratio to obtain the $SDNR_b$, also based on the biomass concentration, for the anoxic basin.
9.	Using the $SDNR_b$, biomass concentration, and anoxic volume compute the amount of nitrate removed in the anoxic basin. Compare the amount of removal required to remove all of the nitrate in the recycle streams fed to the anoxic zone.
10.	For downstream anoxic basins calculate the F/M_b after reducing the influent BOD, bCOD, and rbCOD based on the amount of nitrate removed in the upstream anoxic basin.
11.	Repeat the anoxic zone design steps as necessary to obtain a satisfactory design.
12.	Calculate the oxygen demand.
13.	Determine if alkalinity addition is needed.
14.	Design the secondary clarifier.
15.	Design the aeration oxygen transfer system.
16.	Summarize the final effluent quality.
17.	Prepare a design summary table.

The endogenous decay rate is corrected for temperature using Eq. (1–44), a b_{20} value of 0.12 g VSS/g VSS·d, and temperature coefficient θ value of 1.029. The above relationships are based on empirical observations and do not account for the effect of different rbCOD fractions in the influent wastewater bCOD. Higher SDNR values will occur in the preanoxic zone for wastewaters with a higher rbCOD/bCOD ratios.

The effect of the rbCOD/bCOD ratio, expressed as a percentage, on the SDNR is presented on Fig. 8–31. The values are generally applicable and can be used for wastewaters with different fractions of rbCOD (rbCOD/bCOD) and inert nonbiodegradable volatile solids. On Fig. 8–31, the F/M_b ratio (Eq. 8–56) and $SDNR_b$ (Eq. 8–57 or Eq. 8–58) values are based only on the active heterotrophic biomass concentration in the mixed liquor, so that the rates can be applicable to many situations regardless of the amount of nondegradable solids in the mixed liquor and the SRT. The F/M_b ratio is defined

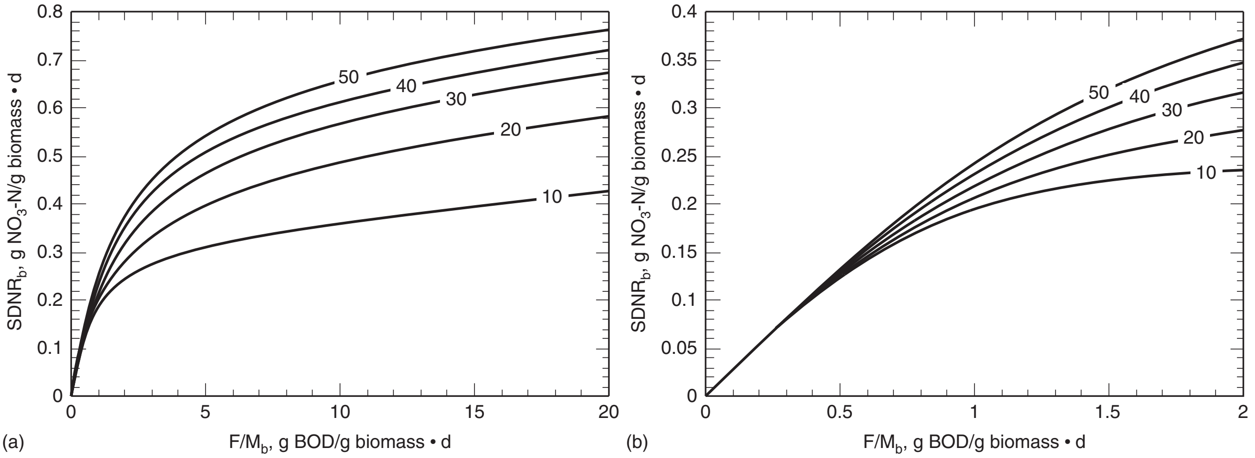

Figure 8–31

Specific denitrification rates (SDNR$_b$) based on biomass concentration at 20°C versus food to biomass (F/M$_b$) ratio for various percentages of rbCOD relative to the influent wastewater bCOD (a) for F/M$_b$ values up to 20 and (b) expanded scale for F/M$_b$ values up to 2.

as a function of the BOD loading to the anoxic volume and active heterotrophic biomass concentration, as follows:

$$\text{F/M}_\text{b} = \frac{QS_o}{(V_\text{nox})X_b} \tag{8–56}$$

where F/M$_\text{b}$ = BOD F/M ratio based on active biomass concentration, g BOD/g biomass·d
X_b = anoxic zone biomass concentration, mg/L

The curves shown on Fig. 8–31 are based on the results of model simulations of biomass, NO$_3$-N, rbCOD, and pbCOD mass balances in the anoxic tank. For lower anoxic τ values, the F/M$_\text{b}$ is higher, which resulted in greater rbCOD concentrations in the anoxic zone and thus a higher biological reaction rate and SDNR. Internal recycle rates from the aerobic zone and temperature effects were accounted for. The biokinetic coefficients used in the model simulation are model parameter default values from the ASM1 model (Grady et al., 1986) along with the rbCOD kinetics under anoxic conditions observed by Stensel and Horne (2000) from testing at different municipal wastewater-treatment facilities. Equations (8–57) and (8–58), derived from the data presented on Fig. 8–31, can be used for calculating SDNR$_\text{b}$ as a function of F/M$_\text{b}$. Values for b_0 and b_1 are given in Table 8–22.

$$\text{For F/M} > 0.50,\ \text{SDNR}_\text{b} = b_0 + b_1\,[\ln(\text{F/M}_\text{b})] \tag{8–57}$$

$$\text{For F/M} \le 0.50,\ \text{SDNR}_\text{b} = 0.24(\text{F/M}_\text{b}) \tag{8–58}$$

Table 8–22

Coefficient values for Eq. (8–57) relating SDNR$_\text{b}$ to percent rbCOD

Percent rbCOD	SDNR equation coefficients	
	b_0	b_1
10	0.186	0.078
20	0.213	0.118
30	0.235	0.141
40	0.242	0.152
50	0.270	0.162

Table 8–23

Computation approach for anoxic/aerobic process design with membrane liquid-solids separation

Item	Description
1.	Establish wastewater flowrates and characteristics, including the rbCOD concentration, and effluent requirements.
2.	Follow the procedure outlined in Table 8–15 and complete steps 1 through 10.
3.	Select the membrane design flux value and determine the installed membrane total surface area.
4.	Determine the membrane separation tank volume based on the membrane surface area needed and membrane suppliers required aerobic membrane tank volume to membrane surface area ratio.
5.	Determine the anoxic tank and preaeration tank MLSS concentrations. Use the selected membrane tank MLSS concentration and return activated sludge recycle ratio.
6.	Determine the preaeration tank volume and active biomass concentration. Determine the biomass concentration in the anoxic zone by calculating the fraction of biomass in the MLSS concentration in the nitrification design and multiplying that by the MLSS determined in Step 5 above.
7.	Using the return activated sludge ratio selected and the NO_x value determined in step 9 of the nitrification design, determine the effluent NO_3-N concentration.
8.	Calculate the amount of nitrate fed to the anoxic tank. The design is based on the assumption that essentially all of the nitrate fed to the anoxic zone will be reduced.
9.	Select the anoxic volume and configuration; single stage or multiple-staged reactors.
10.	Calculate the F/M_b based on the biomass concentration in the anoxic zone.
11.	Use Eq. (8–57) or (8–58) and appropriate corrections for temperature and IR ratio to obtain the $SDNR_b$ for the anoxic basin.
12.	Using the $SDNR_b$, biomass concentration, and anoxic volume compute the amount of nitrate removed in the anoxic basin. Compare the amount of removal required to remove all of the nitrate in the recycle streams fed to the anoxic zone.
13.	For downstream anoxic basins calculate the F/M_b after reducing the influent BOD, bCOD, and rbCOD based on the amount of nitrate removed in the upstream anoxic basin.
14.	Repeat the anoxic zone design steps as necessary to obtain a satisfactory design.
15.	Calculate the oxygen demand accounting for oxygen equivalents supplied by NO_3-N.
16.	Determine if alkalinity addition is needed.
17.	Determine the anoxic zone mixing power.
18.	Design the aeration oxygen transfer system for the aerobic tanks. First determine what fraction of the total oxygen demand is provided in the preaeration basin and membrane separation basin.
19.	Prepare a design summary table.

The design procedure using $SDNR_b$ values from Fig. 8–31 requires calculating the active biomass VSS concentration in the mixed liquor using the procedure presented previously in Example 8–2. By using the calculated biomass concentration, the effects of SRT are accounted for in the design procedure. The BOD F/M_b ratio on Fig. 8–31 is also based on the active biomass VSS concentration. The procedure is applicable to a single-stage anoxic reactor. The $SDNR_b$ for subsequent downstream staged anoxic reactors can be estimated by reducing the value for the influent BOD (S_o) by the amount removed using nitrate as the electron acceptor by 4 g BOD used per g of NO_3-N reduced (see Sec. 7–10).

The computed value should be subtracted from the influent rbCOD concentration, (assuming 1.6 g bCOD/g BOD) as that will be consumed the fastest. Thus, the rbCOD:bCOD ratio of the influent BOD to subsequent anoxic zones decreases.

At high F/M$_b$ ratios shown on Fig. 8–31, the SDNR$_b$ reaches a maximum saturated rate, as the rbCOD concentration will be very high in the anoxic reactor. The maximum saturation rate will only be experienced for high F/M$_b$ anoxic selector designs where the first anoxic zones have detention times of less than 10 to 20 min. For long anoxic detention times (on the order of 3 to 6 h), SDNR$_b$ values will be found at the lower F/M$_b$ ratios.

Temperature and Internal Recycle Corrections for SNDR. The design procedure requires correcting the SDNR values from Eq. (8–57) or (8–58) for temperature and internal recycle ratios. The temperature correction is made by using Eq. (2–25) with a θ value of 1.026. The SDNR in the preanoxic tank is affected by the internal recycle rate, often defined as an internal recycle (IR) ratio. The IR ratio is the recycle flowrate divided by the influent wastewater flowrate. At higher IR ratios, the influent rbCOD is diluted more in the anoxic reactor by mixed liquor from the aerobic reactor, resulting in a lower denitrification rate. The corrections to the SDNR for designs with internal recycle corrections greater than 1.0 are shown below. The SDNR value can be interpolated from the values listed. If the F/M is less than or equal to 1.0, no correction is required.

$$\text{IR} = 2 \qquad \text{SDNR}_{\text{adj}} = \text{SDNR}_{\text{IR1}} - 0.0166 \ln(\text{F/M}_b) - 0.078 \tag{8–59}$$

$$\text{IR} = 3\text{–}4 \qquad \text{SDNR}_{\text{adj}} = \text{SDNR}_{\text{IR1}} - 0.029 \ln(\text{F/M}_b) - 0.012 \tag{8–60}$$

where SDNR_{adj} = SDNR adjusted for the effect of internal recycle
SDNR_{IR1} = SDNR value at internal recycle ratio = 1
F/M_b = BOD F/M ratio based on anoxic zone volume and active biomass concentration, g/g·d

Nitrogen Mass Balance and Internal Recycle. A mass balance on nitrogen must be done to determine (1) how much nitrate is produced in the aeration zone, and (2) what internal recycle ratio must be used to meet the desired effluent nitrate concentration. The mass balance accounts for the nitrate produced in the aerobic zone. The nitrate production rate in the aerobic zone is based on the influent flowrate and nitrogen concentration, the amount consumed for cell synthesis, and the effluent NH_4-N and soluble organic nitrogen concentrations. As a conservative design approach, all of the influent TKN is assumed to be biodegradable and the effluent soluble organic nitrogen concentration is ignored. The nitrate produced is contained in the total flow leaving the aerobic zone, which includes internal recycle, RAS, and effluent flows. The mass balance is expressed as follows and assumes no nitrate reduction in the secondary clarifier.

$$\begin{array}{c} \text{kg/d of nitrate} \\ \text{produced in} \\ \text{aerobic zone} \end{array} = \begin{array}{c} \text{nitrate} \\ \text{in effluent} \end{array} + \begin{array}{c} \text{nitrate in} \\ \text{internal} \\ \text{recycle} \end{array} + \begin{array}{c} \text{nitrate in} \\ \text{return activated} \\ \text{sludge (RAS)} \end{array}$$

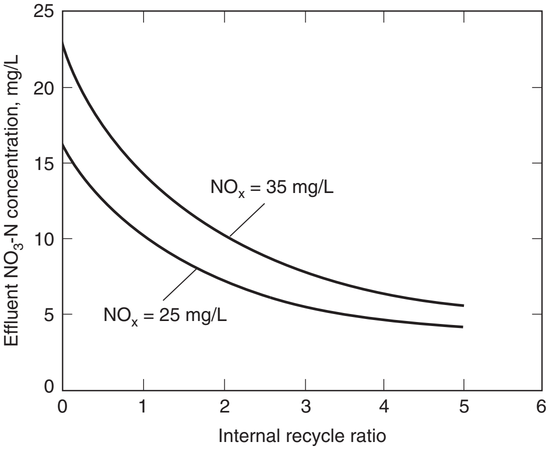
$$Q(\text{NO}_x) = N_e[Q + (\text{IR})Q + (R)Q] \tag{8–61}$$

$$\text{IR} = \frac{\text{NO}_x}{N_e} - 1.0 - R \tag{8–62}$$

where IR = internal recycle ratio (internal recycle flowrate/influent flowrate)
R = RAS recycle ratio (RAS flowrate/influent flowrate)

Figure 8–32

Effect of internal recirculation rate on effluent nitrate concentration (RAS ratio = 0.50) for an anoxic/aerobic process.



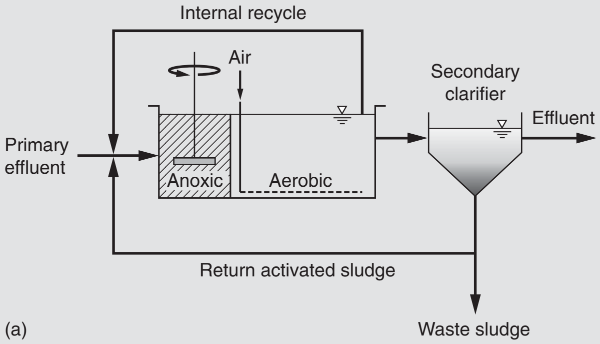
NO_x = nitrate produced in aeration zone as a concentration relative to influent flow, mg NO_3-N/L

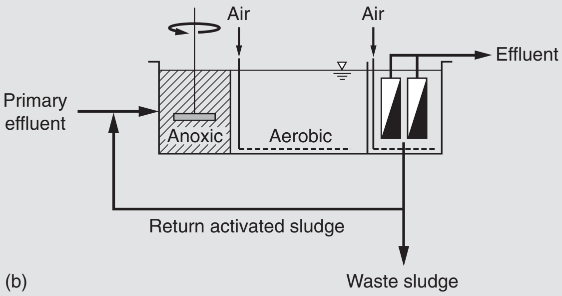
N_e = effluent NO_3-N concentration, mg/L

The effect of the IR ratio on the effluent NO_3-N concentration for a given amount of nitrate produced (NO_x) and for a RAS recycle ratio of 0.50 is illustrated on Fig. 8–32. A greater IR ratio is needed to produce the same effluent NO_3-N concentration when more NO_x is produced in the aerobic zone. To meet a standard of 10 mg TN/L or less, a design effluent NO_3-N concentration of 5 to 7 mg/L should be used. An internal recycle ratio in the range of 3 to 4 is typical, but ratios in the range of 2 to 3 are also applied for wastewaters with a lower influent wastewater TKN concentration. Recycle ratios above 4 are not used for activated sludge/secondary clarifier systems, as the incremental removal of NO_3-N is low, and more DO is recycled from the aeration zone into the anoxic zone. The higher recirculation rate also dilutes the influent rbCOD in the anoxic zone to decrease the SDNR compared to that at lower recirculation ratios. As noted previously, the amount of DO fed to the anoxic zone due to the internal recycle flow from the aerobic zone must be minimized for effective denitrification. In some designs, sections of the aerobic zone are baffled with DO control so that the DO concentration in the recycle can be controlled and minimized.

MBR Internal Recycle Ratio. The internal recycle ratio for MBR systems is typically set at 6.0 to control the MLSS concentration in the membrane separation zone. In applying Eq. (8–62) for an MBR design, the value for R is equal to 6.0 and IR is equal to zero. The effluent NO_3-N concentration (N_e) is then calculated. A concern with the higher recycle flowrate is the potential to feed excessive DO from the membrane separation tank to the preanoxic tank. High DO concentrations in recycle flows to the preanoxic tank can result in the consumption of rbCOD in the influent wastewater, thus reducing the amount of rbCOD available for NO_x reduction. A tank with a relatively short detention time could be used for holding the return activated sludge flow before it enters the preanoxic tank to allow oxygen that may be present to be consumed (e.g., deoxygenation) by the oxygen demand from endogenous decay.

EXAMPLE 8–7 **Preanoxic Denitrification Process Design for MLE Process** Design a preanoxic basin for (a) the CMAS nitrification-secondary clarifier system described in Example 8–3 to produce an effluent NH_4-N and NO_3-N concentration of 0.50 and 6.0 g/m^3, respectively and (b) design an MBR system using hollow fiber membranes to meet the NH_4-N concentration of 0.50 g/m^3 with a return activated sludge ratio of 6.0. Process schematic flow diagrams are shown below for the two systems. The design condition is based on the following information from Example 8–3, and the design steps outlined in Tables 8–22 and 8–23 are followed.





Wastewater characteristics:

Constituent	Concentration, g/m^3
BOD	140
bCOD	224
rbCOD	80
NO_x	28.9
TP	6
Alkalinity	140 as $CaCO_3$

Part A—Design for CMAS Process

1. Design conditions:

Constituent	Unit	Value
Influent flowrate	m^3/d	22,700
Temperature	°C	12.0
MLSS	g/m^3	3000
MLVSS	g/m^3	2370
Aerobic SRT	d	21.0
Aeration basin volume	m^3	13,410
Aerobic	h	14.2
Anoxic mixing energy	kW/10^3 m^3	5
RAS ratio	Unitless	0.6
R_o	kg/h	275.9

Note: g/m^3 = mg/L.

2. Assumptions:
   a. Nitrate concentration in RAS = 6 g/m^3.
   b. Use the same coefficients as the nitrification process design.
   c. Mixing energy for anoxic reactor = 5 $kW/10^3\ m^3$.

Solution

1. Determine the active biomass concentration using Eq. (7–42) and substituting V/Q for τ.

$$X_b = \left[\frac{Q(\text{SRT})}{V}\right]\left[\frac{Y_{\text{H}}(S_o - S)}{1 + b_{\text{H}}(\text{SRT})}\right]$$

where $S_o - S \approx S_o$

$$X_b = \frac{(22{,}700\ \text{m}^3/\text{d})(21.0\ \text{d})(0.45\ \text{g VSS/g COD})(224\ \text{g bCOD/m}^3)}{[1 + (0.088\ \text{g/g·d})(21.0\ \text{d})](13{,}320\ \text{m}^3)}$$
$$= 1267\ \text{g/m}^3$$

2. Determine the IR ratio using Eq. (8–62).
   Aerobic tank NO_3-N concentration = N_e = 6.0 g/m^3

$$IR = \frac{\text{NO}_x}{N_e} - 1.0 - R = \frac{(28.9\ \text{g/m}^3)}{(6\ \text{g/m}^3)} - 1.0 - 0.60 = 3.2$$

3. Determine the amount of NO_3-N fed to the anoxic tank.

$$\text{Flowrate to anoxic tank} = IR\,Q + RQ$$
$$= 3.2(22{,}700\ \text{m}^3/\text{d}) + 0.60(22{,}700\ \text{m}^3/\text{d})$$
$$= 82{,}260\ \text{m}^3/\text{d}$$

NO_x feed = $(82{,}260\ m^3/d)(6.0\ g/m^3)$ = 517,560 g/d

4. Determine the anoxic volume. At 20 percent aerobic τ, anoxic τ = 0.20(14.2h) = 2.8 h. As a first approximation, use a detention time = 2.5 h

$$\tau = \frac{2.5\ \text{h}}{(24\ \text{h/d})} = 0.104\ \text{d}$$

$$V_{\text{nox}} = \tau \times Q = 0.104\ \text{d}(22{,}700\ \text{m}^3/\text{d}) = 2361\ \text{m}^3$$

5. Determine F/M_b using Eq. (8–56).

$$\text{F/M}_\text{b} = \frac{QS_o}{V_{\text{nox}}(X_b)} = \frac{(22{,}700\ \text{m}^3/\text{d})(140\ \text{g BOD/m}^3)}{(2361\ \text{m}^3)(1267\ \text{g/m}^3)} = 1.06\ \text{g/g·d}$$

6. Determine the SDNR using Eq. (8–57).
   Fraction of rbCOD = rbCOD/bCOD = $(80\ g/m^3)/(224\ g/m^3)$ = 0.36 = 36%

$$\text{SDNR}_\text{b} = b_\text{o} + b_1[\ln(\text{F/M}_\text{b})]$$

From Table 8–22, use 30 percent rbCOD, $b_o = 0.235$, $b_1 = 0.141$

$$\text{SDNR}_\text{b} = 0.235 + 0.141[\ln(1.06)] = 0.243\ \text{g NO}_3\text{-N/g MLVSS, biomass·d}$$

Apply temperature correction using $\theta = 1.026$

$$\text{SDNR}_{12} = 0.243(1.026)^{12-20} = 0.198 \text{ g/g·d}$$

Apply recycle correction using Eq. (8–60) for $IR = 3.2$

$$\begin{aligned}\text{SDNR}_{\text{adj}} &= \text{SDNR}_{\text{IR1}} - 0.029\ln(\text{F/M}_b) - 0.012\\ &= 0.198 - 0.029\ln(1.06) - 0.012\\ &= 0.184 \text{ g/g·d}\end{aligned}$$

7. Determine the overall SDNR based on MLVSS.

   $\text{SDNR} = \text{SDNR}_b(\text{MLVSS}_b/\text{MLVSS})$

   $\text{SDNR} = 0.184 \text{ g/g·d}[(1267 \text{ g/m}^3)/(2370 \text{ g/m}^3)] = 0.10 \text{ g NO}_3\text{-N/g MLVSS·d}$

8. Determine the amount of NO_3-N that can be reduced using Eq. (8–51).
   a. Check NO_r based on $\tau = 2.5$ h.

   $$\begin{aligned}\text{NO}_r &= (V_{\text{nox}})(\text{SDNR})(\text{MLVSS, biomass})\\ &= (2361 \text{ m}^3)(0.184 \text{ g/g·d})(1267 \text{ g/m}^3) = 550{,}415 \text{ g/d}\end{aligned}$$

   Comparing 550,415 g/d versus 517,560 g/d, there is about 6% excess nitrate-removal capacity. Thus, $\tau = 2.5$ h is acceptable as the excess capacity calculated is within the range of assumptions used. If excess is greater than 20 percent, a smaller tank volume could be evaluated.

9. Go to nitrification step in design and determine net oxygen required.

   R_o (without denitrification) = 275.9 kg/h (See Step 17, Example 8–3)

   The amount of oxygen supplied by nitrate reduction is as follows:

   $$\text{Oxygen credit} = \left(\frac{2.86 \text{ g O}_2}{\text{g NO}_3\text{-N}}\right)[(28.9 - 6.0) \text{ g/m}^3]\left(\frac{22{,}700 \text{ m}^3}{\text{d}}\right)\left(\frac{1 \text{ kg}}{10^3 \text{ g}}\right)$$

   $$= 1487 \text{ kg/d} = 61.9 \text{ kg/h}$$

   $$\text{Net O}_2 \text{ required} = R_o = (275.9 - 61.9) \text{ kg/h} = 214.0 \text{ kg/h}$$

   Note the required aeration rate will decrease in proportion to a lower R_o. The oxygen required and aeration energy can be reduced by 22.4 percent.

10. Check alkalinity.
    a. Prepare an alkalinity mass balance.

    Alk to be added to maintain pH ~ 7 = Influent Alk − Alk used + Alk produced
       i. Influent alkalinity = 140 g/m^3 as $CaCO_3$
       ii. Alkalinity used = 7.14 (28.9 g NO_3-N/m^3) = 206.3 g/m^3
       iii. Alkalinity produced = 3.57 [(28.9 − 6) g/m^3] = 81.8 g/m^3
       iv. Alkalinity needed to maintain neutral pH = 70 g/m^3 as $CaCO_3$

    b. Solve the above expression for Alk to be added.

    $$\begin{aligned}\text{Alk to be added} &= (70 - 140 + 206.3 - 81.8) \text{ g/m}^3\\ &= 54.5 \text{ g/m}^3 \text{ as CaCO}_3\end{aligned}$$

    $$\begin{aligned}\text{Mass of alkalinity needed} &= (54.5 \text{ g/m}^3)(22{,}700 \text{ m}^3\text{/d})(1 \text{ kg}/10^3 \text{ g})\\ &= 1237 \text{ kg/d as CaCO}_3\end{aligned}$$

    c. Compare to alkalinity needed for nitrification only.

    For the nitrification only design, the alkalinity needed in Step 19b, Example 8–3, was 3094 kg/d as $CaCO_3$.

    $$\text{Alkalinity savings} = 3094 - 1237 = 1857 \text{ kg/d}$$

11. Determine anoxic zone mixing energy.

Mixing energy = 5 kW/10^3 m^3 (given)
Volume = 2361 m^3
Power = (2361 m^3)(5 kW/10^3 m^3) = 12 kW total

12. Prepare summary of anoxic design.

Item	Unit	Value
Effluent NO_3-N	g/m^3	6.0
Internal recycle ratio	Unitless	3.2
RAS recycle ratio	Unitless	0.6
Anoxic volume	m^3	2361
MLSS	g/m^3	3000
Overall SDNR	g NO_3-N/g MLVSS·d	0.10
Detention time	h	2.5
Reduction in oxygen demand	%	22.4
Mixing power	kW	12
Alkalinity required	kg/d as $CaCO_3$	1237

Part B—Design for MBR Process

1. Design conditions:

Item	Unit	Value
Influent flowrate	m^3/d	22,700
Temperature	°C	12.0
Membrane tank MLSS	g/m^3	12,000
Membrane tank MLVSS	g/m^3	9480[a]
Aerobic SRT	d	21.0
Anoxic mixing energy	kW/10^3 m^3	8
RAS recycle ratio	unitless	6.0
R_o	kg/h	275

[a] Same MLVSS/MLSS ratio as (a)

Note: g/m^3 = mg/L

2. Assumptions:
   a. RAS recycle ratio = 6.0
   b. Use same coefficients as the nitrification process design
   c. Mixing energy for anoxic reactor = 8 kW/10^3 m^3
   d. Membrane flux =16.1 L/m^2·h (see Fig. 8–57)
   e. Membrane tank volume to membrane area ratio = 0.025 m^3/m^2 (see Sec. 8–12)
   f. Fine bubble aeration alpha = 0.35 (see Fig. 8–40)
   g. Coarse bubble aeration alpha = 0.50 (see Fig. 8–40)
   h. Fine bubble clean water O_2 transfer efficiency = 35 percent

i. Coarse bubble clean water O_2 transfer efficiency = 10 percent
j. DO in aeration basin = 2.0 g/m^3
k. Site elevation is 500 m (pressure = 95.6 kPa)
l. Fine pore diffuser fouling factor F = 0.20

Solution

1. Determine the membrane surface area.
Flux = 16.1 L/m^2·h

$$\text{Area} = \frac{(22{,}700\ \text{m}^3/\text{d})(\text{d}/24\ \text{h})}{(16.1\ \text{L/m}^2\cdot\text{h})(1\ \text{m}^3/10^3\ \text{L})}$$
$$= 58{,}747\ \text{m}^2$$

2. Determine the membrane separation tank volume, V_m.

$$V_m = (0.025\ \text{m}^3/\text{m}^2)(58{,}747\ \text{m}^2) = 1469\ \text{m}^3$$

Therefore the hydraulic retention time for the separation tank, τ, is

$$\tau = [(1469\ \text{m}^3)/(22{,}700\ \text{m}^3/\text{d})](24\ \text{h/d}) = 1.55\ \text{h}$$

3. Establish MLSS mass balance around preanoxic tank, ignoring incremental solids production.
Membrane tank MLSS = 12,000 g/m^3
RAS flowrate = $6Q$

$$(Q)(0) + (6Q)12{,}000 = (Q + 6Q)X_{\text{NO}_x}$$

$$X_{\text{NO}_x} = \left(\frac{6}{7}\right)12{,}000 = 10{,}286\ \text{g/m}^3$$

$$X_{\text{preanox}} = X_{\text{NO}_x} = 10{,}286\ \text{g/m}^3$$

4. Determine the preaeration tank volume and active biomass concentration.
Tank volume:
From Step 13 of Example 8–3, $P_{X,\text{TSS}}$ = 1916.8 kg/d
Aerobic SRT = 20.6 d
Eq. (7–57) in Table 8–10: $(P_{X,\text{TSS}})\text{SRT} = X_{\text{TSS}}(V)$

$$X_{\text{TSS}}(V) = (X_{\text{pre}})V_{\text{pre}} + X_m(V_m) = (P_{X,\text{TSS}})\text{SRT}$$

$$[(10{,}286\ \text{g/m}^3)V_{\text{pre}} + (12{,}000\ \text{g/m}^3)(1469\ \text{m}^3)]\left(\frac{1\ \text{kg}}{10^3\ \text{g}}\right) = (1916.8\ \text{kg/d})(21.0\ \text{d})$$

$$V_{\text{pre}} = 2200\ \text{m}^3$$

Hydraulic retention time:

$$\tau = [(2200\ \text{m}^3)/(22{,}700\ \text{m}^3/\text{d})](24\ \text{h/d}) = 2.3\ \text{h}$$

Preaeration tank active biomass (X_b) concentration:
From Eq. (8–20) part A in Table 8–10,

$$P_{x_b} = \frac{Q(Y_{\text{H}})(S_o - S)}{1 + b_{\text{H}}(\text{SRT})}$$

$$= \frac{(22{,}700\ \text{m}^3/\text{d})(0.45\ \text{g VSS/g COD})(224\ \text{g bCOD/m}^3)(1\ \text{m}^3/10^3\ \text{L})}{[1 + (0.088\ \text{g/g}\cdot\text{d})(21.0\ \text{d})]}$$

$$= 803.4\ \text{kg/d}$$

$$\text{Fraction } X_b = \frac{P_{X,\text{b}}}{P_{X,\text{TSS}}} = \frac{(803.4 \text{ kg/d})}{(1916.8 \text{ kg/d})} = 0.42$$

$$X_{\text{pre},b} = V_{\text{NO}_x,b} = 0.42(10{,}286 \text{ g/m}^3) = 4320 \text{ g/m}^3$$

5. Determine the effluent NO_3-N concentration.
   Use Eq. (8–60) and $NO_x = 28.9 \text{ g/m}^3$ (see step 9 in nitrification design)

$$Q(\text{NO}_x) = N_e[Q + IRQ + RQ]$$

$$\text{NO}_x = N[1.0 + 0 + 6.0] = 28.9 \text{ g/m}^3$$

$$N_e = 4.1 \text{ g/m}^3$$

6. Determine the amount of NO_3-N fed to the anoxic tank.

$$\begin{aligned}\text{NO}_x \text{ feed} &= 6Q(N_e)\\ &= 6(22{,}700 \text{ m}^3\text{/d})(4.1 \text{ g/m}^3) = 558{,}420 \text{ g/d}\end{aligned}$$

7. Determine the size of anoxic zone.

$$\begin{aligned}\text{Assume } V_{\text{NO}_x} &= 0.20\,(V_{\text{pre}} + V_m)\\ &= 0.20(2200 + 1469) \text{ m}^3 = 734 \text{ m}^3\end{aligned}$$

8. Calculate F/M_b.

$$\text{F/M}_\text{b} = \frac{QS_o}{V_{\text{NO}_x} X_b} = \frac{(22{,}700 \text{ m}^3\text{/d})(140 \text{ g/m}^3)}{(734 \text{ m}^3)(4320 \text{ g/m}^3)} = 1.0 \text{ g/g·d}$$

9. Determine $SDNR_b$ using Eq. (8–57).
   As for activated sludge/clarifier design: $b_o = 0.235$, $b_1 = 0.141$.

$$\text{SDNR}_{20} = 0.235 + 0.141[\ln(1.0)] = 0.235 \text{ g/g·d}$$

Apply temperature correction using $\theta = 1.026$

$$\text{SDNR}_{12} = 0.235(1.026)^{12-20} = 0.191 \text{ g/g·d}$$

Apply recycle correction using Eq. (8–64)

$$\begin{aligned}\text{SDNR}_{\text{adj}} &= \text{SDNR}_{\text{IR1}} - 0.029 \ln(\text{F/M}_\text{b}) - 0.012\\ &= 0.191 - 0.029 \ln(1.0) - 0.012\\ &= 0.179 \text{ g/g·d}\end{aligned}$$

10. Determine the overall SDNR based on MLVSS.

$$\text{SDNR} = \text{SDNR}_\text{b}(\text{MLVSS}_\text{b}/\text{MLVSS})$$

$$\text{SDNR} = 0.179 \text{ g/g·d}(4320 \text{ g/m}^3/8126 \text{ g/m}^3) = 0.10 \text{ g NO}_3\text{-N/g MLVSS·d}$$

11. Determine NO_x removal in anoxic tank.

$$\begin{aligned}\text{NO}_x &= (V_{\text{no}_x})(\text{SDNR})(\text{MLVSS}, X_b)\\ &= (734 \text{ m}^3)(0.179 \text{ g/g·d})(4320 \text{ g/m}^3) = 567{,}360 \text{ g/d}\end{aligned}$$

Removal required (from above) = 558,420 g/d

Use V_{NO_x} assumed.

12. Calculate the oxygen demand with the nitrate used for influent BOD removal. R_o from nitrification design = 275.9 kg/h.

$$\text{Oxygen credit} = \left(\frac{2.86\ \text{gO}_2}{\text{g NO}_3\text{-N}}\right)(28.9 - 4.1)\ \text{g/m}^3\left(\frac{22{,}700\ \text{m}^3}{\text{d}}\right)\left(\frac{1\ \text{kg}}{10^3\ \text{g}}\right)$$
$$= 1610\ \text{kg/d} = 67\ \text{kg/h}$$

Net O_2 received = R_o = (275.9 − 67) kg/h = 208.9 kg/h
Oxygen required can be reduced by 24.3 percent.

13. Check alkalinity
    i. influent alkalinity = 140 g/m^3 as $CaCO_3$
    ii. alkalinity used = 7.14 (28.9 g NO_3/m^3) = 206.3 g/m^3
    iii. alkalinity produced = 3.57 (28.9 − 4.1) g/m^3 = 88.5 g/m^3

    Solve above expressions for alkalinity to be added

$$\text{Alkalinity to be added} = (70 - 140 + 206.3 - 88.5)\ \text{g/m}^3$$
$$= 47.8\ \text{g/m}^3 \text{ as CaCO}_3$$

$$\text{Mass of alkalinity needed} = (47.8\ \text{g/m}^3)(22{,}700\ \text{m}^3/\text{d})\left(\frac{1\ \text{kg}}{10^3\ \text{g}}\right)$$
$$= 1085\ \text{g/m}^3 \text{ as CaCO}_3$$

14. Determine anoxic zone mixing.

Mixing energy = 8 kW/10^3 m^3 (given)
Volume = 734 m^3
Power = (734 m^3)(8 kW/10^3 m^3) = 5.9 kW total

15. Design the aerator oxygen transfer system.

a. Assume same liquid depth as for nitrification design in Example 8–3.

From Example 8–3, Step 8, $C^*_{\infty 20} = 10.64$

Total oxygen demand is divided between preaeration and membrane tank

Total volume = 2200 m^3 + 1469 m^3 = 3669 m^3
Percent preaeration = 60%
Percent membrane tank = 40%

Most of the nitrification and all of the BOD removal will occur in the preaeration tank. Assume 90 percent of O_2 demand in preaeration tank. From Step 11, the total O_2 demand is 208.9 kg/h.

O_2 demand in preaeration tank: 0.90 (208.9 kg/h) = 188.0 kg/h
O_2 demand in membrane tank: 0.10 (208.9 kg/h) = 20.9 kg/h

b. Design oxygen air rate needed for preaeration tank.
From nitrification design and input assumptions,

$\alpha = 0.35$, $\beta = 0.95$, $F = 0.90$
$C^*_{\infty 20} = 10.64$ g/m^3, $P_b/P_s = 0.94$, $C^*_{s20} = 9.09$

$$\text{SOTR} = \left[\frac{\text{OTR}_f}{(\alpha)(F)}\right]\left[\frac{C^*_{\infty 20}}{(\beta)(C_{st}/C^*_{s20})(P_b/P_s)(C^*_{\infty 20}) - C}\right][(1.024)^{20-T}]$$

$$\text{SOTR} = \left[\frac{(188.0\ \text{kg/h})}{(0.35)(0.90)}\right]\left\{\frac{10.64}{\left[(0.95)\left(\frac{10.78}{9.09}\right)(0.94)(10.64) - 2.0\right]}\right\}(1.024^{20-12}) = 828.3\ \text{kg/h}$$

c. Determine the air flowrate for oxygen demand for preaeration tank

$$\text{Air flowrate, m}^3/\text{min} = \frac{(\text{SOTR kg/h})}{[(E)(60\ \text{min/h})(\text{kg O}_2/\text{m}^3\ \text{air})]}$$

Using the data given in Appendix B, the density of air at 12ºC and pressure of 95.2 kPa (0.94 × 101.325 kPa) is 1.1633 kg/m^3. The corresponding amount of oxygen by weight is 0.270 kg O$_2$/m^3 air (0.2318 × 1.1633 kg/m^3). Thus, the required air flowrate is

$$\begin{aligned}\text{Air flowrate, m}^3/\text{min} &= \frac{(828.3\ \text{kg/h})}{[(0.35)(60\ \text{min/h})(0.270\ \text{kg O}_2/\text{m}^3\ \text{air})]}\\ &= 146.1\ \text{m}^3/\text{min}\end{aligned}$$

d. Design oxygen air rate needed for oxygen demand for membrane separation tank.

From nitrification design and input assumptions,

$\alpha = 0.50$, $\beta = 0.95$, $F = 1.0$

$C^*_{\infty 20} = 10.64\ \text{g/m}^3$, $P_b/P_s = 0.94$, $C^*_{s20} = 9.09$

$$\begin{aligned}\text{SOTR} &= \left[\frac{(20.9\ \text{kg/h})}{(0.50)(1.0)}\right]\left\{\frac{10.64}{\left[(0.95)\left(\dfrac{10.78}{9.09}\right)(0.94)(10.64)\ -\ 2.0\right]}\right\}(1.024^{20-12})\\ &= 58.0\ \text{kg/h}\end{aligned}$$

e. Determine the air flowrate for oxygen demand

$$\text{Air flowrate, m}^3/\text{min} = \frac{(\text{SOTR kg/h})}{[(E)(60\ \text{min/h})(\text{kg O}_2/\text{m}^3\ \text{air})]}$$

Using the data given in Appendix B, the density of air at 12ºC and pressure of 95.2 kPa (0.94 × 101.325 kPa) is 1.1633 kg/m^3. The corresponding amount of oxygen by weight is 0.270 kg O$_2$/m^3 air (0.2318 × 1.1633 kg/m^3). Thus, the required air flowrate is

$$\begin{aligned}\text{Air flowrate, m}^3/\text{min} &= \frac{(58.0\,\text{kg/h})}{[(0.10)(60\ \text{min/h})(0.270\ \text{kg O}_2/\text{m}^3\ \text{air})]}\\ &= 35.8\ \text{m}^3/\text{min}\end{aligned}$$

16. Summary table of MBR design.

Design parameter	Unit	Value
Average flowrate	m^3/ d	22,700
Average BOD load	kg/d	3178
Average TKN load	kg/d	795
bCOD	g/m^3	224
rbCOD	%	36
NO$_x$	g/m^3	28.9

(continued)

(*Continued*)

Design parameter	Unit	Value
Temperature	°C	12.0

Alkalinity required (as $CaCO_3$)	kg/d	1085

Comment In the above design example, computations are based on an average design condition. In actual design, allowances should be provided for peak flows and loads or a safety factor should be included, as discussed in Chap. 3. Note that some process engineers have added a *swing zone* between the upstream preanoxic and aerobic nitrification zones. The swing zone provides operational flexibility and can be operated with aeration or with only mixing (anoxic) to provide additional volume where most needed for nitrification or denitrification.

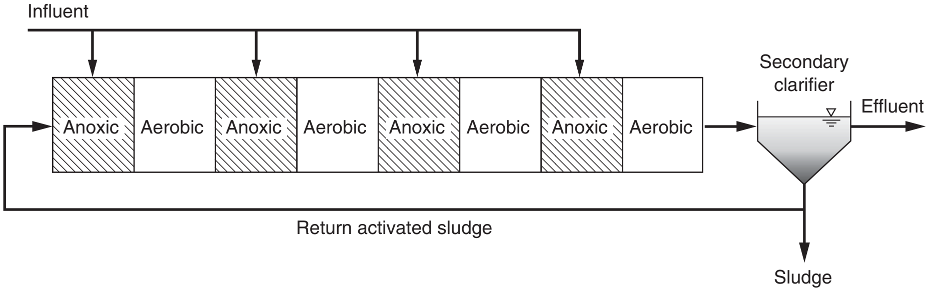

Figure 8–33

Schematic diagram of a step feed biological nitrogen removal process.

Step Feed Nitrification and Preanoxic Denitrification Process Design. Step feed for nitrogen removal is similar to the step feed process described in Sec. 8–4 for BOD and nitrification. For nitrogen removal, wastewater is introduced at several feed points (see Fig. 8–33). In most cases, where a step feed process is used for BOD removal and nitrification, it will be relatively easy to upgrade it to a step feed anoxic/aerobic biological nitrogen-removal process. For such applications the influent feed points and volumes of the individual channels in the reactor (passes) are already determined. The tank layout is generally symmetrical and the volume in each pass is equal. For a new tank design, it is possible to use a nonsymmetrical step feed design where the feed split is somewhat equal, but the volume of each pass increases as the mixed-liquor concentration decreases from the first to last pass. The tank volumes may be utilized more efficiently in the nonsymmetrical design approach by using a similar F/M ratio for each pass.

The variables involved in the design of a step feed biological nitrogen removal process for an existing basin are (1) the flow distribution between passes, (2) the relative split between anoxic and aerobic volumes, and (3) the final pass MLSS concentration. The selection of the final pass MLSS concentration is based on using an acceptable solids loading for the secondary clarifier. As will be illustrated in Example 8–8, selection of the final pass MLSS concentration, the RAS ratio, the influent flow split, and wastewater characteristics will determine the system SRT. With the known SRT value, the biomass and nitrifying bacteria concentration in the mixed liquor can be determined, which can then be used to determine the nitrification and denitrification capacity of the system. The process design procedure involves successive iterations with varying anoxic/aerobic volumes and flow splits evaluated to find the most satisfactory design. Design of a step feed BNR process is presented in Example 8–8.

EXAMPLE 8–8 **Step Feed Biological Nitrogen Removal Process Design** Determine the amount of nitrification and nitrate removal in a four-pass step feed biological nitrogen removal process (see Fig. 8–33), using the same influent flowrate, wastewater characteristics, and temperature as was used in Example 8–7, and total aerobic tank volume obtained for the nitrification solution.

1. Design conditions and assumptions:
    a. The flowrate is 22,700 m^3/d
    b. The step feed aeration tank is divided into four equal passes, with equal volumes used for the anoxic and aerobic zones
    c. The flow split to each pass is 0.10, 0.40, 0.30, and 0.20 of the influent flow, for passes 1 through 4, respectively

d. MLSS concentration in the final aerobic zone is 3000 mg/L (same as in Example 8–7)
e. RAS recycle ratio (Q_{RAS}/Q) is 0.6
f. Anoxic volume is 15% of the total reactor volume
g. Total aeration tank volume = 13,230 m^3
h. Aeration tank DO = 2.0 g/m^3
i. Temperature = 12°C
k. Effluent NH_4-N = 0.5 g/m^3

2. Wastewater characteristics:

Constituent	Concentration, g/m^3
BOD	140
rbCOD	80
bCOD	224
nbVSS	20
TKN	35
$TSS_o - VSS_o$	10

Note: g/m^3 = mg/L.

3. Kinetic coefficients:
The following kinetic coefficients, from Table 8–14, have been adjusted for temperature (Example 8–3)
a. Heterotrophs:

$$Y = 0.45 \text{ g VSS/g bCOD}$$

$$b_{12°C} = 0.088 \text{ g/g·d}$$

$$f_d = 0.15 \text{ g/g}$$

b. Nitrifiers:

$$Y = 0.15 \text{ g VSS/g } NO_x$$

$$b_{AOB,12°C} = 0.135 \text{ g/g·d}$$

$$\mu_{max,AOB,12°C} = 0.52 \text{ g/g·d}$$

$$K_{NH_4} = 0.50 \text{ g/m}^3$$

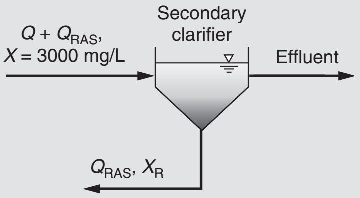
$$K_o = 0.50 \text{ g/m}^3$$

Solution

1. Determine the aeration and anoxic zone volumes. Anoxic volume is 15% of total volume per problem statement.

V = total volume = 13,230 m^3
Anoxic volume = 0.15(13,230 m^3) = 1984.5 m^3
Aerobic volume = 0.85(13,230 m^3) = 11,245.5 m^3
Anoxic volume/pass = (1984.5 m^3)/4 = 496.1 m^3
Aerobic volume/pass = (11,245.5 m^3)/4 = 2811.4 m^3

2. Determine RAS concentration.



Perform a solids balance (neglect the effluent TSS because it is not significant for the clarifier solids balance).

$Q_{\mathrm{RAS}} = 0.6Q$ (recycle ratio from problem statement)

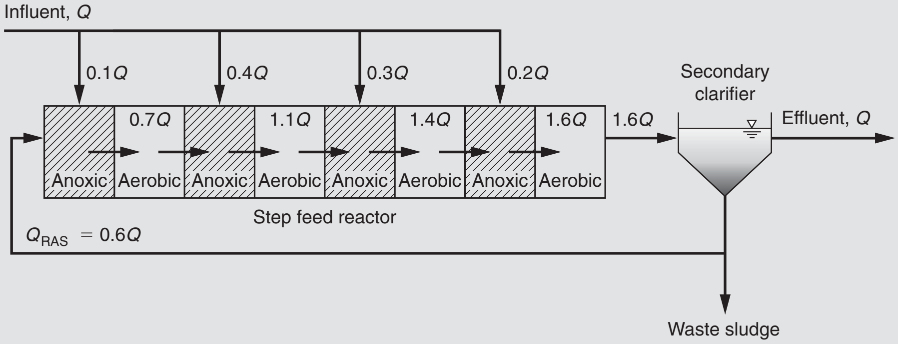
The solids balance is

$$(Q + 0.6Q)3000\ \mathrm{g/m^3} = 0.6QX_{\mathrm{R}}$$

$$X_{\mathrm{R}} = \frac{(Q + 0.6Q)(3000\ \mathrm{g/m^3})}{0.6Q}$$

$$X_{\mathrm{R}} = (1.6Q/0.6Q)(3000\ \mathrm{g/m^3}) = 8000\ \mathrm{g/m^3}$$

3. Determine MLSS concentration in each pass (see figure below).



a. Pass 1 mass balance.
   Solids in = solids out (Note: solids production for a single pass is negligible)

$$0.10Q(0) + (Q_{\mathrm{RAS}})(8000\ \mathrm{g/m^3}) = (\mathrm{RAS} + 0.1Q)X_1$$

$$0.10Q(0) + (0.6Q)(8000\ \mathrm{g/m^3}) = (0.6Q + 0.1Q)X_1$$

$$X_1 = (8000\ \mathrm{g/m^3})(0.6/0.7) = 6860\ \mathrm{g/m^3}$$

b. Pass 2 mass balance.

$$(0.7Q)X_1 + 0.4Q(0) = 1.1QX_2$$

$$X_2 = (0.7/1.1)X_1 = (0.7/1.1)6860\ \mathrm{g/m^3}$$

$$= 4365\ \mathrm{g/m^3}$$

c. Pass 3 and 4 are calculated similarly.
d. Summary of MLSS concentrations and volumes:

Pass	MLSS, g/m^3	Anoxic volume, m^3	Aerobic volume, m^3
1	6860	496	2811
2	4365	496	2811
3	3430	496	2811
4	3000	496	2811

4. Perform solids balance on system and determine aerobic SRT.
   a. Solids balance.

$$\sum X_i V_i = (P_{X,\text{TSS}})(\text{SRT})$$

$$\begin{aligned}\sum X_i V_i &= X_1V_1 + X_2V_2 + X_3V_3 + X_4V_4 \\ &= [(6860 + 4365 + 3430 + 3000)\text{ g/m}^3](2811\text{ m}^3)(1\text{ kg}/10^3\text{ g}) \\ &= 49{,}628\text{ kg}\end{aligned}$$

   b. Apply Eq. (8–20) and (7–57) in Table 8–10 assuming $\text{NO}_x \sim 0.80$ TKN.

MLSS components = heterotrophic biomass + cell debris + nitrifier biomass + nbVSS + inorganic inerts

$$\begin{aligned}(\text{SRT})(P_{X,\text{TSS}}) = {} & \frac{QY_H(S_o - S)\text{SRT}}{[1 + b_H(\text{SRT})](0.85)(10^3\text{ g/1 kg})} + \frac{f_d(b_H)QY_H(S_o - S)(\text{SRT})^2}{[1 + b_H(\text{SRT})](0.85)(10^3\text{ g/1 kg})} \\ & + \frac{QY_n(\text{NO}_x)\text{SRT}}{[1 + b_n(\text{SRT})](0.85)(10^3\text{ g/1 kg})} + \frac{Q(\text{nbVSS})\text{SRT}}{(10^3\text{ g/1 kg})} \\ & + \frac{Q(\text{TSS}_o - \text{VSS}_o)\text{SRT}}{(10^3\text{ g/1 kg})}\end{aligned}$$

$$\text{NO}_x = 0.80(35\text{ g/m}^3) = 28\text{ g/m}^3$$

   c. Solve for SRT.
   Substituting wastewater and coefficient values yields

$$\begin{aligned}49{,}628\text{ kg} = {} & \frac{(22{,}700\text{ m}^3\text{/d})(0.45\text{ g/g})(224\text{ g/m}^3)\text{SRT}}{[1 + (0.088\text{ g/g}\cdot\text{d})(\text{SRT})](0.85)(10^3\text{ g/1 kg})} \\ & + \frac{(0.15\text{ g/g})(0.088\text{ g/g}\cdot\text{d})(0.45\text{ g/g})(22{,}700\text{ m}^3\text{/d})(224\text{ g/m}^3)(\text{SRT})^2}{[1 + (0.088\text{ g/g}\cdot\text{d})(\text{SRT})](0.85)(10^3\text{ g/1 kg})} \\ & + \frac{(22{,}700\text{ m}^3\text{/d})(0.15\text{ g/g})(28\text{ g/m}^3)\text{SRT}}{[1 + (0.135\text{ g/g}\cdot\text{d})(\text{SRT})](0.85)(10^3\text{ g/1 kg})} \\ & + \frac{(22{,}700\text{ m}^3\text{/d})(20\text{ g/m}^3)\text{SRT}}{(10^3\text{ g/1 kg})} \\ & + \frac{(22{,}700\text{ m}^3\text{/d})(10\text{ g/m}^3)\text{SRT}}{(10^3\text{ g/1 kg})}\end{aligned}$$

$$49{,}628\text{ kg} = \frac{2691\text{SRT}}{1 + 0.088\text{ SRT}} + \frac{35.5\text{ SRT}^2}{1 + 0.088\text{ SRT}} + \frac{112.2\text{ SRT}}{1 + 0.135\text{ SRT}} + 454\text{ SRT} + 227\text{ SRT}$$

Solve using spreadsheet solver function or by successive iterations,

SRT = 28.1 d.

Compare to Example 8–3 with nitrification. In Example 8–3, aerobic volume = 13,230 m^3 and SRT = 20.6 d. For step feed, aerobic volume = 11,245 m^3 and SRT = 28.1 d. The lower volume and higher SRT are due to the higher MLSS concentrations in the first 3 passes.

5. Determine the composition of the MLSS and MLVSS using the above solution in Step 4 for MLSS and SRT = 28.1 d. The results of the calculation of the MLVSS components are summarized in the following table which summarizes the solids mass in the aeration tank:

Item	MLVSS, kg	Fraction of total MLVSS	MLSS, kg
Heterotrophs	18,511	0.48	21,777
Cell debris	6861	0.18	8072
Nitrifiers	559	0.04	657
nbVSS	12,748	0.33	12,748
Inert inorganics			6374
Total	38,679		49,628

a. Fraction of biomass solids (from above table).
Thus, MLVSS/MLSS = 38,679/49,628 = 0.78

Biomass = 0.48(MLVSS)

Nitrifiers = 0.01(MLVSS)

b. Nitrogen for nitrifier growth.
With biomass and cell debris calculated, the NO_x for nitrifier growth is calculated as follows:

Daily biomass + debris production = (18,511 + 6861) kg = 25,372 kg

Daily wasting = 25,372 kg/28.1 d SRT = 902.9 kg/d

$$\text{N used for synthesis} = (0.12\text{ g N/g VSS biomass})(902.9\text{ kg/d}) = 108.4\text{ kg/d}$$

Based on influent flow the N synthesis is

$$\text{N synthesis} = \frac{(108.4\text{ kg/d})(10^3\text{ g/1 kg})}{(22{,}700\text{ m}^3\text{/d})} = 4.8\text{ g/m}^3$$

$$NO_x = \text{TKN} - N_{syn} - (NH_4\text{-N})_e = (35 - 4.8 - 0.5)\text{ g/m}^3 = 29.7\text{ g/m}^3$$

c. Nitrifier mass fraction correction.

$$\text{Mass nitrifiers} = \frac{QY_n(\text{NO}_x)\text{SRT}}{[1 + b_n(\text{SRT})]}$$

$$= \frac{(22{,}700\ \text{m}^3/\text{d})(0.15\ \text{g/g})(29.7\ \text{g/m}^3)(28.1\ \text{d})}{[1 + (0.135\ \text{g/g·d})(28.1\ \text{d})](10^3\ \text{g/1 kg})} = 592.8\ \text{kg VSS}$$

Corrected MLVSS = (38,679 − 559 + 593) kg = 38,713 kg

Nitrifiers as fraction of MLVSS = 593/38,713 = 0.015 (as compared to 0.014)

d. Summary Table.
Based on the above data, prepare a summary table of biomass and nitrifier (AOB) concentrations in each pass using ratios from above.

Pass	MLSS, g/m³	MLVSS, kg/d	Nitrifiers, g VSS/m³	Biomass, g VSS/m³
1	6860	5350	80.3	2568
2	4365	3405	51.1	1634
3	3430	2675	40.1	1284
4	3000	2340	35.1	1123

6. Evaluate nitrification rate in each pass and compare to NH_4-N fed to stage.

a. Develop equation for nitrification rate in g/d. Multiply Eq. (7–101) in Table 8–10 by the reactor volume. Eq. (7–101) describes volumetric nitrification rate (g/L-d) as a function of the NH_4-N and DO concentration. The nitrification rate in each stage is:

$$R_n = \frac{\mu_{\text{max,AOB}}}{Y_{\text{AOB}}}\left(\frac{S_{\text{NH}_4}}{K_{\text{NH}_4} + S_{\text{NH}_4}}\right)\left(\frac{S_o}{K_{o,\text{AOB}} + S_o}\right)X_{\text{AOB}}V$$

As indicated in the steady state nitrogen mass balance below for each pass, the rate of oxidizable nitrogen (available nitrogen NH_4-N = NO_x) fed to the pass equals the nitrification rate plus the rate of ammonia nitrogen leaving the pass. The nitrogen entering the pass is related to the influent feed rate of available nitrogen (NO_x) to that pass and the rate of influent nitrogen from a previous pass. Before proceeding with the mass balance, prepare a flowrate summary.

b. Prepare flowrate summary and mass balances.

Pass	Flowrate from previous reactor	Influent flowrate	Total Flowrate
1	0.6 Q	0.1 Q	0.7 Q
2	0.7 Q	0.4 Q	1.1 Q
3	1.1 Q	0.3 Q	1.4 Q
4	1.4 Q	0.2 Q	1.6 Q

The balances for the 4 passes are shown for steady state:

Pass 1 (recycle NH_4-N) = last pass (pass 4) NH_4-N

In general for each pass, rate of influent N = rate of effluent N + nitrification rate

$$\text{RAS}(Q)S_{\text{NH},4} + 0.1(Q)\text{NO}_x = 0.7(Q)S_{\text{NH},1} + R_{n,1}$$

$$0.7QS_{\text{NH},1} + 0.4Q\text{NO}_x = 1.1QS_{\text{NH},2} + R_{n,2}$$

$$1.1QS_{\text{NH},2} + 0.3Q\text{NO}_x = 1.4QS_{\text{NH},3} + R_{n,3}$$

$$1.4QS_{\text{NH},3} + 0.2Q\text{NO}_x = 1.6QS_{\text{NH},4} + R_{n,4}$$

The nitrification rate (Rn) for pass 1 is shown below and the rate expression applies to the other passes also with their respective NH_4-N, DO and AOB concentrations and volumes.

$$R_{n,1} = \frac{\mu_{\max,\text{AOB}}}{Y_{\text{AOB}}}\left(\frac{S_{\text{NH}_4,1}}{K_{\text{NH}_4} + S_{\text{NH}_4,1}}\right)\left(\frac{S_{o,1}}{K_{o,\text{AOB}} + S_{o,1}}\right)X_{\text{AOB},1}V_1$$

c. Solve for nitrification rate in each stage with $\mu_{\max,\text{AOB}} = 0.52$ g/g·d, $Y_{\text{AOB}} = 0.15$ g/g, and X_{AOB} from table above. Thus, N_1, N_2, N_3, and N_4 are solved for each stage using $\text{NO}_x = 29.7\ \text{g/m}^3$ (determined earlier). The value for N_4 is assumed to solve pass 1 and then the final solution is reached by iteration until the value for N_4 equals the value used to solve pass 1. A spreadsheet program with a solver function can assist in the solution. Using the coefficients shown for the design condition, the solution is summarized below.

d. Summary of step-feed solution for NH_4-N per pass:

Pass	Nitrifiers, g/m^3	Influent flowrate, m^3/d	RAS or flow from previous pass, m^3/d	NH_4-N, g/m^3	R_n, g/d
1	80.3	2270	13,620	0.07	73,713
2	51.1	9080	15,890	0.84	249,754
3	40.1	6810	24,970	0.84	196,389
4	35.1	4540	31,780	0.54	142,076

Sufficient volume exists to provide an effluent NH_4-N concentration of 0.54 g/m^3 even though the total aerobic volume for this step feed design is less than that used for the CMAS design in Example 8–7. The volume in pass 1 is much greater than that needed to achieve an effluent NH_4-N concentration of 0.5 g/m^3. Further adjustment of step feed flow splits may be made to optimize NH_4-N removal, but it would also affect the NO_3-N removal.

7. Determine the amount of nitrate removal in the anoxic zones and effluent NO_3-N concentration.

The amount of nitrate fed to each anoxic zone for passes 2, 3, and 4 equals the nitrification rate (g/d) in the previous pass plus the nitrate not removed in the previous anoxic zones. For the first anoxic zone, the nitrate feed is equal to the effluent NO_3-N concentration times the RAS flowrate (assuming no denitrification in the secondary clarifier). For the solution, the first step is to determine the denitrification capacity for each anoxic stage by calculating the F/M_b per pass and using Eq. (8–57) and Table 8–22 to obtain the SDNR as follows:

a. Calculate F/M_b from Eq. (8–56) and BOD = 140 g/m³.

$$F/M_b = \frac{QS_o}{(V_{nox})(X_b)} \; (x_b \text{ is found from Step 5d})$$

b. Obtain $SDNR_b$ using same b_0 and b_1 values in Eq. (8–57) used in Example 8–6 for same wastewater characteristics.

c. Apply $\theta = 1.026$ for temperature correction. There is no correction for recycle flow.

$$SDNR_{12} = SDNR_{20}(1.026)^{12-20} = SDNR_{20}(0.814)$$

d. NO_3-N removed = $(SDNR_b)(V_{nox})X_b$

Sample calculation for pass 1:

$$F/M_b = \frac{(2270\ \text{m}^3/\text{d})(140\ \text{g/m}^3)}{(2568\ \text{g/m}^3)(496\ \text{m}^3)} = 0.25\ \text{g/g·d}$$

$$SDNR = 0.235 + 0.141[\ln(F/M_b)]$$

$$SDNR = 0.235 + 0.141[\ln(0.25)] = 0.04\ \text{g/g·d}$$

$$SDNR_{12} = 0.04(0.814) = 0.03$$

Pass	X_b, g/m³	Influent flowrate, m³/d	Anoxic volume, m³	F/M_b	$SDNR_{12}$, g/g·d
1	2568	2270	496	0.25	0.03
2	1634	9080	496	1.57	0.24
3	1284	6810	496	1.50	0.24
4	1123	4540	496	1.14	0.25

Using the SDNR from the above for each pass, the amount of NO_3-N removed is tabulated below.

Pass	NO_3-N removal capacity, g/g·d
1	40,987[a]
2	195,511
3	152,847
4	139,252

[a] NO_3-N removed = (0.03 g/g·d)(2568 g/m³)(496 m³) = 40,987 g/d.

8. Nitrate balance and effluent NO_3-N concentration.

a. Develop equations for nitrate mass balance.

A nitrate balance for each pass is done to determine how much nitrate remains after the anoxic reactor and the effluent nitrate nitrogen concentration. The nitrogen remaining after each reactor is

$$\begin{array}{c} NO_3\text{-N influent} \\ \text{from RAS or} \\ \text{previous pass} \end{array} + \begin{array}{c} \text{pass anoxic} \\ \text{removal} \\ \text{capacity} \end{array} = \begin{array}{c} NO_3\text{-N} \\ \text{remaining after} \\ \text{anoxic reactor} \end{array}$$

If there is a negative value for NO_3-N remaining because of excess anoxic NO_3-N removal capacity, then a value of zero is assigned [see column (3) in the following table].

The effluent NO_3-N concentration from each pass is then:

$$\begin{matrix} NO_3\text{-N remaining} \\ \text{after anoxic} \end{matrix} - \begin{matrix} NO_3\text{-N produced} \\ \text{in the pass} \end{matrix} = \begin{matrix} \text{effluent} \\ NO_3\text{-N} \end{matrix}$$

b. Prepare table to solve mass balance for each stage. The NO_3-N balance is illustrated in the following table.

Pass	Total NO_3-N to pass, g/d	Anoxic removal capacity, g/d[a]	NO_3-N remaining after anoxic, g/d[b]	NO_3-N produced (R_n) in pass, g/d[c]	Effluent NO_3-N, g/d[d]
	(1)	(2)	(3)	(4)	(5)
1	111,003	40,987	70,016	73,713	143,729
2	143,729	195,511	0	249,754	249,754
3	249,754	152,847	96,907	196,389	293,296
4	293,296	139,252	154,044	142,076	296,120
					Effluent NO_3-N = 8.15 g/m^3

[a] Source of influent nitrate: for pass 1, RAS; other passes, column (5).

[b] (1) − (2).

[c] From Step 6.

[d] (3) + (4).

c. Determine effluent NO_3-N concentration.

The nitrate fed to pass 1 from RAS is calculated as follows:

$$NO_3\text{-N to pass 1} = (Q_{RAS})N_e$$

where N_e = effluent NO_3-N concentration, g/m^3

The value for N_e is obtained using the effluent NO_3-N shown in column (5) for pass 4:

$$(Q + Q_{RAS})N_e = \text{pass 4 effluent } NO_3\text{-N (g/d)}$$

$$N_e = (296{,}120 \text{ g/d})/(Q + 0.6\,Q)$$

$$N_e = (296{,}120 \text{ g/d})/(1.6)(22{,}700 \text{ g/m}^3) = 8.15 \text{ g/m}^3$$

9. Reevaluate design.

Initially, assume an effluent concentration, e.g., 10 g/m^3, to calculate the amount of NO_3-N fed to pass 1. Using the spreadsheet, perform successive iterations until the calculated effluent NO_3-N equals the trial.

Comment Note that some excess capacity is available and is not realized in the initial passes of the symmetrical step feed process design. Different influent flow splits may be used to reduce the effluent nitrate concentration, the anoxic and aerobic volumes can be changed, the anoxic zone may be staged, and the MLSS concentration may be increased. A spreadsheet model is necessary to evaluate various design changes.

Sequencing Batch Reactor Preanoxic Denitrification Process Design. In the SBR process and other batch decant processes [see Figs. 8–1(c) and 8–20] nitrate removal can be accomplished by four methods: (1) nitrate reduction by using a mixed nonaerated fill period, (2) cycling aeration On/Off during the react period, (3) having an anoxic contact time after nitrification is complete and just before a short aeration time, settling and decant, and (4) operating at a low DO concentration to encourage SNdN during the aeration sequence. Under cyclic aeration conditions after the fill and reaction period, the SDNR is driven mainly by endogenous respiration. Denitrification during a mixed nonaerated fill period provides the most efficient means of nitrate removal and also provides a selector operation to prevent filamentous sludge bulking. Most of the nitrate produced during the previous aerobic cycle remains in the SBR tank because the decant volume is only 20 to 30 percent of the total tank volume. The mass of nitrate remaining after decant can be reduced during the fill period if sufficient BOD and time are available. The following example is used to illustrate how to estimate the amount of nitrate removed during a mixed fill period for an SBR reactor.

EXAMPLE 8–9 **Preanoxic Denitrification Process Design for SBR Process** Determine how much nitrate may be removed during a mixed, unaerated fill period in an SBR for the following design conditions. Assume the following design conditions apply.

Design conditions:

Item	Unit	Value
Number of tanks	no.	2
Flowrate/tank	m^3/d	3785
Sequence time	h	
Fill		4.0
Aerate		3.0
Settle		0.5
Decant		0.5
Fill volume fraction	V_F/V_T	0.25
Influent BOD	g/m^3	200
Influent bCOD	g/m^3	320
Influent rbCOD	g/m^3	60
Influent TKN	g/m^3	35
Effluent NH_4-N	g/m^3	0.5
SRT	d	20
Temperature	°C	16

Note: $g/m^3 = mg/L$.

Use kinetic coefficients from Table 8–14.

Solution

1. Determine tank volume.

$$\text{Cycles/day} = \frac{(24\ \text{h/d})}{(8\ \text{h/cycle})} = 3\ \text{cycles/d}$$

$$\text{Fill volume/cycle} = \frac{(3785\ \text{m}^3/\text{d})}{3\ \text{cycles}} = 1261.7\ \text{m}^3/\text{fill cycle}$$

$$V_F/V_T = 0.25$$

$$V_T = \frac{1261.7\ \text{m}^3}{0.25} = 5{,}047\ \text{m}^3$$

2. Determine nitrate produced (NO_x).
   a. Determine heterotrophic biomass produced.
      Determine heterotrophic biomass production including cell debris to estimate the nitrogen used for synthesis using Eq. (8–24) in Table 8–10. Use Eq. (8–20) in Table 8–10 to determine the heterotrophic biomass production. (Biomass produced from nitrification can be ignored, as it represents a small fraction of the biomass.)

$$P_{x,\text{bio}} = \frac{Q(Y_\text{H})(S_o - S)}{1 + b_\text{H}(\text{SRT})} + \frac{f_d(b_\text{H})Y_\text{H}(Q)(S_o - \text{S})\text{SRT}}{1 + b_\text{H}(\text{SRT})}$$

      i. Use coefficients from Table 8–14 and adjust b for temperature.

$$b_\text{H} = 0.12(1.04)^{16-20} = 0.103\ \text{g/g·d}$$

$$Y_\text{H} = 0.45\ \text{g VSS/g bCOD}$$

$$f_d = 0.15$$

      Assume $S_o - S \approx S_o$.

      ii. Substitute and solve for P_X.

$$P_x = \frac{(3785\ \text{m}^3/\text{d})(0.45\ \text{g/g})(320\ \text{g/m}^3)}{[1 + (0.103\ \text{g/g·d})(20\ \text{d})](10^3\ \text{g/1 kg})}$$

$$+ \frac{(0.15\ \text{g/g})(0.103\ \text{g/g·d})(0.45\ \text{g/g})(3785\ \text{m}^3/\text{d})(320\ \text{g/m}^3)(20\ \text{d})}{[1 + (0.103\ \text{g/g·d})(20\ \text{d})](10^3\ \text{g/1 kg})}$$

$$= (178.1 + 55.0)\ \text{kg/d} = 233.1\ \text{kg/d}$$

   b. Determine N synthesis.

$$NO_x = \text{TKN} - \text{N}_\text{syn} - (\text{NH}_4\text{-N})_e$$

$$\text{N}_\text{syn} = 0.12(P_x) = 0.12(233.1\ \text{kg/d}) = 28.0\ \text{kg/d}$$

$$\text{N}_\text{syn} = \frac{(28.0\ \text{kg/d})(10^3\ \text{g/1 kg})}{(3785\ \text{m}^3/\text{d})} = 7.4\ \text{g/m}^3$$

      Effluent NH_4-N = 0.5 g/m^3

      NO_x produced $= (35.0 - 7.4 - 0.5)\ \text{g/m}^3 = 27.1\ \text{g/m}^3$

3. Determine amount of nitrate left in SBR mixed liquor after decant.
   Assume: NO_3-N = 0 before aeration period, which means that all of the nitrate remaining in the SBR in the liquid volume after decanting is removed by denitrification during the mixing and unaerated fill period.
   a. Determine NOx produced per cycle.

$$\text{g NO}_x\text{ produced per cycle} = 27.1\text{ g/m}^3\,(1261.7\text{ m}^2\text{/fill}) = 34{,}192\text{ g NO}_x\text{/fill}$$

NO_3-N concentration at end of aeration with tank full: (V = 5047 m^3)

$$= \frac{34{,}192\text{ g}}{5047\text{ m}^3} = 6.8\text{ g/m}^3$$

Effluent NO_3-N = 6.8 g/m^3

based on all NO_3-N that is produced in the aeration period is removed by denitrification during the unaerated fill period.

   b. Determine nitrate remaining in SBR after decant (assuming no denitrification in settling and decant).

Volume remaining after decant: 0.75(5047 m^3) = 3785 m^3

NO_3-N present = 6.8 $g/m^3(V_s)$ = (6.8 g/m^3)(3785 m^3) = 25,740 g

4. Determine $SDNR_b$ in fill period.
   Active biomass concentration (from Step 2aii, biomass = 178.1 kg/d)

$$X_b = \frac{(\text{biomass})(\text{SRT})}{V_T} = \frac{(178.1\text{ kg/d})(20\text{ d})(10^3\text{ g/1 kg})}{5047\text{ m}^3}$$

$$= 705.8\text{ g/m}^3\text{ at full volume}$$

   a. Determine F/M_b ratio in fill period.

Biomass in tank = (705.8 g/m^3)(5047 m^3)(1 kg/10^3 g) = 3562 kg

BOD feed rate = $Q_F S_o$

$$Q_F = \frac{V_F}{t_F} = (1261.7\text{ m}^3\text{/4 h})(24\text{ h/d})$$

$$= 7570\text{ m}^3\text{/d}$$

$$Q_F S_o = (7570\text{ m}^3\text{/d})(200\text{ g/m}^3\text{ BOD})(1\text{kg}/10^3\text{ g}) = 1514\text{ kg/d}$$

$$\text{F/M}_b = \frac{(1514\text{ kg/d})}{3562\text{ kg}} = 0.43\text{ g/g·d}$$

   b. Determine the $SDNR_b$.

Fraction rb COD = (60 g/m^3)/(320 g/m^3) = 0.19

Use Eq. (8–57)

$$\text{SDNR}_b = b_0 + b_1[\ln(\text{F/M}_b)]$$

From Table 8–21; $b_0 = 0.213$ and $b_1 = 0.118$

At 20°C, $\text{SDNR}_b = 0.213 + 0.118\,[\text{L}_n(0.43)] = 0.112 \text{ g/g·d}$

At 16°C, $\text{SDNR}_{16} = 0.112\theta^{16-20};\ \theta = 1.026$

$= 0.102 \text{ g/g·d}$

5. Determine NO_3-N removal capacity during the fill period.

$$\begin{aligned} NO_x &= (\text{SDNR}_b)(X_b)(V_T) \text{ [Note: } (X_b)(V_T) = \text{biomass in system]} \\ &= (0.102 \text{ g/g·d})(705.8 \text{ g/m}^3)(5407 \text{ m}^3) \\ &= 390{,}410 \text{ g/d} \end{aligned}$$

Fill time = 4 h

$$NO_r \text{ at 4 h} = \frac{(390{,}410 \text{ g/d})(4 \text{ h})}{(24 \text{ h/d})} = 65{,}068 \text{ g}$$

NO_3-N available from Step 3 = 25,740 g

Therefore, all of NO_3-N can be removed in the fill period.

Note: V_F/V_T controls effluent NO_3-N concentration.

Postanoxic Denitrification Processes

A number of postanoxic denitrification processes have been introduced including the single, two, and three stage processes. The Bardenpho process is a good example of a postanoxic denitrification application after the aerobic nitrification step. At this point in the biological treatment process there is minimal rbCOD and pbCOD available as electron donors for denitrification. Thus, the electron donor that creates the demand for nitrate reduction is mainly from activated sludge endogenous respiration. Observed SDNRs have ranged from 0.01 to 0.04 g NO_3-N/g MLVSS·d under endogenous respiration (U.S. EPA, 1993; Stensel et al., 1995). Denitrification with external carbon addition is considered later in this section.

Endogenous Respiration Denitrification Rates. The equivalent endogenous oxygen utilization rate under anoxic conditions has been found to be about 50 percent of that under aerobic conditions (Randall et al., 1992; Wuhrman, 1964). Based on the cited references, the SDNR under endogenous conditions (SDNR_b) can be calculated from the endogenous decay rate as follows:

$$NO_r = \left(\frac{1.42}{2.86}\right)(b_{\text{H,anox}})X_{\text{H}} \tag{8–63}$$

$$\text{SDNR}_b = \frac{1.42(b_{\text{H,anox}})}{2.86} = 0.5(b_{\text{H,anox}}) \tag{8–64}$$

where 1.42 = g O_2/g biomass VSS

$b_{\text{H,anox}}$ = biomass endogenous decay coefficient under anoxic conditions, g VSS/g VSS biomass·d

2.86 = g O_2 equivalent/g NO_3-N.

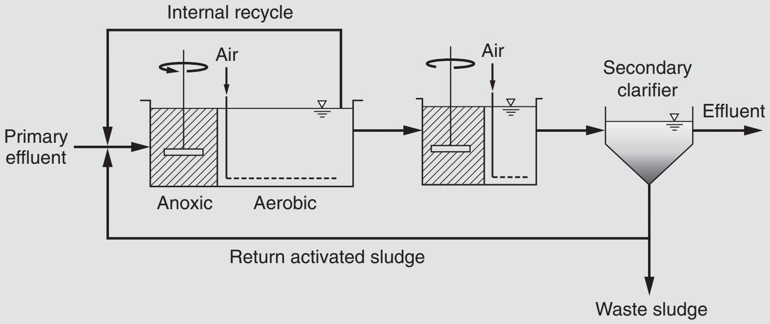
X_{H} = heterotrophic bacteria concentration, g VSS/m^3

NO_r = nitrate reduction rate, g/m^3·d

The specific endogenous decay rate under anoxic conditions is about 60 percent of that under aerobic conditions (Henze et al., 2000). As discussed previously, the $SDNR_b$ is based on the biomass concentration. As shown in Chap. 7, the fraction of biomass from the MLVSS declines as the SRT increases, so the SDNR value based on the MLVSS concentration would decrease with increasing SRT.

Ammonia Production. Ammonia is produced from endogenous decay as a result of deamination of cellular organic nitrogen released during cell lysis. About 50 percent of the biomass nitrogen is converted to ammonia during the relatively short postanoxic tank detention time, or about 0.06 g NH_4-N/g biomass VSS decayed.

EXAMPLE 8–10 **Design of Postanoxic Denitrification Tank** Add a postanoxic tank to further reduce the effluent nitrate concentration to 1.0 g/m^3 after the anoxic/aerobic process steps in Example 8–7 for the activated sludge/clarifier system as shown in the figure below. Determine (a) the postanoxic tank volume for denitrification due to endogenous decay and (b) the change in NH_4-N concentration across the postanoxic tank. Note: This configuration is the Bardenpho process as the anoxic/aerobic/anoxic tanks would be followed by a tank with short aerobic detention time (20–30 min).



Design conditions and assumptions:

1. Information from the anoxic/aerobic system in Example 8–7.

Item	Unit	Value
Flowrate	m^3/d	22,700
RAS ratio	unitless	0.60
Temperature	°C	12
MLSS	g/m^3	3000
MLVSS	g/m^3	2370
Biomass, X_H	g/m^3	1267
Anoxic Endogenous decay, $b_{H,12}$	g/g·d	0.06
Aerobic SRT	d	20.6
Aerobic basin volume	m^3	13,230
Aerobic tank NO_3-N	g/m^3	6.0

Note: g/m^3 = mg/L.

1. NH_4-N used for cell synthesis = 0.12 g NH_4-N/g VSS produced
2. NH_4-N release in endogenous decay = 0.06 g NH_4-N/g VSS
3. DO concentration = 0.0 g/m^3
4. Postanoxic effluent NO_3-N concentration = 1.0 g/m^3

Solution

1. Determine the amount of nitrate to remove in the postanoxic tank using Eq. (8–74). The rate of removal is the difference in NO_3-N concentration across the tank times the flowrate.

$$R_{NO_3} = (Q,\ \text{m}^3/\text{d})(1 + R)(6.0 - 1.0)\ \text{g/m}^3$$

$$R_{NO_3} = 22{,}700\ \text{m}^3/\text{d}\ (1 + 0.60)(6.0 - 1.0)\ \text{g/m}^3 = 181{,}600\ \text{g/d}$$

2. Determine the postanoxic tank volume.
   a. Nitrate reduction from endogenous decay using Eq. (8–63),

$$R_{NO_3} = \left(\frac{1.42}{2.86}\right)(b_{H,12})(X_H)(V_{anox})$$

$$181{,}600\ \text{g/d} = \left(\frac{1.42}{2.86}\right)(0.06\ \text{g/g·d})(1267\ \text{g/m}^3)(V_{anox})$$

$$V_{anox} = 4810\ \text{m}^3$$

$$\tau = (4810\ \text{m}^3)(24\ \text{h/d})/(22{,}700\ \text{m}^3/\text{d}) = 5.09\ \text{h}$$

3. Determine the change in NH_4-N concentration.
   a. Rate of biomass decay in anoxic tank

$$R_{VSS} = b_{H,12}(X_H)(V_{anox}) = (0.06\ \text{g/g·d})(1267\ \text{g/m}^3)(4811\ \text{m}^3)$$

$$= 365{,}732\ \text{g VSS/d}$$

   b. Ammonia production rate

$$R_{NH_4-N} = (0.06\ \text{g}\ NH_4\text{-N/g VSS})(365{,}732\ \text{g VSS/d}) = 21{,}944\ \text{g/d}$$

   c. Change in NH_4-N concentration:

$$\text{Increase} = \frac{R_{NH_4\text{-N}}}{Q(1 + R)} = \frac{(21{,}944\ \text{g}\ NH_4\text{-N/d})}{(22{,}700\ \text{m}^3/\text{d})(1 + 0.6)} = 0.60\ \text{g/m}^3$$

4. What is the observed SDNR?

$$\text{SDNR} = \frac{R_{NO_3}}{(X_{VSS})V_{anox}} = \frac{(181{,}600\ NO_3\text{-N/d})}{(2370\ \text{g/m}^3)(4811\ \text{m}^3)} = 0.016\ \text{g}\ NO_3\text{-N/g VSS·d}$$

Low DO and Cyclic Nitrification/Denitrification Processes

Low DO SNdN and cyclic NdN nitrogen removal processes are typically done in single reactor systems or single reactor compartmentalized systems with relatively long τ and SRT conditions. Thus, for design estimates of denitrification rates, the reactor can be treated as a completely mixed reactor with continuous addition of influent flow and bCOD. In contrast to the preanoxic denitrification zone, the reactor bCOD concentration and SDNR are relatively low due to the larger reactor volume. In comparison to postanoxic denitrification, the SDNR is higher.

The effect of low DO concentration on nitrification rates as well as denitrification rates must be considered. The activated sludge floc will be only partially aerobic, and denitrification occurs in the anoxic zones established within the floc particles due to oxygen depletion, with the result that simultaneous nitrification and denitrification takes place. The nitrification and denitrification rates are a function of the reaction kinetics, floc size, floc density, floc structure, rbCOD loading, and bulk liquid DO concentration. It is possible that NH_4-N is oxidized mainly to NO_2-N, with NO_2-N reduction within the anoxic portion of the floc. Because of the complex physical factors, the nitrification and denitrification rates cannot be predicted accurately with present models.

Effects of Low DO. Basic modifications to the Monod growth model, however, can be used to estimate and illustrate the effects of a low DO concentration on nitrification and denitrification rates and system performance. The effect of DO concentration on nitrification rate is described by Eq. (7–101) given in Table 8–10. The kinetic coefficient values can be very site specific as a function of the simultaneous NdN system operating conditions and ammonia-oxidizing and heterotrophic microorganism population selection. The effect of DO concentration on the design SRT is illustrated on Fig. 8–34 for a completely-mixed reactor effluent NH_4-N concentration of 1.0 mg/L at 20°C using the kinetic coefficient values for nitrification given in Table 8–14. No safety factor is used for these calculations. The actual SRT value used for design would be higher depending on the safety factor selected for a specific system. The nitrification rate at a DO concentration of 0.2 mg/L is 24 percent of the rate at 2.0 mg/L, based on the calculated SRT values of 19.9 and 4.7 d, respectively. SNdN and cyclic NdN systems are normally operated at SRT values of 20 to 30 d, so the ability to produce complete nitrification at low DO is apparent.

Nitrate Reduction Rate. The nitrate reduction rate can be related to the rate of substrate utilization as given by Eq. (7–133) in Table 8–10. In addition, nitrate reduction is also driven by substrate released by endogenous decay as shown by Eq. (8–63).

$$r_{NO_x} = NO_r = \left(\frac{1.42}{2.86}\right) b_H (X_H) \tag{8–63}$$

Figure 8–34

Effect of DO concentration on SRT required to achieve an effluent NH_4-N concentration of 1.0 mg/L at 20°C in a CMAS system based on kinetic coefficients in Table 8–14.

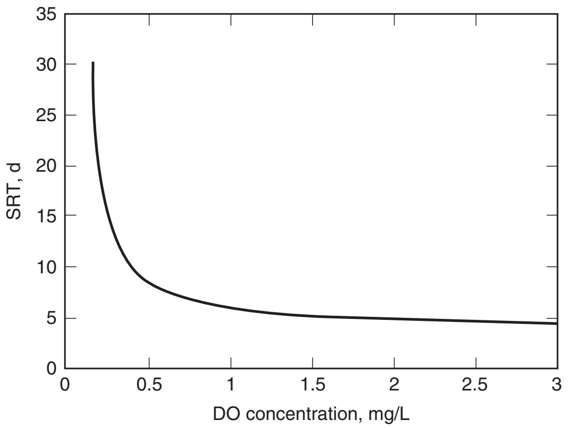


Figure 8–35

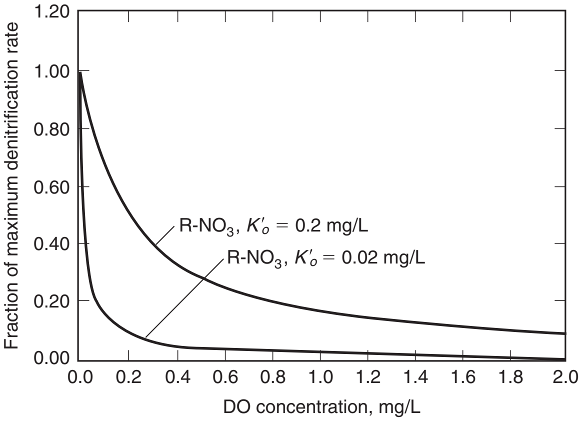
Effect of mixed liquor DO concentration on maximum denitrification rates.



Combining Eqs. (7–133) and (8–63) yields a general rate expression [(Eq. (8–65)] that can be used to describe the nitrate reduction rate in an anoxic reactor as function of bCOD, heterotrophic biomass, NO_3-N, and DO concentrations as well as various biokinetic coefficients. For NO_2-N reduction instead of NO_3-N reduction, due to ammonia oxidation to only nitrite, the 2.86 value in Eq. (8–65) is replaced by 1.71, the oxygen equivalent of NO_2-N.

$$r_{\mathrm{NO_3}} = \left(\frac{1 - 1.42Y_{\mathrm{H}}}{2.86}\right)\left[\frac{\mu_{\mathrm{H,max}} S_S}{Y_{\mathrm{H}}(K_s + S_S)}\right]\left(\frac{S_{\mathrm{NO_3}}}{K_{\mathrm{NO_3}} + S_{\mathrm{NO_3}}}\right)\left(\frac{K'_o}{K'_o + S_o}\right)(\eta)X_{\mathrm{H}} + \left(\frac{1.42}{2.86}\right)b_{\mathrm{H}}(X_{\mathrm{H}}) \tag{8–65}$$

The DO inhibition coefficient K'_o is difficult to estimate and will be site-specific, depending on the floc size and structure. The effect of DO concentration on the denitrification rate is shown on Fig. 8–35 for K'_o values of 0.02 and 0.2 mg/L. At a DO concentration of 0.2 mg/L, the denitrification rate may be 10 to 50 percent of its maximum rate. For long SRT systems with τ values in the range of 18 to 30 h, sufficient time may be available for high nitrate removal efficiency, even though the rate is somewhat inhibited by having DO present at low concentrations.

Completely-Mixed Tank SDNR. Many SNdN and cyclic NdN denitrification systems are single tank reactors with long τ and SRT values. Because of the long SRT and τ, the denitrification kinetics are related to the overall degradation of bCOD, pbCOD, and endogenous decay and are not as strongly influenced by the rbCOD fraction as for the preanoxic denitrification application with the relatively short τ. During the complete-mix anoxic period in an oxidation ditch operation or in the anoxic period of a continuously-mixed oxidation ditch, the specific denitrification rate is affected by both the endogenous respiration rate and the bCOD in the influent wastewater as continuous feeding occurs. The average specific denitrification rate, which includes these effects, can be estimated using Eq. (8–66) [based on Stensel (1981) and modified to account for the rate as a function of active heterotrophic biomass]:

$$\mathrm{SDNR_b} = \frac{0.175A_n}{Y_{\mathrm{net}}(\mathrm{SRT})} \tag{8–66}$$

where $\mathrm{SDNR_b}$ = specific denitrification rate relative to heterotrophic biomass concentration, g NO_3-N/g biomass·d

A_n = net oxygen utilization coefficient, g O_2/g bCOD removed

Y_{net} = net yield for heterotrophic biomass, g VSS/g bCOD

0.175 = based on 2.86 g O_2 equivalent/g NO_3-N and the assumption that only 50 percent of heterotrophic biomass can use nitrate in place of oxygen

Note that Eq. (8–66) can be adjusted with information from Fig. 8–33 to account for a reduced SDNR for operation with low residual DO concentration. For a complete-mix activated sludge reactor, A_n and Y_{net} are determined as follows (Stensel, 1981):

$$A_n = 1.0 - 1.42Y_{\text{H}} + \frac{1.42(b_{\text{H}})(Y_{\text{H}})\text{SRT}}{1 + b_{\text{H}}(\text{SRT})} \tag{8–67}$$

$$Y_{\text{net}} = \frac{Y_{\text{H}}}{1 + b_{\text{H}}(\text{SRT})} \tag{8–68}$$

The SDNR_{b} in Eq. (8–66) is relative to the biomass concentration that is a portion of the MLVSS concentration. Thus, the design procedure used to determine the amount of nitrate removed in the anoxic period during cyclic aerobic/anoxic operation incorporates some of the elements of the computational steps for anoxic/aerobic design described in Table 8–21. In Step 3 in Table 8–21, the heterotrophic biomass concentration has to be determined. As detailed in Step 9, the biomass concentration, SDNR_{b}, anoxic volume, and anoxic time are used to determine the amount of nitrate nitrogen removed. Use of the above equations is illustrated in Example 8–11.

EXAMPLE 8–11 **Determine Fraction of Anoxic Time Needed in Oxidation Ditch Cyclic NdN Nitrogen Removal System** Determine what fraction of the time an oxidation ditch system must be operated as an anoxic reactor for an intermittent aeration process to produce an effluent NO_3-N concentration of 7 g/m^3, based on the following design conditions.

Design conditions:

Item	Unit	Value
Oxidation ditch volume	m^3	8700
SRT	d	25
MLSS	g/m^3	3500
MLVSS	g/m^3	2500
Fraction of biomass	g biomass/g MLVSS	0.40
Temperature	°C	15
Y_{H}, b_{H}		Values given in Table 8–14
Influent flowrate	m^3/d	7570
NO_x produced in oxidation ditch, based on influent flowrate	g/m^3	27

Note: g/m^3 = mg/L.

Solution

1. Determine the SDNR.
   a. Obtain Y_H and b_H from Table 8–14 and correct b for temperature using Eq. (2–25).

$$Y_H = 0.45 \text{ g VSS/g bCOD}$$

$$b_{H,20} = 0.12 \text{ g/g·d}$$

$$b_{H,15} = b_{H,20}(1.04)^{15-20}$$

$$= 0.12(1.04)^{15-20} = 0.099 \text{ g/g·d}$$

   b. Using Eq. (8–67), determine A_n.

$$A_n = 1.0 - 1.42Y_H + \frac{1.42(b_H)(Y_H)\text{SRT}}{1 + b_H(\text{SRT})}$$

$$A_n = 1.0 - 1.42(0.45) + \frac{1.42(0.099 \text{ g/g·d})(0.45 \text{ g/g})(25 \text{ d})}{1 + (0.099 \text{ g/g·d})(25 \text{ d})}$$

$$= 0.82 \text{ g } O_2/\text{g bCOD}$$

   c. Using Eq. (8–68) determine Y_{net}.

$$Y_{net} = \frac{Y_H}{1 + b_H(\text{SRT})}$$

$$= \frac{0.45}{1 + (0.099 \text{ g/g·d})(25 \text{ d})} = 0.13 \text{ g VSS/g bCOD}$$

   d. Using Eq. (8–66), determine SDNR_b.

$$\text{SDNR}_b = \frac{0.175A_n}{(Y_{net})\text{SRT}}$$

$$\text{SDNR}_b = \frac{0.175(0.82 \text{ g } O_2/\text{g bCOD})}{(0.13 \text{ g VSS/g bCOD})(25 \text{ d})} = \frac{0.044 \text{ g } NO_3\text{-N}}{\text{g biomass·d}}$$

2. Determine biomass concentration in the mixed liquor.

$$X_b = (2500 \text{ g/m}^3 \text{ MLVSS})\left(\frac{0.40 \text{ g biomass}}{\text{g MLVSS}}\right)$$

$$= 1000 \text{ g/m}^3 \text{ biomass}$$

3. Determine amount of NO_3-N removal needed in g/d.

Nitrate removed concentration (NO_r) = (27.0 – 7.0) g/m^3 = 20 g/m^3

$$NO_r = (7570 \text{ m}^3\text{/d})(20 \text{ g/m}^3)$$

$$= 151{,}400 \text{ g/d}$$

4. Determine NO_3-N removal rate under anoxic reaction time.

$$\text{Anoxic } NO_r = (\text{SDNR}_b)(X_b)(V)$$

$$(0.044 \text{ g } NO_3\text{-N/g biomass·d})(1000 \text{ g/m}^3)(8700 \text{ m}^3)$$

$$= 382{,}800 \text{ g/d}$$

5. Determine anoxic time needed per day.

$$\text{Anoxic time} = \frac{(151{,}400 \text{ g/d})(24 \text{ h/d})}{(382{,}800 \text{ g/d})} = 9.5 \text{ h}$$

$$\text{Fraction of day} = 9.5 \text{ h}/24 \text{ h} = 0.40$$

Comment The computed value is within the range of values reported for the anoxic fraction for cyclic aeration processes as given in U.S. EPA (1993). The actual time may be less or the amount of nitrogen removal may be greater due to denitrification within the floc during low DO aeration periods and in the secondary clarifier. By knowing the approximate amount of time needed for the anoxic conditions, the aerobic SRT available for nitrification can be estimated.

Alternative Process Configurations for Biological Nitrogen Removal

A variety of activated sludge process configurations are used to accomplish biological nitrogen removal. Representative process schematics, descriptions, and nitrogen removal capability for biological nitrogen removal processes are given in Table 8–24 and are discussed below. The advantages and disadvantages for the various processes are also discussed.

MLE Process. The MLE process is one of the most common methods used for biological nitrogen removal, and can be adapted easily to existing activated sludge facilities. The amount of nitrate removal is limited by the practical levels of internal recycle to the preanoxic zone, and the process is used more generally to achieve effluent total nitrogen concentrations between 6 and 10 mg/L. About 2–4 mg/L of the effluent total nitrogen concentration is associated with NH_4-N and dissolved and particulate organic nitrogen. With an internal recycle ratio of 4.0, the MLE process can remove about 80 percent of the NO_x produced in the nitrification process. As more water conservation is implemented and influent TKN concentrations increase, it will be more difficult to achieve an effluent TN concentration of <10 mg/L. Dissolved oxygen control should be used in the zone from which the recycle stream is taken to limit the amount of DO fed to the anoxic zone. The MLE membrane process has a high recycle flow to the preanoxic zone and if there is sufficient BOD available for DO and NO_3-N consumption, effluent TN concentrations less than 6.0 mg/L are possible.

Step Feed Process. The step feed process is also applicable for meeting effluent total nitrogen concentrations of less than 10 mg/L. However, it is theoretically possible to achieve lower effluent nitrogen total concentrations of less than 5.0 mg/L with step feed BNR. The DO concentration in the upstream aerobic zone before the step feed BNR anoxic zone must be controlled to minimize dissolved oxygen addition to the anoxic zone and consumption of rbCOD needed for NO_3-N removal. Multiple DO control points are required to optimize nitrogen removal in step feed BNR process. Influent flow splitting control and measurement are necessary to optimize the step feed reactor volume for nitrogen removal.

Table 8–24

Description of suspended growth processes for nitrogen removal

Process	**Description**
Preanoxic Processes	
(a) Ludzak-Ettinger 	The first concept of a preanoxic BNR was an anoxic-aerobic operating sequence by Ludzak and Ettinger (1962). The influent wastewater was fed to an anoxic zone, which was followed by an aerobic zone. The process relies on the nitrate formed in the aerobic zone being returned via the RAS to the anoxic zone. Because the only nitrate fed to the anoxic zone is that in the RAS, denitrification is limited greatly by the RAS recycle ratio. However, more recently, this process has been used with increased RAS recycle rates to prevent rising sludge in the secondary clarifiers due to denitrification.
(b) Modified Ludzak-Ettinger (MLE) 	One of the most commonly used BNR processes is the Modified Ludzak-Ettinger (MLE) process. Barnard (1973) improved on the original Ludzak-Ettinger design by providing the internal recycle to feed more nitrate to the anoxic zone directly from the aerobic zone. Both the denitrification rate and overall nitrogen removal efficiency are increased. The internal recycle flow ratio (recycle flowrate divided by influent flowrate) typically ranges from 2 to 4. With sufficient influent BOD and anoxic contact time, these recycle ratios result in an average effluent NO_3-N concentrations from 4 to 7 mg/L when treating domestic wastewater. The MLE process is very adaptable to existing activated sludge facilities and can easily meet a common effluent standard of less than 10 mg/L total nitrogen. A BOD/TKN ratio of 4:1 in the influent wastewater is usually sufficient for effective nitrate reduction by preanoxic processes. Typical anoxic tank detention times for the MLE process range from 2 to 4 h, but when the anoxic zone is divided into 3 to 4 stages in series, denitrification kinetic rates are increased and the total detention time needed may then be 50 to 70 percent of the single-tank design.
(c) MLE- Membrane Bioreactor 	Preanoxic designs are commonly used in MBR systems, which are typically operated at SRTs that result in full nitrification. The return activated sludge recycle ratio (typically 6.0) is significantly higher than that used for the activated sludge/secondary clarifier systems with the MLE process. The return activated sludge is taken directly from the aerated membrane separation tank, and thus some of the influent wastewater rbCOD will be consumed by bacteria using dissolved oxygen as an electron acceptor with less rbCOD then available for denitrification.

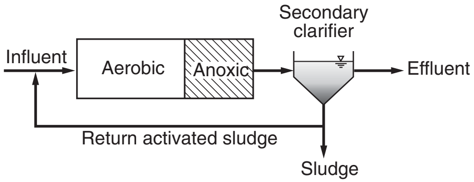
(*continued*)

Table 8–24 *(Continued)*

Process	**Description**
(d) Step feed biological nitrogen removal  	Preanoxic zones can also be used in a step feed BNR process. Because step feed BNR processes are usually adapted to existing multiple-pass full-scale tanks, symmetrical anoxic/aerobic stages are generally used. However, non-symmetrical designs with smaller initial anoxic/aerobic stages can take better advantage of the higher MLSS concentration in the early stages, due to less RAS dilution, resulting in greater treatment capacity. A possible influent flow splitting percent distribution for a 4-pass system is 15/35/30/20. The final flow portion to the last anoxic/aerobic zone is critical as the nitrate produced in the aerobic zone from that flow will not be reduced, and will, thus, determine the final effluent NO_3-N concentration. Effluent NO_3-N concentrations of less than 5 mg/L are possible. Depending on the influent TKN concentration, carbon addition, such as methanol or glycerol, may be added to reduce the anoxic zone size and to compensate for a weak influent BOD concentration.
(e) Step feed MBR  	A step feed preanoxic design can also be used with a MBR process to give a lower effluent NO_3-N concentration than for the MLE-MBR system. Effluent NO_3-N concentrations of less than 3.0 mg/L are possible. An exogenous carbon source can also be added to the final anoxic zones.
(f) Sequencing batch reactor (SBR)  	The SBR system [see Table 8–18(l)] also employs preanoxic denitrification using BOD in the influent wastewater. Mixing is used during the fill period to contact the mixed liquor with the influent wastewater. For many domestic applications, depending on the wastewater strength, sufficient BOD and fill time are available to remove almost all of the nitrate remaining in the mixed liquor after the settle and decant steps. Some nitrate removal also occurs during the non-aerated settle and decant periods. Separate mixing provides operating flexibility and is useful for anoxic operation during the aeration period, as well as anaerobic or anoxic contacting during the fill period. Mixing without aeration during the fill period is effective in improving sludge settling properties in addition to nitrogen removal. Effluent NO_3-N concentrations of less than 5 mg/L are possible.

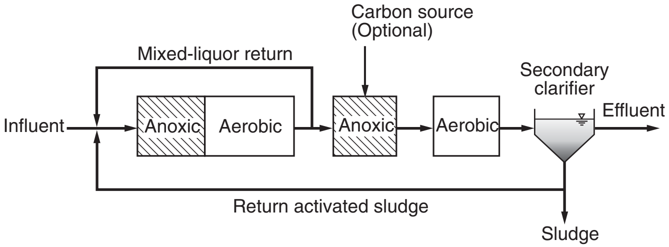
Postanoxic Processes

(g) Single-sludge



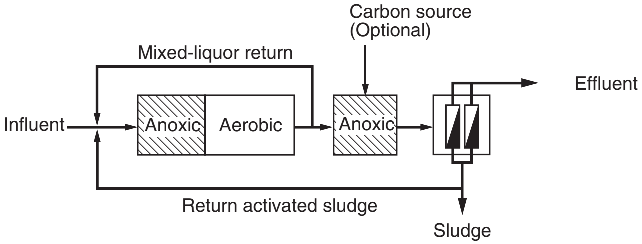
In the single-sludge process (developed by Wuhrmann, 1964), nitrogen removal was accomplished in the activated sludge process by adding a mixed anoxic tank after aerobic nitrification. To achieve high nitrate removal efficiency, a carbon source would have to be added. NH_4-N is released during endogenous respiration in postanoxic zones, which adds to the effluent total nitrogen concentration.

(h) Bardenpho (4-stage)



Both preanoxic and postanoxic denitrification are incorporated in the Bardenpho process, which was developed and applied at full-scale facilities in South Africa in the mid-1970s, before making its way to the United States in1978. The detention time of the postanoxic stage is about the same or larger than that used for the preanoxic zone. In the postanoxic zone, the NO_3-N concentration leaving the aeration zone is typically reduced from about 5 to 7 mg/L to less than 3 mg/L. During pilot plant testing with higher strength wastewaters, Barnard (1974) found that biological phosphorus removal occurred as well as nitrogen removal, hence the basis for the process name (the name comes from the first three letters of the inventor's name, Barnard, and from denitrification, and phosphorus). Carbon can be added to the postanoxic zone to provide lower effluent NO_3-N concentrations and to reduce the postanoxic tank volume. Effluent NO_3-N concentrations of less than 1.0 or 2.0 mg/L are possible.

(i) Bardenpho (4-stage) MBR



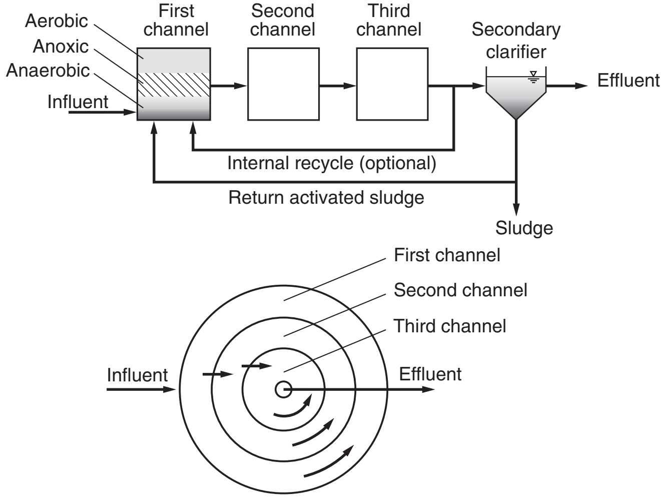
A 4-stage Bardenpho process can be incorporated in MBR systems. As with the activated sludge/secondary clarifier system, carbon addition is optional in the postanoxic zone, but is needed when a very low effluent total nitrogen concentration is required. Effluent NO_3-N concentrations of less than 1 or 2 mg/L are possible.

(*continued*)

Table 8–24 (*Continued*)

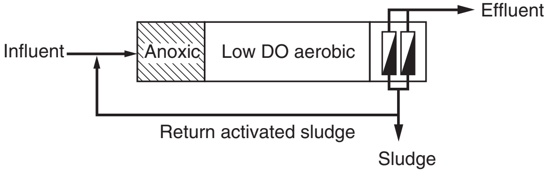
Process	Description
(j) Dual-sludge system with an external carbon source  	An approach that was most popular in the 1970s is a postanoxic design with exogenous external carbon addition, usually methanol. The anoxic zone (1 to 3 h) is mixed and a short aeration time ($<$ 30 min) follows to strip nitrogen gas bubbles from the floc and to provide aerobic conditions to improve liquid-solids separation in the clarifier.
(k) MLE-Packed bed postanoxic  	A more common approach today for postanoxic treatment is to use denitrification filters with carbon addition after the nitrification process (see Chap. 9 for postanoxic packed bed designs). An effluent NO_3-N concentration of less than 1.0 mg/L is possible.
Simultaneous nitrification/denitrification	
(l) Low DO oxidation ditch  	Oxidation ditches that have sufficient volume available are able to accommodate both nitrification and denitrification at lower rates under low DO conditions. An oxidation ditch may be used to maintain DO concentrations below 0.5 mg/L with manual or automated DO control. Where multiple aerators are used, for example with brush aerators, a low to zero DO is maintained throughout the channel. The use of variable frequency drives on the aeration equipment and the improved accuracy and reliability of low DO concentration measurements by luminescence DO probes facilitates the application of low DO control methods.

(m) Orbal™



The channels in the Orbal process are operated in series with a zero to low DO (<0.3 mg/L) concentration in the first channel, a 0.5 to 1.5 mg/L DO concentration in the second channel, and a higher DO concentration (2 to 3 mg/L) in the third channel. The first channel receives the influent wastewater and return activated sludge and generally contains about one-half the total basin volume. Volumes of the second and third channels are about one-third and one-sixth of the total basin volumes, respectively. Recycle of mixed liquor from the inner loop to the outer loop allows denitrification of nitrates resulting from nitrification in the inner channels. Variations of the process include operation with and without internal recycle flow (Bionutre™ process) from the third channel to the first channel. An oxygen supply rate of about 50 percent of the estimated design requirement has been recommended to support SNdN in the first zone.

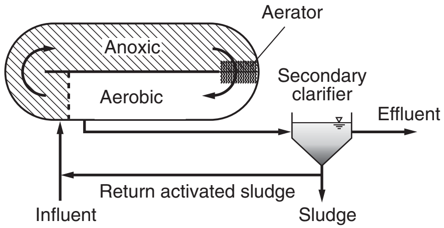
(n) Low DO MBR



MBR systems have been operated with low DO in the aerobic zone prior to the aerobic membrane separation zone. The high mixed liquor concentration results in a higher volumetric oxygen uptake, which helps to assure that anoxic zones exist within the floc at bulk liquid DO concentrations of 0.30 to 0.70 mg/L.

Cyclic NdN Processes

(o) Oxidation ditch



Depending on the aeration design and length of the oxidation ditch channel, anoxic denitrification zones can be established in oxidation ditches to accomplish biological nitrogen removal in a single tank. An aerobic zone exists after the aerator, and as the mixed liquor flows down the channel away from the aerator, the DO concentration decreases due to oxygen uptake by the biomass. At a point where the DO is depleted, an anoxic zone is created in the ditch channel and the nitrate will be used for endogenous respiration activity by the mixed liquor. Most of the readily degradable BOD had been consumed previously in the aerobic zone. Because of the large tank volumes and long SRTs used in oxidation ditch processes, sufficient capacity is available to accommodate nitrification and denitrification zones. DO control is necessary, however, to maintain a sufficient anoxic zone volume to allow for significant nitrogen removal.

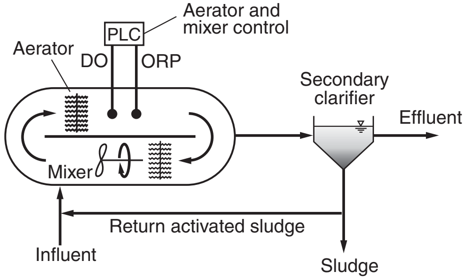
Table 8–24 (*Continued*)

<table>
<tr><th>Process</th><th>Description</th></tr>
<tr><td>

(p) dNOx™



</td><td>

In the dNOx™ process, the oxidation ditch operation is switched from an aerobic to an anoxic operating condition by turning off the aeration and operating a submerged mixer to maintain channel velocity. The process depends on the use of oxidation-reduction potential (ORP) control to (1) determine when the nitrate is depleted during the anoxic operation and (2) restart aeration. At selected times, the aerators are turned off and the mixer is turned on. When the nitrate is depleted in the aeration OFF period, the ORP drops dramatically. The ORP data are interpreted by a PC, which starts the aeration. A typical operating condition for the dNOx™ process is to turn the aerators off at least twice per day, usually in the morning when the load is increasing and then in the early evening hours (Stensel and Coleman, 2000). The off-time for the nitrate depletion usually lasts 3 to 5 h depending on the plant load and amount of nitrate in the oxidation ditch. Effluent NO_3-N concentrations of less than 8 mg/L and NH_4-N concentrations ranging from 1.0 to 1.5 mg/L have been reported.

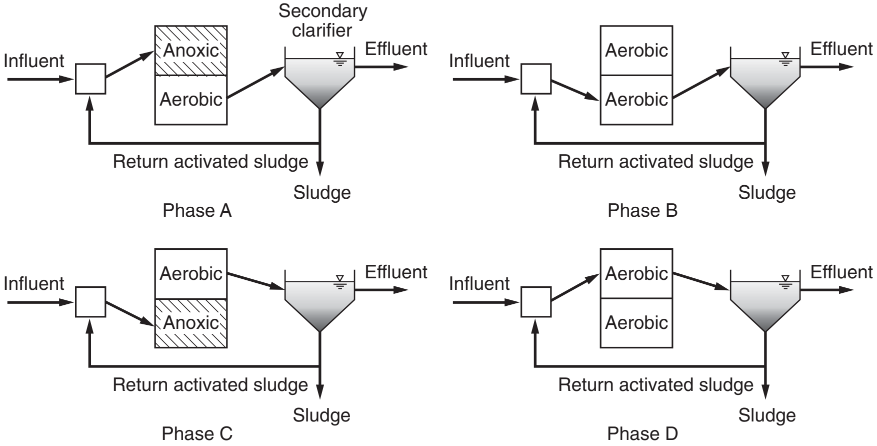
Phased NdN Processes

</td></tr>
<tr><td>

(q) BioDenitro



</td><td>

The BioDenitro process has also been referred to as a phased-isolation oxidation ditch technology. The process was developed in Denmark for nitrogen removal and has been installed in over 75 full-scale facilities producing effluent total nitrogen concentrations of less than 8 mg/L (Stensel and Coleman, 2000). The technology uses at least two oxidation ditches in a series configuration in which the operating sequence of the ditches and operation of the aeration and anoxic zones is varied. Submerged mixers are installed in the ditches so that for some operating phases, the basin is only mixed and not aerated. The basin continues to receive influent wastewater and operates as a preanoxic zone. Similar to the SBR operation, nitrate is available from a previous aerobic nitrification operation. Besides denitrification in the preanoxic zones, nitrate reduction is also possible during the aerobic operation depending on the DO concentration level. A typical duration for phases A, B, C, and D are 1.5, 0.5, 1.5, and 0.5 h, respectively.

</td></tr>
</table>

Sequencing Batch Reactor Process. The sequencing batch reactor process provides a high degree of flexibility for nitrogen removal. Mixing during the fill period provides an opportunity for anoxic conditions for nitrate removal. During the aeration react period, the DO concentration may be cycled to provide anoxic operating periods. A modification of the conventional SBR process involves the formation of a dense granular activated sludge. This process is described in Table 8–24(n) for biological nitrogen and enhanced biological phosphorus removal.

Large Reactor Volume Process. BioDenitro™, dNO_x™, and the oxidation ditch with DO control are all processes with large reactor volumes for nitrogen removal, and represent various methods for optimizing biological nitrogen removal in oxidation ditch systems. Very low effluent total nitrogen concentrations (less than 5 mg/L) have been reported for the Bio-dNO_x ™ process. The dNO_x™ process is generally limited to effluent total nitrogen concentrations of 5 to 8 mg/L. During the aeration "off period" in the dNO_x™ process, ammonia accumulates in the oxidation ditch, resulting in higher effluent NH_4-N concentrations from the process. The effluent NH_4-N and total nitrogen concentration is dependent on the total reactor volume and influent nitrogen concentrations. Higher influent TKN concentrations can result in higher effluent ammonia concentrations.

Bardenpho Process. In full-scale applications, the Bardenpho process and other postanoxic processes with carbon addition have demonstrated the ability to achieve less than 3 mg/L total nitrogen. The second anoxic zone of the Bardenpho process has a very low denitrification rate, resulting in less efficient reactor volume utilization. The addition of an exogenous carbon to the second anoxic zone reduces the reactor volume requirements and results in less NH_4-N release that would contribute to the effluent total nitrogen concentration.

Nitrogen Removal in Anaerobic Digestion Recycle Streams.
Recycle flows from dewatering of anaerobically digested solids contain high NH_4-N concentrations (>1000 mg/L) that can increase the wastewater influent nitrogen load by 20 to 25 percent. The recycle steam is also characterized by relatively high temperature and pH. A number of sidestream treatment processes have been developed that can reduce the ammonia load to the main stream biological treatment system, provide nitrifier seed to the mainstream biological treatment system and reduce the amount of exogenous carbon needed for nitrogen removal. These include the SHARON® (single-reactor high-activity ammonia removal over nitrite) process, anammox (anaerobic ammonia oxidation) and sidestream nitrification with bioaugmentation. These processes and their designs are presented in detail in Chap. 15.

Advantages and Disadvantages of Various Processes. The advantages and limitations of the processes commonly used and their treatment capability in terms of effluent total nitrogen concentrations are summarized in Table 8–25. Advantages and disadvantages of the processes identified in Table 8–25 are considered further in the following discussion.

Process Categories. The nitrogen removal process designs can be divided into two categories; (a) processes in which the aerobic SRT and volume is based on meeting an effluent NH_4-N goal and (b) processes with long SRT values with excess aerobic nitrification capacity and a high degree of flexibility for operation with intermittent aeration or low DO concentration. The former includes the MLE, MLE-Membrane, Bardenpho, Bardenpho-MBR, step feed BNR, and dual sludge processes. The design temperature and effluent NH_4-N goal will affect the SRT needed for nitrification. The latter includes oxidation ditch, SBR and Orbal® processes. The internal recycle ratio to preanoxic zones ranges from 2 to 4 for MLE and Bardenpho processes. A higher internal recycle ratio of 6.0 is used for MLE-MBR

Table 8–25

Advantages and limitations of nitrogen removal processes

Process	Advantages	Limitations
MLE	Saves energy; BOD is removed before aerobic zone Alkalinity is produced before nitrification Higher MLSS due to selection against filamentous bacteria Very adaptable to existing activated sludge processes <10 mg/L TN is achievable	Effluent TN concentration Nitrogen removal capability is a function of internal recycle Potential *Nocardioform* foam problems DO control is required for internal recycle
MLE-Membrane	Similar to MLE in using recycled NO_3 for BOD removal, and alkalinity Smaller footprint due to high MLSS and no clarifier <6 mg/L TN is achievable High quality effluent due to complete TSS removal. Can meet Class A reclaimed water.	Nitrogen removal capability is a function of internal recycle Potential *Nocardioform* foam problems DO control is required for recycle Uses more energy than MLE Membrane fouling control needed
Step Feed BNR	Adaptable to existing plug flow activated sludge processes	Nitrogen removal capability is a function of flow distribution
	<5 mg/L TN is achievable	More complex operation than MLE; requires flow split control to optimize operation
	No internal recycle piping and pumping needed	Potential *Nocardioform* foam problems
	Has higher treatment capacity for tank volume than MLE	Requires DO control in each aeration zone
Sequencing batch reactor	Process has high flexibility	Suitable mostly for smaller flows
	Simple treatment system layout	Needs more volume for nitrogen removal than only BOD removal
	Mixed liquor solids cannot be washed out by hydraulic surges because flow equalization is provided	Redundant units are required for operational reliability
	Quiescent settling provides low effluent TSS concentration	More complex process design
	5 to 8 mg/L TN is achievable	Effluent quality depends upon reliable decanting facility May need effluent equalization of batch discharge before filtration and disinfection
BioDenitro	5 to 8 mg/L TN is achievable	Complex system to operate
	Large reactor volume is resistant to shock loads	Two oxidation ditch reactors are required; increases construction cost

(*continued*)

Table 8–25 (*Continued*)

Process	Advantages	Limitations
dNO_x™	Large reactor volume is resistant to shock loads	Nitrogen removal capability is limited by higher influent TKN concentrations
	Easy and economical to upgrade existing oxidation ditch processes	Process is susceptible to ammonia bleed-through
	Provides SVI control	Performance is affected by influent variations
	Provides energy savings	
Bardenpho (4 stage)	Capable of achieving effluent nitrogen levels less than 3 mg/L	Large reactor volumes required
	Same advantages as MLE	Second anoxic tank has low nitrogen removal efficiency without exogenous carbon addition
Oxidation ditch	Large reactor volume is resistant to load variations without affecting effluent quality significantly	Nitrogen removal capability is related to skills of operating staff and control methods if no preanoxic
	Simple plant layout and operation	
	Has good capacity for nitrogen removal; less than 5 mg/L effluent TN is possible	Large area required
	Can be effective with preanoxic zones	
Postanoxic with carbon addition	Capable of achieving effluent nitrogen levels less than 3 mg/L	Higher operating cost due to purchase of carbon source
	May be combined with effluent filtration	Carbon source feed control required
Simultaneous nitrification/denitrification	Low effluent nitrogen level possible (3 mg/L lower limit)	Large reactor volume; skilled operation also required
	Significant energy savings possible	Process control system required
	Process may be incorporated into existing facilities without new construction	
	Produces alkalinity	

applications. The MLSS concentration for activated sludge/clarifier systems with preanoxic zones range from 3000 to 4000 mg/L and for MBR systems it may range from 8000 to 14,000 mg/L. Low DO or intermittent aeration systems to promote simultaneous nitrification/denitrification can be applied to oxidation ditch, Orbal®, SBR and MLE, and MLE-Membrane processes operated at longer SRTs than in their normal application.

Advantages of Preanoxic and SNdN Over Postanoxic Processes. Preanoxic processes are normally used with and without postanoxic processes. The selection of the postanoxic suspended growth process is driven mainly by the site layout, existing reactor configuration, and equipment considerations. A major disadvantage of a postanoxic only process is the cost of providing an exogenous carbon source. The preanoxic and SNdN processes have additional important advantages over the use of only postanoxic processes. By removing nitrate before or during the nitrification step, the alkalinity produced by denitrification is made available to offset the alkalinity depleted by nitrification. Because 3.57 g of alkalinity (as $CaCO_3$) are produced per g NO_3-N oxidized, and 7.14 g alkalinity (as $CaCO_3$) are consumed per g NH_4-N oxidized, almost half of the alkalinity used for nitrification can be provided by preanoxic or SNdN processes. The recovery of alkalinity is very important for wastewaters that have low alkalinity. In some applications, alkalinity may have to be added in the form of lime or sodium hydroxide, at significant cost, to maintain an acceptable pH for the nitrification process. In addition, the preanoxic process serves a selector against filamentous bacteria growth to provide for good settling activated sludge.

Denitrification with External Carbon Addition

The use of external carbon sources for denitrification is necessary for biological nitrogen removal facilities faced with stringent effluent nitrogen limits and/or that have weak wastewaters relative to the influent BOD to TKN ratio. If the effluent total nitrogen concentration goal is less than 6 to 8 mg/L, an external carbon source is generally required. External carbon addition may be to a postanoxic zone of a Bardenpho process, the latter anoxic tanks in a step feed BNR process, an anoxic operating period towards the end of an SBR process react cycle, and an effluent denitrification filter. Seasonal wet weather operating conditions may also call for the addition of an external carbon source to improve denitrification rates with weaker wastewater. Advantages of adding external carbon to a post anoxic zone in a Bardenpho process are the ability to use a smaller anoxic tank volume and to achieve a lower effluent TN concentration due to less NH_4-N release from endogenous decay.

Sources of External Carbon. External carbon sources are primarily from industrial production, byproducts of industrial processing, and in plant fermentation of waste primary sludge. Common organic compounds that have been used include methanol, ethanol, sugar, high fructose corn syrup, acetate, glycerol, corn starch, molasses, distillery fusel oil, and commercial products such as Unicarb and MicroC^{TM} and other industrial wastes (Gu and Onnis-Hayden, 2010 and Swinarski et al., 2012). Historically, methanol has been used most commonly as the carbon source for the following reasons: (1) highest effectiveness ratio in terms of g NO_x reduced/g methanol consumed in the anoxic zone, (2) generally the lowest cost per kg of NO_x removed, (3) readily available, and (4) considerable experience with its application for denitrification. Major disadvantages of using methanol are (1) safety issues associated with its transportation and storage, (2) the need for acclimation time when first added, and (3) lower denitrification rates compared to other substrates. The use of external carbon sources such as methanol or other flammable substances requires special storage and handling designs and concern for worker safety. Issues related to storage and safety, denitrification rates, and acclimation time has led to interest in other carbon sources. Important considerations in the use of external carbon sources, discussed in this section, are carbon effectiveness, denitrification rates, carbon dose and anoxic volume, acclimation needs, and reduction end products.

External Carbon Effectiveness. The external carbon effectiveness ratio is defined as the g NO_3 reduced/g COD consumed in the anoxic zone. For substrates with a higher synthesis yield coefficient, a greater fraction of the COD removed goes to biomass and a lower fraction is oxidized, which results in a lower effectiveness ratio.

The effectiveness ratio (E_{CNO_3}) is the inverse of the consumptive ratio (C_R), defined by McCarty et al. (1969) and described in Eq. (7–127) in which the yield is the synthesis yield with consumption of the external carbon source.

$$\frac{1}{E_{CNO_3}} = C_{R,NO_3} = \frac{2.86}{1 - 1.42\,Y_H} \tag{8–69}$$

where Y_H = synthesis yield, g VSS/g COD removed

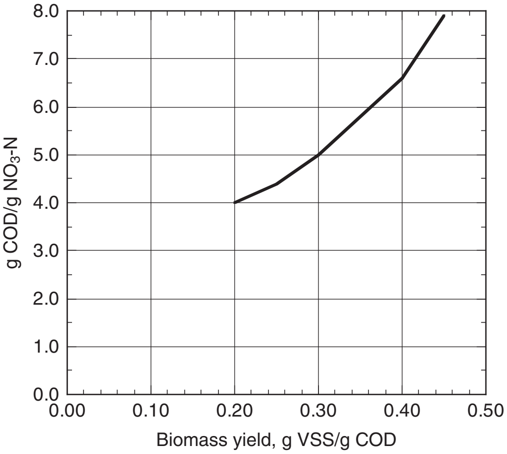


Figure 8–36

Exogenous carbon dose for nitrate removal is related to the biomass yield in g VSS produced per g COD consumed.

For the reduction of nitrite and DO the value of the numerator in Eq. (8–69) is 1.71 and 1.0, respectively. External carbon sources that result in lower synthesis yield values have a lower required C_R value, which results in a lower carbon dose for a given amount of nitrate removal. The effect of the synthesis yield on the C_R value is illustrated on Fig. 8–36. Reported synthesis yield values for methanol range from 0.20 to 0.30 (Gu and Onnis-Hayden, 2010) and thus the methanol $C_{R,\mathrm{NO_3}}$ values range from 4.0 to 5.0 g COD/g NO_3-N. Anoxic synthesis yield values for other external carbon sources may range from 0.35 to 0.40. It should be noted that the synthesis yield under anoxic conditions is 70 to 80 percent of that under aerobic respiration (Muller et al., 2003, Henze et al., 2008). Using reported synthesis yields with nitrate reduction of 0.36 (g VSS/g COD) (Christensen et al., 1994) for ethanol and 0.34 (g VSS/g COD) for glycerol (Bilyk et al., 2009), their respective C_R values from Eq. (8–69) are 5.9 and 5.5 g COD/g NO_3-N, which is higher than the corresponding values for methanol. The respective effectiveness factors for methanol, ethanol, and glycerol, based on these $C_{R,\mathrm{NO_3}}$ values are 0.22, 0.18, and 0.17 g NO_3-N/g COD consumed.

The amount of external carbon added per unit of NO_3-N removal in a postanoxic zone is higher than that predicted by the consumptive ratio. Methanol has a COD equivalent of 1.5 g COD/g CH_3OH, so the C_R based on methanol is 2.7 to 3.3 g CH_3OH/g NO_3-N removed. Methanol dosage in field application has ranged from 3.3 to 3.8 g CH_3OH/g NO_3-N removed, which is due to the net effect of the true C_R value, methanol in the anoxic zone effluent, methanol consumed by DO entering the anoxic zone, and nitrate reduction by substrate available from mixed liquor endogenous decay. For a smaller anoxic tank (lower τ) a higher denitrification rate is needed, which requires a higher concentration of the external carbon in the reactor and effluent, and thus a higher external carbon dose. The external carbon dose is related to the amount of carbon consumed to provide the demand for respiration with NO_3-N reduction and its concentration in the reactor to drive the necessary denitrification rate.

Denitrification Rates. The NO_3-N reduction rate (g/L·d) is a function of the carbon substrate, NO_3-N, and heterotrophic biomass concentrations as given by Eq. (7–133).

$$r_{\mathrm{NO_3}} = \left(\frac{1 - 1.42Y_{\mathrm{H}}}{2.86}\right)\left[\frac{\mu_{\mathrm{H,max}}S_S}{Y_{\mathrm{H}}(K_s + S_S)}\right]\left(\frac{S_{\mathrm{NO_3}}}{K_{\mathrm{NO_3}} + S_{\mathrm{NO_3}}}\right)\left(\frac{K_o'}{K_o' + S_o}\right)(\eta)X_{\mathrm{H}} \tag{7–133}$$

where $(\eta)X_{\mathrm{H}}$ = biomass concentration capable of degrading the external carbon substrate under anoxic conditions, mg VSS/L

Some external carbon substrates, such as acetate and ethanol, are readily biodegradable by most of the heterotrophic bacteria grown from BOD in the influent wastewater so that typical values of η, (0.60 to 0.80 for anoxic/aerobic systems) may be used in Eq. (7–133) with calculated values for X_H. A similar assumption cannot be used for anoxic degradation with methanol addition.

Methylotrophic bacteria, capable of degrading methanol, are more specialized bacteria capable of growing on single carbon compounds so that the value for X_H in Eq. (7–133) with methanol is related mainly to the amount of methanol fed and degraded. These bacteria can utilize other external carbon sources added to a denitrification system, but would be competing with other bacteria for the substrate. It has been shown that anoxic culture grown on methanol can contain populations also capable of ethanol degradation (Baytshtok et al., 2009). The other substrates noted in this section can be degraded by a wide range of bacteria that can also degrade substrates contained in the influent wastewater BOD.

Denitrification rates with methanol are much lower compared to those for acetate, ethanol, a commercial product MicroC™, and corn syrup, based on the maximum specific growth rates reported in Table 8–26 for bacteria consuming these substrates with nitrate reduction.

While Eq. (7–133) can be used in reactor mass balances and simulation models to analyze anoxic zone volume and external carbon needs, a desktop design approach can be done using SDNR values as was shown for the design of preanoxic tanks in Example (8–7) and Eq. (8–52).

$$\mathrm{NO}_r = (V_{\mathrm{nox}})(\mathrm{SDNR})(\mathrm{MLVSS}) \tag{8–52}$$

where NO_r = $\mathrm{NO_3}$-N removal rate, g/d

The SDNR as a function of biodegradation kinetics for the carbon source is obtained by dividing Eq. (7–133) above by the MLVSS (X_{VSS}) concentration.

$$\mathrm{SDNR} = \left(\frac{1 - 1.42Y_{\mathrm{H}}}{2.86}\right)\left[\frac{\mu_{\mathrm{H,max}}S_{\mathrm{S}}}{Y_{\mathrm{H}}(K_s + S_{\mathrm{S}})}\right]\left(\frac{S_{\mathrm{NO_3}}}{K_{\mathrm{NO_3}} + S_{\mathrm{NO_3}}}\right)\left(\frac{K'_o}{K'_o + S_o}\right)\left[\frac{(\eta)X_{\mathrm{H}}}{X_{\mathrm{VSS}}}\right] \tag{8–70}$$

where SDNR = specific denitrification rate, g $\mathrm{NO_3}$-N/g VSS·d
X_{H} = the mixed liquor biomass concentration, mg/L
η = the fraction of biomass able to degrade the external carbon with nitrate reduction
X_{VSS} = mixed liquor volatile suspended solids concentration, mg/L

SDNR values for the non-methanol carbon sources are about 2 to 2.5 times higher than that for methanol. SDNRs in anoxic activated sludge determined by Fillos et al. (2007) for

Table 8–26

Comparison of kinetics for various external carbon sources for denitrification

Substrate	$\mu_{\max}$ at 20°C, g/g·d	Arrhenius coefficient, θ	Reference
Methanol	1.12	1.12	Mokhayeri et al. (2006)
	1.3	1.1	Christensson et al. (1994)
	1.3	1.09	Dold et al. (2008)
Acetate	4.46	1.21	Mokhayeri et al. (2006)
Ethanol	3.02	1.1	Christensson et al. (1994)
MicroC™	2.05	1.02	Onnis-Hayden et al. (2011)
Corn Syrup	4.13	1.18	Mokhayeri et al. (2006)

ethanol and methanol at high substrate concentration are given by Eqs. (8–71) and (8–72). The SDNR with ethanol is about 2.1 times faster than with methanol.

$$\text{Methanol:} \quad \text{SDNR} = 0.0738(1.11)^{T-20} \tag{8–71}$$

$$\text{Ethanol:} \quad \text{SDNR} = 0.161(1.13)^{T-20} \tag{8–72}$$

Carbon Dose and Postanoxic Tank Volume. The amount of external carbon that must be added to a postanoxic tank is a function of the amount of nitrate to be removed due to consumption of the external carbon, the denitrification kinetics for the carbon selected, the reactor external carbon substrate concentration and the anoxic tank volume. The design procedure involves selecting an anoxic volume as a first step. Based on the maximum specific growth rate for anoxic methanol degradation and an endogenous decay rate of 0.05 g/g·d (Stensel et al., 1973), an anoxic zone with methanol addition needs an SRT value >1.0 d at 20°C and >2.0 d at 10°C to prevent washout. The anoxic zone SRT for other external carbon sources is 20 to 50 percent less.

The nitrate removal rate in the postanoxic zone equals the removal rate due to the external carbon consumption plus the removal rate due to endogenous decay (Eq. 8–63).

$$R_{\text{NO}_3} = \text{SDNR}(X_{\text{VSS}})(V_{\text{anox}}) + \left(\frac{1.42}{2.86}\right)(b_{\text{H,anox}})(X_{\text{H}})(V_{\text{anox}}) \tag{8–73}$$

where R_{NO_3} = NO_3-N removal rate in the anoxic tank, g/d

The removal rate equals the change in the NO_3-N concentration between the tank influent and effluent times the flowrate to the postanoxic tank.

$$R_{\text{NO}_3} = Q(1 + R)(\text{NO}_o - \text{NO}_e) \tag{8–74}$$

where: NO_o = Postanoxic tank influent NO_3-N concentration, g/m^3
NO_e = Postanoxic tank effluent NO_3-N concentration, g/m^3
R = Return activated sludge recycle ratio

For a given anoxic volume the SDNR necessary using the external carbon source is determined from Eq. (8–75).

$$\text{SDNR} = \frac{R_{\text{NO}_x} - \left(\frac{1.42}{2.86}\right)(b_{\text{H}})(X_{\text{H}})(V_{\text{anox}})}{(X_{\text{VSS}})(V_{\text{anox}})} \tag{8–75}$$

The anoxic tank external carbon substrate concentration (S_s) needed to satisfy the SDNR value in Eq. (8–75) is determined from Eq. (8–70). At higher SDNR values the anoxic tank effluent substrate concentration is higher.

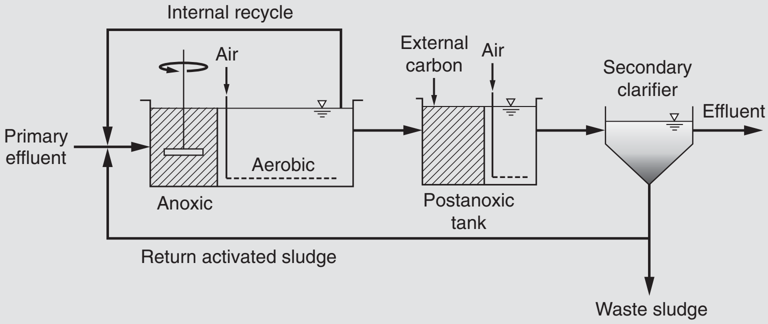
The carbon dose is a function of the carbon consumed for nitrate reduction plus the amount of carbon in the effluent needed to sustain the necessary SDNR.

$$C_{\text{D}} = \text{SDNR}(X_{\text{VSS}})(V_{\text{anox}})C_{\text{R,NO}_3} + Q(1 + R)(S_s) \tag{8–76}$$

where C_{D} = carbon dose or amount of external carbon added, g COD/d

For a smaller anoxic volume, the SDNR must be increased, which increases the effluent external carbon concentration. In addition there is less NO_3-N removal due to endogenous decay. These effects result in a higher carbon dose requirement. The application of these relationships to estimate an external carbon dose is illustrated in Example 8–12.

EXAMPLE 8–12 **Design of Postanoxic Tank with External Carbon Addition for Nitrate Removal** Using the results of the MLE design in Example 8–7 and the postanoxic design in Example 8–10, evaluate the postanoxic design use ethanol or methanol for external carbon sources. Determine (a) the amount of ethanol needed in kg/d and g/m^3 (based on the influent flowrate) for a postanoxic tank at 1/3rd the volume of that needed for nitrate reduction with only endogenous decay in Example 8–10; (b) the amount of methanol needed as a function of the postanoxic tank volume; and (c) prepare a plot of the percent NO_3-N removed by endogenous decay, the percent of the feed methanol in the effluent, and the ratio of the methanol added versus the NO_3-N removed as a function of the postanoxic tank volume and discuss the impact of increasing the volume of the postanoxic tank. Determine the change in NH_4-N concentration across the postanoxic tank for part (a). As noted in Example 8–10 the postanoxic tank is part of a Bardenpho process.



Design conditions and assumptions:

1. Information from the anoxic/aerobic system and postanoxic tank in Examples 8–7 and 8–10.

Item	Unit	Value
Flowrate	m^3/d	22,700
RAS ratio	unitless	0.60
Temperature	°C	12
MLSS	g/m^3	3000
MLVSS	g/m^3	2370
Biomass, X_H	g/m^3	1267
Endogenous decay, $b_{H,12}$	g/g·d	0.06
Aerobic SRT	d	20.6
Aerobic basin volume	m^3	13,230
Aerobic NO_3-N	g/m^3	6.0
Postanoxic basin volume	m^3	4,811

Note: g/m^3 = mg/L.

1. $\eta = 0.80$
2. NH_4-N used for cell synthesis = 0.12 g NH_4-N/g VSS produced
3. NH_4-N release in endogenous decay = 0.06 g NH_4-N/g VSS

4. Ethanol $\mu_{\max}$ at 20°C (Table 8–26) = 3.02 g/g·d
5. Ethanol $\mu_{\max}$ θ value (Table 8–26) = 1.1
6. Ethanol synthesis yield, $Y_H = 0.36$ g VSS/g COD
7. Ethanol half-velocity coefficient, K_S, = 5.0 g COD/m^3
8. Ethanol is degraded by all the mixed liquor denitrifying biomass
9. Nitrate half-velocity coefficient, $K_{NO_3} = 0.10$ g/m^3
10. DO concentration = 0.0 g/m^3
11. Methanol $\mu_{\max}$ at 20°C (Table 8–26) = 1.2 g/g·d
12. Methanol $\mu_{\max}$ θ value (Table 8–26) = 1.1
13. Methanol synthesis yield (Gu and Onnis-Hayden, 2010), $Y_H = 0.30$ g VSS/g COD
14. Methanol decay coefficient (Stensel et al., 1973) = 0.04 g/g·d
15. Methanol half-velocity constant (Torres et al., 2011) = 1.0 g/m^3
16. Postanoxic effluent NO$_3$-N concentration = 1.0 g/m^3

Solution, Part A—Postanoxic volume with ethanol dose

1. Select the anoxic volume.

$$V_{anox} = 1/3(4811\text{ m}^3) = 1604\text{ m}^3$$

$$\tau = (1604\text{ m}^3)(24\text{ h/d})/(22{,}700\text{ m}^3/\text{d}) = 1.7\text{ h}$$

2. Determine required SDNR by heterotrophic biomass utilizing ethanol with Eq. (8–73). From Example 8–10, $R_{NO_3} = 181{,}000$ g/d.

$$R_{NO_3} = \text{SDNR}(X_{VSS})(V_{anox}) + \left(\frac{1.42}{2.86}\right)(b_{H,anox})(X_H)(V_{anox})$$

$$181{,}600\text{ g/d} = \text{SDNR}(2370\text{ g/m}^3)(1604\text{ m}^3) + \frac{1.42}{2.86}(0.06\text{ g/g·d})(1267\text{ g/m}^3)(1604\text{ m}^3)$$

$$181{,}600\text{ g/d} = 3{,}801{,}480\text{ g/d(SDNR)} + 60{,}542\text{ g/d}$$

$$\text{Required SDNR} = 0.032\text{ g NO}_3\text{-N/gVSS·d}$$

3. Determine effluent ethanol concentration to provide the required SDNR by solving for S_S in Eq. (8–70) and assuming DO concentration = zero.

$$\text{SDNR} = \frac{1 - 1.42Y_H}{2.86}\left[\frac{\mu_{\max}S_S}{Y_H(K_S + S_S)}\right]\left(\frac{S_{NO_3}}{K_{NO_3} + S_{NO_3}}\right)\left[\frac{(\eta)X_H}{X_{VSS}}\right]$$

a. $\mu_{\max,12°C} = 3.02\text{ g/g·d}\,(1.1^{12-20}) = 1.41\text{ g/g·d}$

$$0.032\text{ g/g·d} = \left[\frac{1 - 1.42(0.36\text{ g/g})}{2.86}\right]\left[\frac{1.41\text{ g/g·d}(S_S)}{(0.36\text{ g/g})(5.0 + S_S)}\right]\left[\frac{(1.0\text{ g/m}^3)}{(0.1 + 1.0)\text{ g/m}^3}\right]\left[\frac{(0.80)(1267\text{ g/m}^3)}{(2370\text{ g/m}^3)}\right]$$

$$S_S = 0.70\text{ g/m}^3$$

4. Determine the ethanol dose.
   a. Determine the ethanol consumptive ratio for nitrate reduction using Eq. (8–69).

$$C_{\text{R,NO}_3} = \frac{2.86}{1 - 1.42(0.36 \text{ g VSS/g COD})} = 5.85 \text{ g COD/g NO}_3\text{-N}$$

   b. Calculate the ethanol dose using Eq. (8–76).

$$\text{Dose} = \text{SDNR}(X_{\text{VSS}})(X_{\text{anox}})C_{\text{R,NO}_3} + Q(1 + R)(S_S)$$

$$\text{Dose} = (0.032 \text{ g/g·d})(2370 \text{ g/m}^3)(1604 \text{ m}^3)(5.85 \text{ g COD/g NO}_3\text{-N}) + 22{,}700 \text{ m}^3\text{/d}(1 + 0.60)(0.70 \text{ g/m}^3)$$

$$\text{Dose} = 711{,}637 \text{ g COD/d} + 25{,}424 \text{ g COD/d}$$

$$\text{Dose} = 737{,}061 \text{ g COD/d}$$

$$\text{COD of ethanol } (CH_3CH_2OH) = 2.09 \text{ g COD/g ethanol}$$

$$\text{Dose as ethanol} = \frac{(737{,}061 \text{ g COD/d})}{(2.09 \text{ g COD/g ethanol})} = 352{,}661 \text{ g ethanol/d}$$

$$= 352.6 \text{ kg ethanol/d}$$

Dose as concentration of ethanol added to flow to anoxic tank (influent plus recycle flowrates):

$$= \frac{(352{,}661 \text{ g ethanol/d})}{[(1 + 0.6)22{,}700 \text{ m}^3\text{/d}]} = 9.7 \text{ g ethanol/m}^3 = 20.3 \text{ g COD/m}^3$$

$$\text{Dose normalized to influent flowrate} = \frac{(352{,}661 \text{ g ethanol/d})}{(22{,}700 \text{ m}^3\text{/d})}$$

$$= 15.5 \text{ g ethanol/m}^3$$

5. Determine the change in NH_4-N across the postanoxic tank. The change is due to NH_4-N release from endogenous decay and NH_4-N uptake for cell synthesis from ethanol consumption. The amount of NH_4-N released is equal to the ratio of the anoxic volume in this problem (1604 m^3) to that in Example 8–10, step 3 (4811 m^3) times the NH_4-N release (0.60 g/m^3) in Example 8–10 as the specific endogenous decay rates and biomass concentrations are the same.

$$\Delta NH_4\text{-N released} = \frac{NH_4\text{-N}(V_{\text{anox}})}{V_{\text{anox}}}$$

$$= \frac{(0.60 \text{ g/m}^3)(1604 \text{ m}^3)}{4811 \text{ m}^3}$$

$$\Delta NH_4\text{-N} = 0.20 \text{ g/m}^3$$

$$\Delta\text{biomass} = Y(\Delta\text{COD}) = (0.36 \text{ g VSS/g COD})(20.3 \text{ g COD/m}^3) = 7.3 \text{ g VSS/m}^3$$

Nitrogen uptake to biomass needed with ethanol consumption

$$= 0.12 \text{ g N/g VSS}(7.3 \text{ g VSS/m}^3) = 0.88 \text{ g/m}^3$$

$$\text{Net change in } NH_4\text{-N} = 0.20 \text{ g/m}^3 - 0.88 \text{ g/m}^3 = -0.68 \text{ g/m}^3$$

Thus, a decrease in effluent NH_4-N will occur across the anoxic zone fed ethanol. As the NH_4-N concentration is decreased, it is possible that some of the nitrogen needs will also be met with NO_3-N.

Solution, Part B—Methanol dose versus postanoxic volume

The solution procedure with methanol as the carbon source is modified from that using ethanol. It is assumed that the methanol-degrading biomass is only from growth on methanol and not from BOD in the wastewater. The solution steps require an iterative procedure (or one that can be solved with Excel Solver) to determine the postanoxic reactor methanol concentration to provide the necessary nitrate reduction rate.

1. Using the same procedure as with ethanol (Part A), determine the required methylotrophic SDNR with Eq. (8–73) for $V_{\text{anox}} = 1604\ \text{m}^3$:

$$R_{NO_3} = \text{SDNR}(X_{\text{VSS}})(V_{\text{anox}}) + \left(\frac{1.42}{2.86}\right)(b_{\text{H}})(X_{\text{H}})(V_{\text{anox}})$$

$$\begin{aligned} 181{,}600\ \text{g/d} &= \text{SDNR}(2370\ \text{g/m}^3)(1604\ \text{m}^3) \\ &\quad + \frac{1.42}{2.86}(0.06\,\text{g/g·d})(1267\ \text{g/m}^3)(1604\ \text{m}^3) \end{aligned}$$

$$181{,}600\ \text{g/d} = 3{,}801{,}480\ \text{g/d(SDNR)} + 60{,}542\ \text{g/d}$$

Required methylotrophic SDNR = 0.032 g NO_3-N/gVSS·d. The second term in the above equation is nitrogen removed by endogenous decay.

$$\text{Percent removal by endogenous decay} = \frac{60{,}542(100)}{181{,}600} = 33.3\%$$

2. Determine effluent methanol concentration to provide the required SDNR by solving for S_S in Eq. (8–70) and assuming DO concentration = zero. Note that the biomass concentration (ηX_{H}) in this case is the methylotrophic biomass or X_{M}.

$$\text{SDNR} = \frac{1 - 1.42Y_{\text{H}}}{2.86}\left[\frac{\mu_{\max} S_S}{Y_{\text{H}}(K_S + S_S)}\right]\left(\frac{S_{NO_3}}{K_{NO_3} + S_{NO_3}}\right)\left(\frac{X_{\text{M}}}{X_{\text{VSS}}}\right)$$

a. $\mu_{\max,12^\circ\text{C}} = 1.2\ \text{g/g·d}(1.1^{12-20}) = 0.56\ \text{g/g·d}$

$$\begin{aligned} 0.032\ \text{g/g·d} &= \left[\frac{1 - 1.42(0.30\ \text{g/g})}{2.86}\right]\left[\frac{(0.56\ \text{g/g·d})(S_S)}{(0.30\ \text{g/g})(1.0 + S_S)}\right] \\ &\quad \left\{\frac{(1.0\ \text{g/m}^3)}{[(0.1 + 1.0)\text{g/m}^3]}\right\}\left[\frac{(X_{\text{M}}\ \text{g/m}^3)}{(2370\ \text{g/m}^3)}\right] \end{aligned}$$

$$0.032\ \text{g/g·d} = 0.000144\left(\frac{S_S}{1.0 + S_S}\right)(X_{\text{M}})$$

b. Determine the methylotrophic biomass concentration (X_{M}) as a function of the methanol consumed. The amount of methanol consumed is equal to the methanol dose (assumes that all of the methanol added will be consumed in the anoxic tank or in the subsequent post aeration tank). Calculate the methanol dose using Eq. (8–76).

$$\text{Dose} = \text{SDNR}(X_{\text{VSS}})(V_{\text{anox}})C_{\text{R},NO_3} + Q(1 + R)(S_S)$$

The value for $[\text{SDNR}(X_{\text{VSS}})(V_{\text{anox}})]$ is determined from step 1, as it is the rate of nitrate removal minus the rate removed by endogenous decay.

$$[\text{SDNR}(X_{\text{VSS}})(V_{\text{anox}})] = 181{,}600 \text{ g/d} - 60{,}542 \text{ g/d} = 121{,}058 \text{ g NO}_3\text{-N/d}$$

$$C_{R,\text{NO}_3} = \frac{2.86}{1 - 1.42(Y_{\text{H}})},\ Y_{\text{H}} = 0.30 \text{ g VSS/g COD}$$

$$= \frac{2.86}{1 - 1.42(0.30 \text{ g VSS/g COD})} = 4.98 \text{ gCOD/g NO}_3\text{-N}$$

Thus, the methanol consumed is:

$$\text{Dose, g COD/d} = (121{,}058 \text{ g NO}_3\text{-N/d})(4.58 \text{ g COD/g NO}_3\text{-N}) + (22{,}700 \text{ m}^3\text{/d})(1.0 + 0.6)(S_S \text{ g/m}^3)$$

$$\text{Dose, g COD/d} = 554{,}445.6 + 36{,}320(S_S)$$

X_{M} is related to the biomass produced from the methanol consumed and the system SRT and τ as given by Eq. (7–42) in Table 10.

$$X_{\text{M}} = \left(\frac{\text{SRT}}{\tau}\right)\left[\frac{Y_{\text{H}}(S_o)}{1 + b_{\text{H}}(\text{SRT})}\right]$$

where S_o = methanol consumed normalized to the influent flowrate, g/m^3.

$$S_o = \frac{[554{,}445.6 + 36{,}320(S_S)]\text{g/d}}{22{,}700 \text{ m}^3\text{/d}} = [24.43 + 1.6(S_S)]\text{g/m}^3$$

The SRT and τ are based on the total Bardenpho system volume. A 0.33 h post aeration time, τ, is the assumed after the postanoxic tank. The total SRT can be estimated as proportionate to the aerobic volume and its SRT determined in example problem 8–7.

Bardenpho Tanks	Volume, m^3
Preanoxic	2361
Aerobic (SRT = 20.5 d)	13,230
Postanoxic	1604
Postaerobic	315
Total	17,510

$$\tau = \frac{(17{,}510 \text{ m}^3)}{(22{,}700 \text{ m}^3\text{/d})} = 0.77 \text{ d}$$

$$\text{SRT} = \frac{17{,}510 \text{ m}^3}{13{,}230 \text{ m}^3}(20.5 \text{ d}) = 27.1 \text{ d}$$

$$X_{\text{M}} = \left(\frac{\text{SRT}}{\tau}\right)\left[\frac{Y_{\text{H}}(S_o)}{1 + b_{\text{H}}(\text{SRT})}\right]$$

$$= \left(\frac{27.1 \text{ d}}{0.77 \text{ d}}\right)\left[\frac{(0.30 \text{ g VSS/g COD})(S_o)}{1 + (0.04 \text{ g/g·d})(27.1 \text{ d})}\right] = 5.066(S_o)$$

and from above $S_o = 24.43 + 1.6\text{SS}$, thus $X_\text{M} = 123.76 + 8.106S_S$. Using the equation for SDNR from 2a, X_M and S_S are solved.

$$0.032\text{ g/g·d} = 0.000144\left(\frac{S_S}{1.0 + S_S}\right)(X_\text{M})$$

$$S_S = 12.6\text{ g COD/m}^3 \text{ and } X_\text{M} = 236.3\text{ g VSS/m}^3$$

3. The methanol dose is now determined.

$$\text{Dose} = \text{SDNR}(X_\text{VSS})(V_\text{anox})C_{\text{R,NO}_3} + Q(1 + R)(S_S)$$

$$= (0.032\text{ g NO}_3\text{-N/g VSS·d})(2370\text{ g/m}^3)(1604\text{ m}^3)(4.98\text{ g COD/g NO}_3\text{-N})$$
$$+ (22{,}700\text{ m}^3\text{/d})(1 + 0.6)(12.6\text{ g COD/m}^3)$$

$$\text{Dose} = 605{,}803\text{ g COD/d} + 456{,}905\text{ g COD/d} = 1{,}062{,}709\text{ g COD/d}$$

The percent of methanol dose in the effluent flow from the anoxic tank:

$$\text{Percent of methanol dose in anoxic tank effluent} = \frac{100(456{,}905)}{1{,}062{,}709} = 43.0\%$$

Dose based on flowrate to the anoxic tank:

$$= \frac{(1{,}062{,}709\text{ g COD/d})}{(22{,}700\text{ m}^3)(1.0 + 0.6)} = 29.3\text{ g COD/m}^3$$

Normalized to influent flowrate:

$$= \frac{(29.3\text{ g COD/m}^3)(1.0 + 0.6)(22{,}700\text{ m}^3)}{(22{,}700\text{ m}^3)} = 46.8\text{ g COD/m}^3$$

Dose as methanol:

$$\text{Total methanol added/day} = \frac{(1{,}062{,}709\text{ g COD/d})}{(1.5\text{ g COD/g CH}_3\text{OH})(1000\text{ g/kg})} = 708.5\text{ kg CH}_3\text{OH/d}$$

$$\text{Based on flowrate to anoxic tank} = (29.3\text{ g COD/m}^3)/(1.5\text{ g COD/g CH}_3\text{OH})$$
$$= 19.5\text{ g CH}_3\text{OH/m}^3$$

$$\text{Based on influent flowrate} = (48.9\text{ g COD/m}^3)/1.5 = 32.6\text{ g CH}_3\text{OH/m}^3$$

The following solution is summarized:

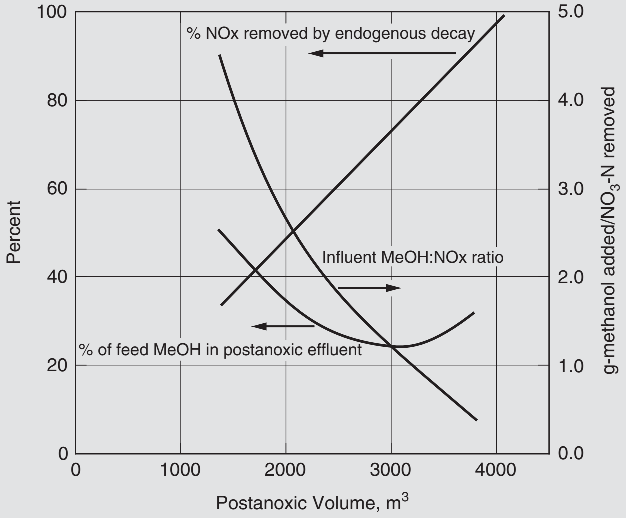
Parameter	Unit	Value
Anoxic volume	m^3	1604
Methanol dose	kg/d	708.5
Methanol dose based on influent flowrate	$\text{g CH}_3\text{OH/m}^3$	32.6
Methanol dose based on flowrate to anoxic tank	$\text{g CH}_3\text{OH/m}^3$	19.5
Percent of feed methanol in postanoxic tank effluent	percent	43.0

Solution, Part C—Prepare required plot and discuss results

1. Percent NO_3-N removed by endogenous decay:
   The percent values are obtained as illustrated in Part B, Step 1.
   Percent removal by endogenous decay for a tank volume of 1604 m^3 = 33.3%.
2. Percent of the feed methanol in the effluent is obtained as illustrated in Part B, Step 3:
   Percent of the feed methanol in the effluent for a tank volume of 1604 m^3 = 43%.
3. Ratio of the methanol added versus the NO_3 removed for a tank volume of 1604 m^3:
   The methanol added from Part B, Step 3 = 708,500 g CH_3OH /d.
   The NO_3 removed = 181,600 g/d.
   Ratio = g CH_3OH/g NO_3-N = 708,500/181,600 = 3.9.
4. Prepare summary computation table following similar calculations for different assumed anoxic volumes

Postanoxic volume, m^3	Percent of NO_3-N removed by endogenous decay	Percent of feed CH_3OH in effluent	CH_3OH/NO_3-N
1604	33.3	43.0	3.9
1800	37.4	38.5	3.4
2000	41.6	33.9	2.9
2500	52.0	25.3	2.1
3000	62.4	23.0	1.6
3500	72.7	22.2	1.2
4000	83.1	29.2	0.8

5. Prepare plot and analyze the effect of increasing the postanoxic tank volume.
   a. The required plot is given below.



b. As the postanoxic tank volume is increased, the methanol dose decreases because more nitrate removal is by endogenous decay and there is a lower effluent methanol concentration due the fact that a lower denitrification rate with the external carbon substrate was allowable. At an anoxic volume around 2000 m^3, the methanol dose is in the range of the consumptive ratio (C_{R,NO_3}) at 2.5 to 3.5 g CH_3OH/g NO_3-N removed (3.8 to 5.3 on a COD basis), but this apparent match to the C_{R,NO_3} value is the net result of methanol utilization for denitrification in the postanoxic reactor, nitrate removed by endogenous decay, and methanol in the effluent.

Comment The result of these analyses on the effect of removing nitrate in the postanoxic zone by endogenous decay only, with ethanol addition and with methanol addition illustrate the effect of the substrate utilization rate kinetics associated with a particular exogenous carbon source and the effect of the postanoxic volume size on the carbon dose needed. Because of the greater substrate utilization kinetics with ethanol, the ethanol concentration could be lower in the postanoxic reactor and less of the ethanol added was in the reactor effluent compared to methanol. This resulted in a lower dose requirement for ethanol compared to that needed with methanol.

Acclimation Needs. Applications in which an external carbon must be added on a seasonal basis or intermittently must consider if the carbon selected is readily degradable in the activated sludge mixed liquor (such as acetate) or if an acclimation time is needed to develop a sufficient biomass. An acclimation time is needed to develop a methylotrophic population as they are not present to much extent in activated sludge systems treating domestic wastewater. At least 2 weeks are needed to develop an effective methanol-degrading population, and longer times of two to three SRTs have been recommended by Nyberg (1996) to reach full population development. Glycerol requires a few days acclimation time to reach full degradation capacity (Dailey et al., 2012). If the need for an external carbon source is quite variable due to changing demand during wet weather or other local variations, a carbon source that requires little acclimation would be appropriate.

Reduction End Products. The goal in denitrification is to reduce the nitrate to nitrogen gas but in some instances a portion of the nitrate may be reduced to only nitrite. This may be due to insufficient carbon with the faster conversion of nitrate to nitrite consuming the available carbon, an insufficient detention time, or the selection of a denitrifying population that only converts nitrate to nitrite. In recent denitrification studies with acetate as the carbon source, nitrite accumulation has been observed along with nitrate reduction (Cherchi. et al., 2009). Nitrite accumulation was also observed in studies with glycerol addition (Uprety et al., 2012). Acetate is a product of glycerol fermentation (Gall et al., 2008) and thus acetate was likely produced and consumed in an anoxic reactor fed glycerol. Nitrite accumulation has been attributed to decreased nitrite reductase activity in the presence of acetate (Van Rijn, 1996), whereas Uprety et al. (2012) attribute it to a high F/M loading and substrate storage by the biomass so that limited carbon is left to drive the nitrite reduction reaction. No nitrite accumulation was observed when a second external carbon (methanol) was added with glycerol addition (Oreskovich et al., 2011).

Process Control and Performance

Process control methods for nitrogen removal systems are important with regard to the following treatment process considerations: (1) maintaining nitrification performance, (2) online instrumentation to enable the application of specific nitrogen removal processes, and (3) the use of online instrumentation to minimize effluent inorganic nitrogen concentrations and external carbon dosage. These applications involve the use of one or more of the following instruments that have been applied successfully for online measurements and control in biological nitrogen removal suspended growth systems (WERF, 2007): DO probes, suspended solids analyzers, ORP probes, ammonia analyzers, and nitrate and nitrite analyzers.

Nitrification Performance. The treatment efficiency of biological nitrogen removal processes is related to the ability to meet the desired level of nitrification. The conversion of ammonia to nitrate and nitrite, as noted previously, is related to the aerobic zone DO concentration and the ability to maintain an adequate aerobic SRT. The importance of DO and SRT control with respect to treatment kinetics was presented and discussed in Sec. 8–3. In addition, DO control is also important with respect to (1) the aeration system performance optimization and energy usage in nitrification systems, and (2) the minimization of the DO concentration in the internal recycle flows to a preanoxic zone. If surface wasting is employed to control *Nocardioform* foam, a common occurrence in MLE processes, it is of critical importance that the solids lost with the foam be accounted for in computing the SRT for process control.

Nitrogen Removal Processes with Online Analyzers. Certain types of nitrogen removal processes are dependent on the use of specific online analyzers. The low DO SNdN process depends on DO probes for aeration control at low DO concentrations. The more recently developed optical DO probes have allowed reliable, accurate, and continuous measurements of low DO concentrations for SNdN systems. Optical methods measure changes in light emitted by a luminescent chemical, which is related the solution DO concentration. The control of DO is also important in cyclic and phased operation NdN processes.

Measurements with ORP probes are important for an intermittent aeration NdN process such as the oxidation ditch shown on Fig. 8–29. In the aerobic/anoxic cycling, the aeration can be turned off at selected times and online ORP measurements can be used to determine when to start aeration again. The ORP response during an aeration-off period is shown on Fig. 8–29(c). As the DO concentrations decline, the ORP value decreases. When the NO_3-N is depleted, a dramatic decline in the ORP value occurs. The ORP decline is called the ORP knee and can be identified by calculating the ORP slope with time. The ORP values are logged onto a computer, which is programmed to turn on the aeration based on the changing slope of the ORP. The aeration-off periods are selected to occur during different times of the day; the more ideal time is when the influent BOD concentration is high so that nitrate reduction occurs at a faster rate. ORP control for nitrogen removal has also been shown for nitrogen removal in aerobic digestion (Koch et al., 1985) and in SNdN systems (Mavinic et al., 2005). It may also be useful in determining when nitrate is removed in cyclic and phased operation NdN systems.

Effluent Inorganic Nitrogen Concentration and External Carbon Dose. Continuous online measurements of ammonia and nitrate/nitrite concentrations are very useful for process optimization to achieve minimal effluent inorganic nitrogen concentrations and to control the external carbon dose in postanoxic denitrification processes.

Ion-selective electrode probes have been used for ammonia measurements; the most common method for nitrate and nitrite measurements is by UV absorbance techniques. Suspended solids filtration is often used with these methods to prevent interferences.

Online nitrate/nitrite measurements are particularly important for control of external carbon dosing in systems where the goal is to meet a minimal effluent inorganic nitrogen concentration. The amount of carbon needed varies due to diurnal variations in flow and nitrogen loadings. A high carbon dose can be used to maximize nitrate removal, but is wasteful and can also increase the effluent BOD concentration. A feed forward control scheme is used normally in which the flowrate and upstream nitrate concentration measurements before the anoxic tank are used to adjust the external carbon feed rate. In some cases, an online measurement of nitrate concentration in the anoxic zone is done to prevent over dosing by maintaining a residual low nitrate concentration.

8–8 PROCESSES FOR ENHANCED BIOLOGICAL PHOSPHORUS REMOVAL

The fundamental principles of enhanced biological phosphorus removal (EBPR) have been described in section 7–13 in Chap. 7. The process is based on contacting activated sludge mixed liquor with the influent wastewater or other feed stream containing volatile fatty acids (VFAs) in an anaerobic tank prior to entering anoxic or aerobic tanks. In contrast to the other heterotrophic organisms, the phosphorus accumulating organisms (PAOs) are able to assimilate and transform acetate and propionate to intracellular carbohydrate storage products in the anaerobic zone. These VFAs may be available in the influent feed to the anaerobic zone and/or produced by fermentation of influent rbCOD. The anaerobic zone provides a competitive advantage for PAOs and thus has been referred to as an anaerobic selector process for PAOs. A PAO-enriched activated sludge also contains a dense, well developed floc with good settling and thickening properties for the reasons discussed in Sec. 8–4 which dealt with selectors. The material on phosphorus removal presented in this section is organized into the following topics: (1) process development, (2) overview of EBPR processes, (3) general process design considerations, (4) operational factors that affect EBPR processes, (5) EBPR process design, (6) provision for chemical addition, and (7) process control and performance optimization.

Process Development

From the mid-1960s to 1971 there were many observations of high levels of phosphorus removal at municipal activated sludge treatment plants at the District of Columbia (Levin and Shapiro, 1965), San Antonio, TX (Vacker et al., 1967), Los Angeles, CA (Bergman et al., 1970), and Baltimore, MD (Milbury et al., 1971). Phosphorus removal efficiencies were greater than 80 percent, compared to typical removals of 20 to 25 percent for activated sludge treatment of domestic wastewaters due to phosphorus needs for biomass growth from BOD removal. Levin and Shapiro (1965) presented experimental results on the occurrence of excess phosphorus uptake by biological activity and termed the process *luxury uptake* of phosphorus. They further proposed the sidestream *Phostrip* process for biological release of phosphorus from return activated sludge and subsequent chemical precipitation of the phosphorus in the separated liquid from the Phostrip process. Further designs were stymied at that time due to a lack of understanding of the basic causes and mechanisms behind the so called luxury uptake of phosphorus.

Barnard (1974) was the first to clarify the need for anaerobic contacting between activated sludge and influent wastewater before aerobic degradation to accomplish what is now called EBPR instead of luxury uptake. Other modifications of the basic process include (1) combining the anaerobic/aerobic sequence with various biological nitrogen-removal designs, (2) introducing mixed liquor to the anaerobic zone from a downstream anoxic zone instead of return activated sludge after liquid-solids separation in clarifiers or with membranes, (3) adding VFAs to the anaerobic zone as either acetate or a liquid stream from a fermentation reactor processing primary clarifier sludge, and (4) using multiple-staged anaerobic and aerobic reactors. The alternating exposure to anaerobic conditions can be accomplished in the main biological treatment process, or "mainstream EBPR," or in the return activated sludge stream or "sidestream EBPR". The first "mainstream" biological phosphorus removal process in the United States, a modified Bardenpho process, that also included biological nitrogen removal was placed in operation in 1979 at Palmetto, FL, and is shown on Fig. 8–3(b).

Overview of Enhanced Biological Phosphorus Removal Processes

A variety of EBPR process designs have been developed and applied at WWTPs; the design selection has depended on the wastewater treatment process and equipment in place before converting to EBPR, the wastewater characteristics, and the treatment needs. Usually EBPR is done in mainstream processes, but sidestream processes, such as Phostrip, may be of more interest today at WWTPs where struvite recovery systems are installed. Commonly used mainstream EBPR process configurations are shown on Fig. 8–37. The three different EBPR process configurations are used for applications in which,

1. Nitrification is not required
2. Nitrification is required with high BOD/P ratios in the influent wastewater
3. Nitrification is required with low BOD/P ratios in the influent wastewater

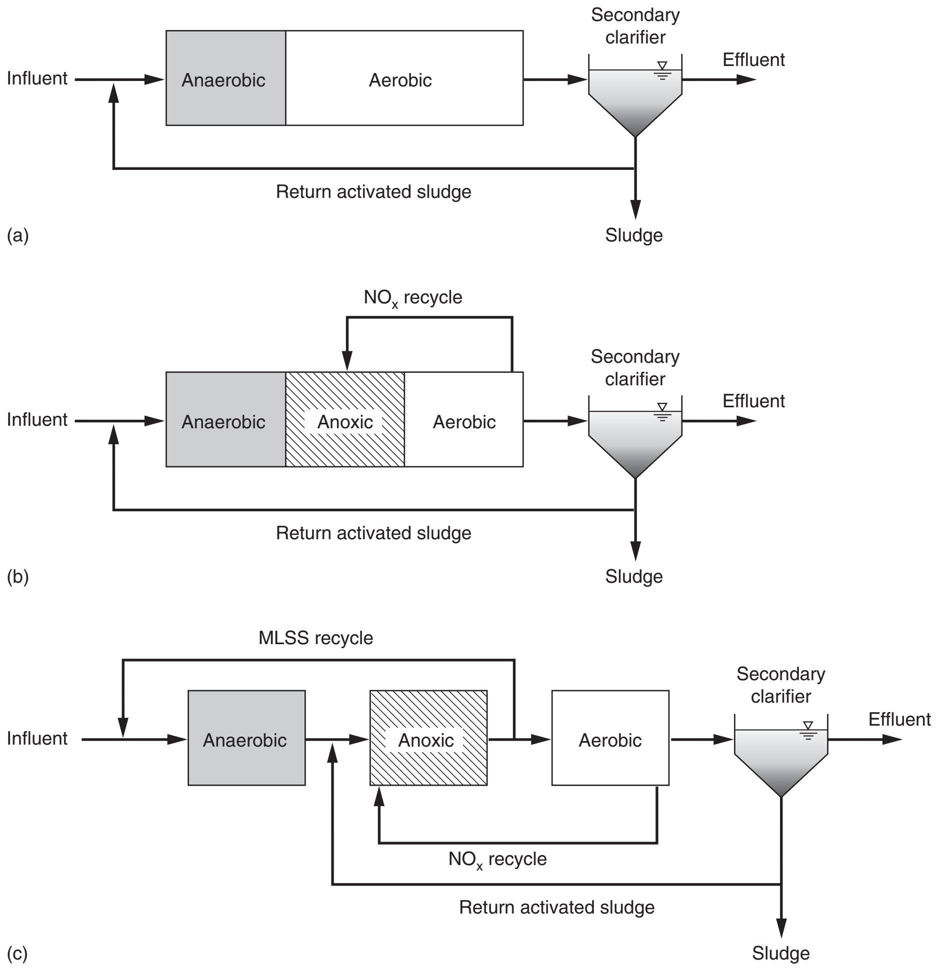
Each of these process configurations is considered in the following discussion along with a summary review of the available phosphorus removal processes and the sidestream removal of phosphorus.

Phosphorus Removal Without Nitrification. The term *Phoredox*, introduced by Barnard (1975), is used to represent any process with an anaerobic/aerobic sequence to promote EBPR. The Phoredox process, shown on Fig. 8–37(a), has also been referred to as an A/O (anaerobic/aerobic) process. As shown on Fig. 8–37(a), settled and thickened activated sludge is returned to the anaerobic reactor. Nitrification does not occur to any appreciable extent in the A/O process, as it is designed with low aerobic SRT values from 2 to 3 d at 20°C and 4 to 5 d at 10°C. These relatively low SRTs are adequate for growth and proper performance of the PAOs. Although EBPR has been done in activated sludge systems without nitrification, combined biological phosphorus and nitrogen removal processes are favored to minimize the negative impact of nitrate on EBPR performance and to reduce energy requirements.

Phosphorus Removal with Nitrification and High Influent Wastewater BOD/P Ratios. For applications where nitrification is needed to meet discharge requirements, nitrate can be present in the return activated sludge flow to the anaerobic contact zone of an EBPR process and can be detrimental to EBPR performance. Other non-PAO heterotrophic bacteria will use nitrate fed to the anaerobic zone to consume rbCOD for nitrate reduction, leaving less rbCOD available for PAOs. With less rbCOD available, there is less PAO growth and less phosphorus removal by EBPR. If no nitrate removal occurs with nitrification systems, EBPR is not possible.

Figure 8–37

Common enhanced biological phosphorus removal processes: (a) Phoredox (A/O), (b) Anaerobic/Anoxic/Aerobic (A^{2}O), (c) University of Capetown (UCT).



A very common process for nitrate removal is the Modified Ludzack-Ettinger (MLE) process as described in Sec. 8–7, and when preceded by an anaerobic contact zone for EBPR, it has been referred to as the A^{2}O (anaerobic-anoxic-aerobic) process as shown on Fig. 8–37(b). In the A^{2}O process, nitrate is removed by the anoxic/aerobic sequence shown, but the return activated sludge (RAS) recycle to the anaerobic zone still contains nitrate. If the wastewater has a high favorable influent BOD/P ratio (typically greater than 30/1) there will likely be enough rbCOD for both the nitrate removal and sufficient PAO growth. For weaker wastewaters or wastewaters with a lower BOD/P ratio, the amount of influent rbCOD consumed by heterotrophic denitrifying bacteria is such where there is not enough rbCOD left to support the amount of PAO growth needed for removal of the desired amount of influent phosphorus.

Phosphorus Removal with Nitrification and Low Influent Wastewater BOD/P Ratios. In some applications it is necessary to have very little or no nitrate in the mixed liquor recycle to the anaerobic contact zone, so that all of the rbCOD can be used by PAOs to meet the desired amount of EBPR. Avoidance of nitrate in mixed liquor returned to the anaerobic contact zone is desired for EBPR with weak wastewater, low influent BOD/P ratios and/or for a treatment goal to maximize phosphorus removal without chemical addition. The University of Capetown (UCT) process [see Fig. 8–37(c)] is a common EBPR process that has been used in anoxic/aerobic nitrogen removal processes to prevent the addition of nitrate to the anaerobic contact zone. In this process the return activated sludge is directed to an anoxic zone instead of the anaerobic contact zone. The return mixed liquor to the anaerobic contact zone is taken from the anoxic zone or effluent where the nitrate concentration is typically below 0.50 mg/L.

Sidestream Removal of Phosphorus. The Phostrip process [see Table 8–27(o)] is a sidestream EBPR process in which a portion of the return activated sludge flow is added to an anaerobic contact zone. In some cases a portion of the mainstream influent wastewater is diverted to the sidestream anaerobic contact zone to provide additional rbCOD. Growth of PAOs occurs in the anaerobic contact zone due to acetate uptake from fermentation of substrates released during cell lysis of the return activated sludge biomass and from rbCOD from wastewater, if added. Liquid-solids separation occurs, usually by gravity thickening as part of the anaerobic contact zone, and the liquid containing the released or *stripped* phosphorus is treated separately before it is returned to the mainstream process. The phosphorus-rich liquid is typically treated with lime or metal salts for phosphorus precipitation, but it could instead be added to a struvite recovery process.

The residual biomass is added back to the mainstream process with the return activated sludge flow where the PAOs take up phosphorus from the influent wastewater. The PAOs have a more efficient uptake of the influent phosphorus because they do not have to take up all of the phosphorus released in the anaerobic contact zone, as is done with the mainstream processes. In the Phostrip process, the phosphorus-removal efficiency depends less on the influent rbCOD concentrations than for other enhanced biological phosphorus removal processes. Also as noted previously, variants of the Phostrip sidestream process have gained popularity for the removal of phosphorus in the form of struvite (see Sec. 15–4 in Chap. 15).

Summary Review of EBPR Processes. A summary of the basic design features for EBPR processes, including those presented above are described in Table 8–27. They include (1) basic nitrogen removal processes that reduce the amount of nitrate fed to the EBPR process anaerobic contact zone [A^2O (b), Modified Bardenpho (d)], (2) processes to remove most all nitrates fed to the EBPR anaerobic contact zone [UCT (f), VIP (h), JHB (i,), Westbank (l)], (3) the processes in (1) and (2) using MBRs instead of an activated sludge/secondary clarifier system [(c), (e), (g), (j)], (4) processes including primary sludge fermentation for VFA production to maximize EBPR performance [VFA addition to A^2O-EBPR at Kelowna and to trickling filter-EBPR at OWASA (k), and Westbank (l)], (5) EBPR in an SBR process design (m, n), and (6) EBPR with sidestream anaerobic contacting [Phostrip (o)].

Process selection for EBPR is very site specific and a number of factors must be considered including (1) effluent phosphorus concentration needed, (2) existing process and equipment, (3) process needs for nitrification and nitrogen removal, (4) wastewater characteristics, (5) phosphorus recovery, and (6) operational requirements. Advantages and disadvantages for the most commonly used processes are given in Table 8–28 on page 871.

General Process Design Considerations

Most of the mainstream processes described for enhanced biological phosphorus removal incorporate the necessary anaerobic contacting between influent wastewater and activated

Table 8–27

Description of suspended growth processes for phosphorus removal

Process	**Description**
(a) Phoredox (A/O) Process 	The basic process configuration for biological phosphorous removal consists of an anaerobic zone followed by an aerobic zone. Barnard (1974) was the first to clarify the need for anaerobic contacting between activated sludge and influent wastewater before aerobic degradation to accomplish enhanced biological phosphorous removal. Barnard identified it as the Phoredox process and has also been referred to as the anaerobic/oxic (A/O) process. The SRT of the aerobic zone mixed liquor is 2 to 4 d, depending on the temperature, so that nitrification does not occur. The anaerobic contact time is 30 min to 1 h to provide the selective condition described in Sec. 7–13 for enhanced biological phosphorous removal.
(b) Anaerobic/Anoxic/Aerobic (A^2O) Process 	The A^2O process has an anoxic zone located between the anaerobic and aerobic zones and is used for EBPR systems that have nitrification. Nitrate is recycled from the aerobic zone to the anoxic zone for denitrification. The detention time in the anoxic zone is 1 to 3 h, depending on the wastewater characteristics and the amount of nitrate to remove. Use of the anoxic zone minimizes the amount of nitrate fed to the anaerobic zone in the return activated sludge.
(c) A^2O MBR Process 	A common approach for incorporating the A^2O process in an MBR is shown. Mixed liquor is recycled from the membrane separation aerobic zone to the anoxic zone for nitrate removal at a recycle ratio of about 6:1, based on the influent flowrate. Mixed liquor is recycled from the aerobic zone for contact with the influent wastewater in the anaerobic zone.

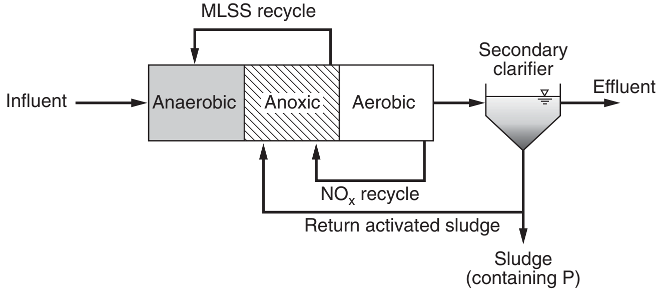
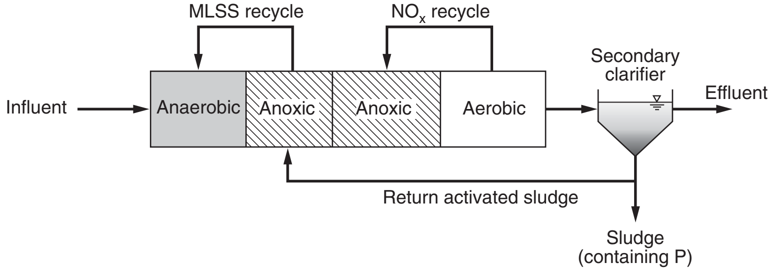
Table 8–27 (*Continued*)

Process	Description
(d) Modified Bardenpho Process  	The Bardenpho process, described in Table 8–24, can be modified for combined nitrogen and phosphorus removal. The 5– stage system provides anaerobic, anoxic, and aerobic stages for phosphorus, nitrogen, and carbon removal. Mixed liquor from the first aerobic zone is recycled to the preanoxic zone. A second anoxic stage is provided for additional denitrification using nitrate produced in the first aerobic zone as the electron acceptor, and the endogenous organic carbon as the electron donor. An option is to add an exogenous carbon source to the second anoxic zone so that it has a shorter detention time and can produce lower effluent NO_3-N concentration. The final aerobic stage is used to strip residual nitrogen gas from solution and to raise the DO concentration to minimize phosphorus release in the secondary clarifier. The 5-stage process produces a lower NO_3-N concentration in the return activated sludge flow to minimize the effect of NO_3-N in the anaerobic zone.
(e) Modified Bardenpho -MBR Process  	A postanoxic zone is added to the A^2O–MBR process to create the modified Bardenpho–MBR process. Carbon addition to the second anoxic zone is also optional. Full-scale MBR plants using the modified Bardenpho–MBR process may employ three recycle streams. Mixed liquor from the aerobic membrane separation reactor is recycled to the aerobic reactor at a recycle ratio of about 6/1, based on the influent flowrate. NO_x is fed from the aerobic zone to the preanoxic zone at a rate of about 3 to 4 times the influent flowate. Mixed liquor is recycled from the preanoxic zone to the anaerobic zone at a rate equal to 1 to 2 times the influent flowrate. This recycle contains a near zero DO concentration and low NO_3-N concentration. The additional NO_3-N removal provides better EBPR performance than the A^2O-MBR process.

(f) University of Capetown (UCT) Process - Standard and Modified

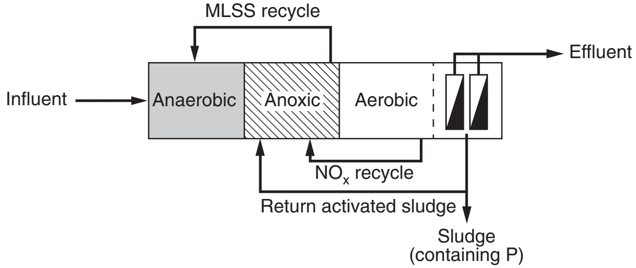




The UCT process was developed at the University of Cape Town (South Africa) to minimize the effect of nitrate entering the anaerobic contact zone in EBPR processes treating weak wastewaters. The UCT process has three recycle streams instead of two as in the A^{2}O process. The return activated sludge from the secondary clarifier is directed to the anoxic zone instead of the anaerobic zone. Similar to the A^{2}O process, internal recycle feed NO_x to the anoxic zone from the aerobic zone. The anaerobic zone receives mixed liquor from the anoxic zone instead of the return activated sludge flow so that the introduction of nitrate to the anaerobic stage is eliminated. Thus, more of the influent rbCOD is available for the PAOs in the anaerobic zone which can improve the EBPR efficiency. Because the anaerobic zone receives mixed liquor at a lower concentration than in the A^{2}O process, the anaerobic detention time must be longer than that used in the Phoredox process, and is the range of 1 to 2 h. The anaerobic recycle rate is typically 2 times the influent flowrate.

In the modified UCT process shown on the second diagram, the return activated sludge is directed to an anoxic reactor that does not receive internal nitrate recycle flow. The nitrate is reduced in this tank, and the mixed liquor from the reactor is recycled to the anaerobic tank. The second anoxic tank follows the first anoxic tank and receives internal nitrate recycle flow from the aeration tank to provide the major portion of nitrate removal for the process.

(g) Modified UCT-MBR Process



The modified UCT-MBR process also has three recycle streams, which are applied in the same manner as in the UCT process with secondary clarifiers. The return activated sludge flow from the aerobic membrane separation tank is directed to the preanoxic zone at a flowrate of about 6 times the influent flowrate. NOx produced in the aerobic zone is recycled back to the preanoxic zone at a flowrate of about 3 times the influent flowrate. The anaerobic zone receives mixed liquor with no dissolved oxygen and minimal nitrate in recycle from the preanoxic zone at a rate of 1 to 2 times the influent flowrate. By minimizing dissolved oxygen and nitrate entering the anaerobic contact zone, most of the influent rbCOD can be used by the PAOs to maximize EBPR efficiency.

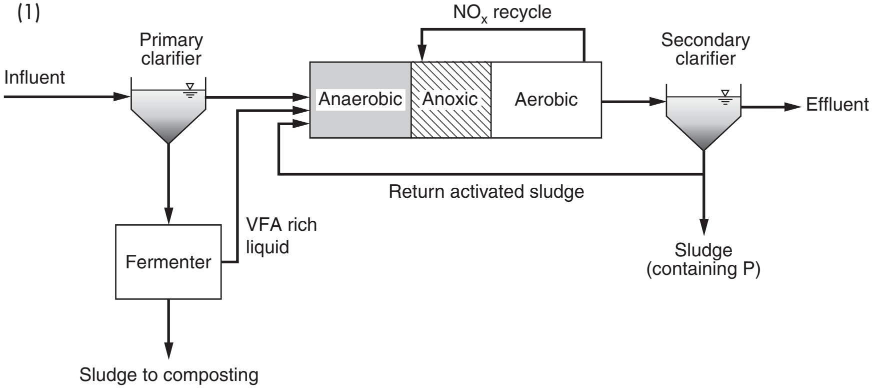
(*continued*)

Table 8–27 *(Continued)*

Process	Description
(h) Virginia Initiative Plant (VIP) Process  	The VIP process stands for the Virginia Initiative Plant (Daigger et al., 1988). The VIP process is similar to the A^2/O and UCT processes except for the increased staging and methods used for recycle systems. In the VIP process, all the zones are staged consisting of at least 2 completely mixed cells in series. The return activated sludge is discharged to the inlet of the anoxic zone along with nitrified recycle from the aerobic zone. The mixed liquor from the anoxic zone is returned to the head end of the anaerobic zone. The VIP process is also designed as a high rate system, operating with much shorter SRTs, which maximizes EBPR efficiency. The combined SRT of the anaerobic and anoxic zones is generally 1.5 to 3 d, while the anaerobic and anoxic τ values are typically 60 to 90 min each. The aeration zone is designed for nitrification.
(i) Johannesburg (JHB) Process  	The JHB process originated in Johannesburg, South Africa as an alternative to the UCT or modified UCT processes to minimize nitrate addition to the anaerobic zone to maximize EBPR for weak wastewaters. The return activated sludge is directed to an anoxic zone that has sufficient detention time to reduce the nitrate in the mixed liquor before it is fed to the anaerobic zone. The nitrate reduction is driven by the endogenous respiration rate of the mixed liquor, and the anoxic zone detention time depends on the mixed liquor concentration, temperature, and the nitrate concentration in the return sludge stream. NO_x produced in the aerobic zone is recycled to a preanoxic zone at a flowrate of 3 to 4 times the influent flowrate. Compared to the UCT process, a higher MLSS concentration and lower detention time can be maintained in the anaerobic zone (detention time of about 1 h) and two recycle streams are used instead of three.
(j) JHB-MBR Process  	The JHB process can also be Incorporated in an MBR system, also with the use of 2 recycle streams. Return activated sludge from the aerobic membrane separation zone is directed to an anoxic zone in which nitrate is reduced by the mixed liquor endogenous respiration. The high mixed liquor concentration in the MBR process results in a smaller anoxic tank volume than that required for the JHB process in an activated sludge/secondary clarifier system. An internal recycle flow from the aerobic zone to the anoxic zone is also used to remove NO_x produced in the aerobic zone.

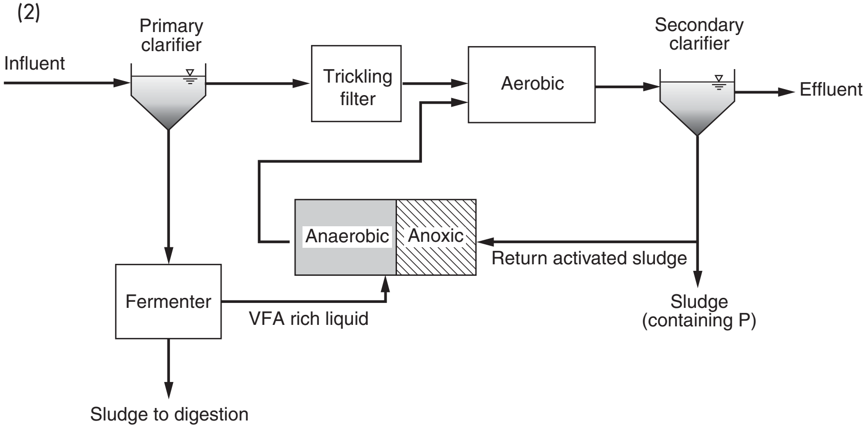
(k) EBPR with Primary Sludge Fermentation

(1)



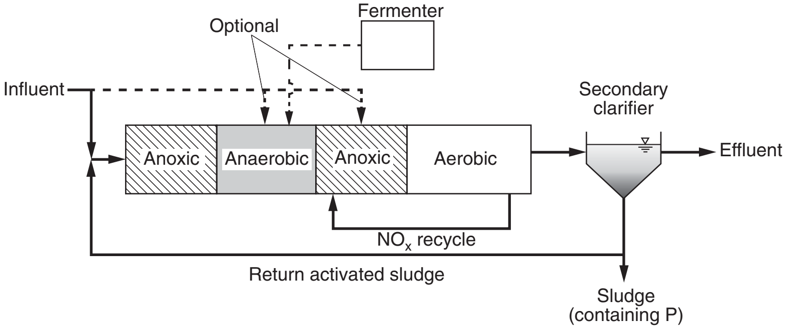
System (1) is used at the Kelowna WWTP and represents the more typical application. Fermenter liquid is added to the anaerobic zone of an EBPR process, which also receives the primary effluent. The additional VFAs in the fermenter liquid provides more substrate for PAO growth to improve phosphorus removal.

(2)



System (2) is used at the OWASA facility, which has trickling filter treatment prior to the activated sludge aeration tank. In this case the anaerobic contact zone necessary for EBPR receives the VFA-rich stream from the primary sludge fermenter in the return activated sludge flow, and is not after trickling filter effluent which has very little rbCOD.

(l) Westbank EBPR Process



The Westbank EBPR Process gets its name due to its location relative to another EBPR process used in Kelowna, British Columbia, Canada. The process anoxic/anaerobic/anoxic/aerobic zone sequence and recycle flow locations are similar to that used in the JHB process. However, the first anoxic zone receives influent wastewater in addition to the return activated sludge flow to assure complete nitrate removal. Some influent may also be added to the downstream anaerobic and anoxic zones. The subsequent anaerobic zone process is fed liquid from a primary sludge fermentation tank that is rich in volatile fatty acids (acetate and propionate) to provide substrate for PAO growth and efficient EBPR performance.

(*continued*)

Table 8–27 *(Continued)*

Process	Description
(m) SBR with EBPR  	If sufficient nitrate is removed during the SBR operation, an anaerobic reaction period can be developed during the SBR fill period for rbCOD fermentation and VFA uptake by PAOs. An anoxic operating period is used after a sufficient aerobic time elapses for nitrification and nitrate production. Alternatively cyclic aerobic and anoxic periods can be used during the react period. The nitrate concentration is thus minimized before settling, and little nitrate is available to compete for rbCOD in the fill and initial react period. Thus, anaerobic conditions occur in the fill and initial react period, so that rbCOD can be used by PAOs instead of by nitrate-reducing bacteria.
(n) EBPR in SBR with granular activated sludge  	An SBR system with granular activated sludge is a promising emerging technology. A selector process based on upflow velocity produces dense, granular activated sludge aggregates ($>$0.20 mm diameter) (de Kreuk and van Loosdrecht, 2007) that have the same degree of settling in 5 min as that for 30 min in an SVI test with conventional activated sludge. As a result the SBR design and operation is different from a conventional SBR. After a short settling time ($<$10 min) the influent is added upflow with the effluent being the treated upper zone liquid after settling. The fill period is anaerobic to promote EBPR. During the aeration period SNdN occurs with nitrification in the outer layer of the granules and denitrification in the inner layers. Stored carbon is oxidized by the PAOs with phosphorus uptake. The aeration efficiency is improved due to the constant liquid level and the uptake of rbCOD in the anaerobic fill results in a more uniform oxygen uptake rate during aeration. Effluent filtration may be needed for effluent TSS concentrations less than 15 mg/L. A commercial process named Nereda™ has been developed by DHV with full-scale facilities in the Netherlands.
(o) Phostrip with anoxic/aerobic activated sludge treatment  	The Phostrip process is in essence an anaerobic/aerobic EBPR process with stripping of phosphorus from the PAOs. The anaerobic condition is created by holding return activated sludge long enough in a gravity thickener (termed a *phosphorus stripper*) with residence times generally in the range of 8 to 12 h (Levin et al., 1975). Substrates released from sludge endogenous decay and lysis are fermented to VFAs for uptake by the PAOs resulting in phosphorus release. The released phosphorus is elutriated by circulation of underflow from the thickener to the thickener inlet. The thickener underflow solids are returned to the activated sludge process, where the PAOs take up phosphorus under anoxic and aerobic conditions. The overflow from the stripper tank is then treated chemically with lime or metal salts for phosphorous removal. The lime dose needed to raise the pH for phosphorus removal is a function of the wastewater alkalinity and not the amount of phosphorus present. If alum and ferric salts are used instead, the dose is proportional to the amount of phosphorus released but it can be used at minimal molar ratios for phosphorus removal. The Phostrip process can be similarly applied in systems without nitrification. For anoxic/aerobic processes the recycle may be held in an anoxic reactor for denitrification prior to its addition to the stripper tank.

Table 8–28

Advantages and limitations of phosphorus removal processes

Process	Advantages	Limitations
Phoredox (A/O)	Operation is relatively simple when compared to other processes Low influent BOD/P ratio possible Relatively short hydraulic retention time Produces good settling sludge Good phosphorus removal	Phosphorus removal declines if nitrification occurs Requires careful SRT control to prevent nitrification Difficult to operate without nitrification in warm climates
A^2O	Removes both nitrogen and phosphorus Provides alkalinity for nitrification Produces good settling sludge Operation is relatively simple Saves energy Compatible with MBRs	RAS containing nitrate is recycled to anaerobic zone thus affecting phosphorus removal capability Nitrogen removal is limited by internal recycle ratio Needs higher influent BOD/P ratio than the A/O process
UCT	Nitrate loading on anaerobic zone is reduced thus increasing phosphorus removal capability For weaker wastewater, process can achieve improved phosphorus removal Produces good settling sludge Good nitrogen removal Compatible with MBRs	More complex operation Requires additional recycle system
VIP	Nitrate loading on anaerobic zone is reduced thus increasing phosphorus removal capability Produces good settling sludge Requires lower BOD/P ratio than UCT Good nitrogen removal Compatible with MBRs	More complex operation Requires additional recycle system More equipment, baffles, and headloss required for staged design
Modified Bardenpho	Can achieve 3 to 5 mg/L TN in unfiltered effluent Produces good settling sludge Less nitrate fed to anaerobic zone than for A^2O Compatible with MBRs	Less efficient phosphorus removal due to longer SRT Requires larger tank volumes
JHB	Prevents nitrate feed to anaerobic zone Promotes high EBPR efficiency Can be used with A^2/O, Modified Bardenpho, Westbank, and Steppe processes Compatible with MBRs	Requires more tank volume Increased operational complexity
SBR with EBPR	Both nitrogen and phosphorus removal are possible Provides good settling sludge Mixed liquor solids cannot be washed out by hydraulic surges Quiescent settling may produce lower effluent TSS concentration Flexible operation Simple system layout Good plug flow kinetics for P uptake efficiency	More complex operation for N and P removal Needs larger volume than SBR for N removal only Effluent quality depends upon reliable decanting facility Design is more complex Skilled maintenance is required More suitable for smaller flowrates

(*continued*)

Table 8–28 (*Continued*)

Process	Advantages	Limitations
SBR with granular activated sludge	Both nitrogen and phosphorus removal are possible Excellent settling sludge Less space than conventional activated sludge Simple system operation Good plug flow kinetics Good aeration efficiency with constant liquid depth	Limited long-term experience Higher effluent suspended solids concentration May not be compatible with chemical addition for phosphorus removal High peak hydraulic loads not desired
Westbank	High EBPR efficiency Operational flexibility Stable EBPR performance Less susceptible to wastewater loading variations Compatible with MBRs	Needs extra tanks Increased unit process/increased operations Odor control for fermenter
Phostrip	Can be incorporated easily into existing activated sludge plants Process is flexible; phosphorus removal performance is less controlled by influent BOD/phosphorus ratio Less chemical usage than mainstream chemical precipitation process Can achieve reliable effluent orthophosphate concentrations less than 1 mg/L	Requires metal salts or lime addition for phosphorus precipitation Additional tanks needed Increased operations Increased sludge production Lime scaling may be a maintenance problem

sludge, followed by an anoxic or aerobic zone for biooxidation of stored intracellular poly-β-hydroxyalkanoates (PHA) and phosphorus uptake by the PAOs. In light of these basic requirements, process design considerations for EBPR processes include (1) treatment needs, (2) influent wastewater characteristics, (3) anaerobic contact time, (4) supplemental sources of VFAs, (5) SRT, and (6) aerobic zone and aeration design. Operational factors including (1) the effect of nitrate and oxygen addition to the anaerobic contact zone, (2) waste sludge processing, and (3) alkalinity and pH, are considered separately. The need for the provision of chemical addition is also considered separately following the presentation of the EBPR process design. The reaction kinetics for BOD removal, nitrification, and denitrification are similar to those discussed in Secs. 8–4 and 8–5. Typical parameters used in the design of EBPR processes are presented in Table 8–29.

Treatment Needs. The specific process design details are affected by effluent nitrogen concentration requirements as well as the required effluent phosphorus concentration. In addition to the process configuration selection, the treatment needs affect the design SRT, reactor staging and DO concentrations, the need for carbon addition and waste sludge handling methods.

Wastewater Characteristics. Because EBPR is affected by the influent wastewater characteristics, including rbCOD and VFAs, the measurement of these

Table 8–29

Typical design parameters for commonly used biological phosphorus removal processes

Design parameter/ process	SRT, d	MLSS, mg/L	τ, h Anaerobic zone	τ, h Anoxic zone	τ, h Aerobic zone	RAS, % of influent	Internal recycle, % of influent
A/O	2–5	3000–4000	0.5–1.5	–	1–3	25–100	
A^2/O	5–25	3000–4000	0.5–1.5	1–3	4–8	25–100	100–400
Modified Bardenpho	10–20	3000–4000	0.5–1.5	1–3 (1st stage) 2–4 (2nd stage)	4–12 (1st stage) 0.5–1 (2nd stage)	50–100	200–400
UCT	10–25	3000–4000	1–2	2–4	4–12	80–100	200–400 (anoxic) 100–300 (aerobic)
VIP	5–10	2000–4000	1–2	1–2	4–6	80–100	100–200 (anoxic) 100–300 (aerobic)
SBR	20–40	3000–4000	1.5–3	1–3	2–4		
Phostrip	5–20	1000–3000	10–12		4–10	50–100	10–20

constituents is essential to evaluate the design and performance of EBPR systems. The amount of enhanced biological phosphorus removal is related directly to the amount of acetate and propionate taken up by PAOs in the anaerobic contact zone and converted to carbon storage products that provide energy and growth in the subsequent anoxic and aerobic zones (Gerber et al., 1986). Different influent wastewater characterization parameters have been used to assess the potential for EBPR performance. The wastewater characteristics shown in Table 8–30 are arranged in order of the most direct to indirect correlation with VFA utilization in EBPR systems, to achieve an effluent soluble P concentration ≤ 0.50 mg/L. Because acetate and propionate are the substrates consumed by PAOs in the anaerobic contact zone, a VFA to P ratio is a good predictor of the amount of P that can be removed. The amount of VFA available to the PAOs in the anaerobic

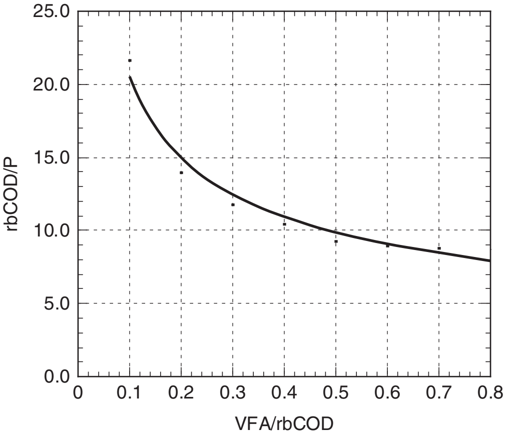
Table 8–30

Minimal influent wastewater ratios for achieving a soluble P effluent concentration of less than 0.50 mg/L in EBPR systems.

Influent substrate parameter	Value	Reference
VFA:P	8	Wentzel (1990)
rbCOD:P	18	Barnard (2006)
BOD:P	30	Sedlak (1991)
COD:P	60	U.S. EPA (2010)

Figure 8–38

Amount of rbCOD used for enhanced biological phosphorus removal is related to its volatile fatty acid content.



contact zone is greater than the influent wastewater VFA concentration due to fermentation of other rbCOD in the wastewater.

Influent rbCOD to P Ratio. Knowledge of the influent rbCOD/P ratio is very useful. A minimum value of 18 is recommended to achieve a soluble P concentration of less than 0.50 mg/L, but as the influent VFA/rbCOD ratio increases, the required rbCOD/P ratio decreases, as shown on Fig. 8–38 (Barnard, 2012). In some cases, the potential P removal must be estimated with only influent BOD or COD data. Higher BOD/P ratios for domestic wastewater generally lead to improved EBPR performance. A BOD/P ratio above 30 will generally result in high EBPR performance with effluent soluble P concentrations below 0.50 mg/L. The ratios given above are based on the assumption that the EBPR process does not have an excessively long SRT and that minimal nitrates are fed to the anaerobic contact zone. Higher values for the ratios shown in Table 8–30 will be required for EBPR processes with long SRTs (>15 to 20 d) and/or with high DO or nitrate feed to the anaerobic zone.

Diurnal Variation. The diurnal variation in wastewater strength is also an important process consideration. Because the performance of phosphorus-storing bacteria depends on the availability of fermentation substrates, it is important to know if periods of low influent wastewater strength may affect EBPR performance. For domestic wastewaters, the influent total BOD and rbCOD concentrations will vary with time over a 24-h period, with lower concentrations in the late evening and early morning hours. For smaller-sized communities, the variations are usually more pronounced and very little rbCOD may be present at certain times. During wet-weather conditions, especially in the winter, EBPR may be difficult to achieve due to cold, low strength wastewater that does not readily become anaerobic.

Extended periods of reduced rbCOD concentration will decrease EBPR performance for a number of hours after the occurrence of low substrate concentration (Stephens and Stensel, 1998). The impact of continuous acetate feeding at plants where sludge fermentation has been done to produce additional VFAs has shown the benefit of a steady supply of rbCOD for EBPR. In parallel modified Bardenpho trains at Kelowna, Canada, one train was fed fermentation liquor and the other train was used as the control. With continuous VFA addition, the effluent soluble phosphorus concentration decreased from 2.5 to 0.3 mg/L (Oldham and Stevens, 1985), and the incremental VFA/P ratio was 6.7 g/g, an amount lower than the 8 g/g ratio in Table 8–30. Based on these results, it appears that continuous acetate addition provides more efficient EBPR.

Anaerobic Contact Time. Anaerobic contact by PAOs and the availability of VFA is the most critical elements of an EBPR process design as described in Sec. 7–11. Acetate and propionate are taken up rapidly and detention times of 0.25 to 1.0 h are adequate for fermentation of rbCOD. To account for the effect of the MLVSS concentration in the anaerobic contact zone, a 1-d SRT is recommended for the anaerobic contact zone design (Grady et al., 1999). If the anaerobic contact time is too long, a *secondary release* of phosphorus can occur, which is not associated with acetate uptake (Barnard, 1984). When secondary phosphorus release occurs, the PAOs have not accumulated polyhydroxyalkanoates (PHA) for subsequent oxidation in the aerobic zone. Polyhydroxybutyrate provides energy for phosphorus uptake and storage. From SBR bench-scale studies, it has been found that secondary phosphorus release occurred for anaerobic contact times in excess of 3.0 h (Stephens and Stensel, 1998).

Supplemental Volatile Fatty Acid. The performance of EBPR systems is very site-specific and depends on the wastewater characteristics and the plant process design and operation. For wastewaters with relatively low influent rbCOD/P concentration ratios, effluent soluble phosphorus concentrations may exceed 1.0 to 2.0 mg/L, whereas effluent concentrations below 0.5 or 1.0 mg/L have been achieved with higher-strength wastewaters. The addition of VFAs to the anaerobic contact zone can result in effluent soluble P concentrations from 0.10 to 0.20 mg/L on a consistent basis, as shown for example at the Westbank BC (Rabinowitz and Barnard, 1996) and Durham, Oregon EBPR facilities (Stephens, 2004).

Additional Sources of VFAs. Additional VFAs can be obtained by importing (purchase) an acceptable exogenous carbon source or by production on site by fermentation of primary clarifier waste sludge. Primary sludge fermentation processes produce VFAs with about 50 percent acetate and 30 percent propionate. The presence of propionate is favorable for the selection of PAOs over glycogen-accumulating organisms (GAOs). Primary sludge fermentation process configurations are shown on Fig, 8–39, and key design factors are summarized in Table 8–31. The process configurations shown on Figs. 8–39(b), (c), and (d) are used at Penticton, B.C.; Kelowna, B.C.; and Kalispell, MT., respectively to achieve effluent P concentrations ranging from 0.10 to 0.20 mg/L. The primary clarifier tank (PCT) fermenter [see Fig. 8–39(a)] is the simplest design (Barnard, 1984), but there are problems associated with the high sludge blanket that must be maintained including the potential carryover of suspended solids to the secondary treatment process. The simplest and most common approach is to use primary sludge gravity thickeners for VFA production [see Fig. 8–39(c)].

Primary Sludge Fermenters. Primary sludge fermentation can occur in a separate unheated tank, clarifier sludge blanket, and gravity sludge thickener. Sludge SRTs in the range of 3 to 6 d, depending on temperature, are used to prevent methanogenic activity, which would result in consumption of the VFAs produced (Rabinowitz and Oldham, 1985). At these SRT values, the VFA production ranges from 0.1 to 0.2 g VFA/g VSS applied to the fermenters. The fermenter liquid VFA concentration can range from 150 to 300 mg/L, depending on the design and operation. Assuming an untreated wastewater influent VSS concentration of 200 mg/L with 65 percent VSS removal in primary clarification, the VFA production potential is 13 to 26 mg/L (normalized to the influent flow). The potential increase in enhanced biological phosphorus removal is 2 to 4 mg/L for this amount of VFA production. However, not all of the VFAs produced are sent to the anaerobic contact zone as a portion of the VFAs are contained in the waste sludge flow from the fermenter.

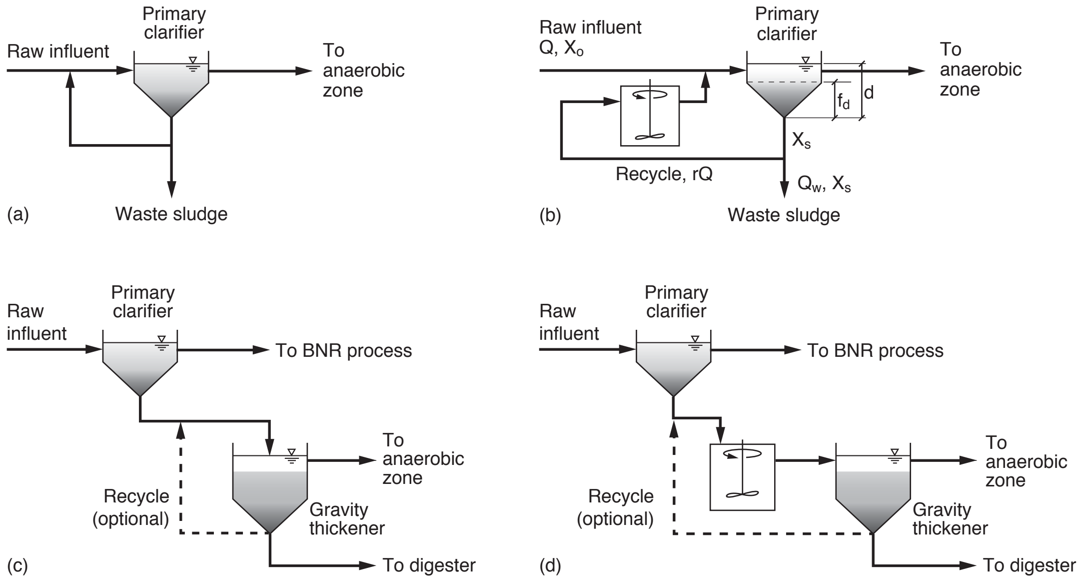


Figure 8–39

Primary sludge fermentation designs for supplying volatile fatty acids used for enhanced biological phosphorus removal: (a) primary sedimentation deep tank sludge blanket fermenter, (b) mixed fermenter tank/primary sedimentation (c) gravity thickener fermenter, and (d) mixed fermenter tank/gravity thickener.

Recycle streams around primary sludge fermenters are used to elutriate VFAs in thickened sludge processes on Fig. 8–39(a) and (b) and are optional in processes on Fig. 8–39(c) and (d). For sludge thickener fermenters, a more dilute waste primary sludge is fed to the gravity thickener, so that a higher ratio of the thickener effluent flow is in the overflow to the anaerobic contact zone, which results in feeding a higher fraction of the VFA produced to the EBPR system. Design criteria for primary sludge fermentation are reported in Table 8–31.

Estimating SRT Values and VFA Production Rates. The SRT and the VFA production rates can be estimated for primary sludge fermenters by performing mass balances on waste sludge and recycle flows and VSS concentrations, and accounting for

Table 8–31

Design criteria for primary sludge fermentation

Type of primary sludge fermentation[a]	Sludge SRT, d	Elutriation recycle ratios: Raw influent	Elutriation recycle ratios: Thickener influent	Contact tank τ, d	Thickener feed, fraction of raw influent flow	Thickener loading, kg/m²·d
(a) Activated PST[b]	2–4	0.05–0.10				
(b) Completely mixed fermenter/PST[b]	4–6	0.05–0.10		0.25–0.50		
(c) Gravity thickener fermenter	4–6		0.10–0.20		0.04–0.08	20–40
(d) Two-stage fermenter/thickener	4–6		0.30–0.50	2.0–4.0	0.02–0.04	100–150

[a] Refer to Fig. 8–39.
[b] PST – primary sedimentation tank.

sludge fermentation tank contact times. For the fermenter/PST combination system shown on Fig. 8–39(b), the sludge fermentation total SRT is determined as follows:

$$\mathrm{SRT} = \mathrm{SRT}_{\text{mixed tank}} + \mathrm{SRT}_{\text{sludge blanket}} \tag{8–77}$$

$$\mathrm{SRT} = r(T_f)t_c + \frac{f_d(d)(T_f)}{\mathrm{SOR}}$$

$$T_f = \frac{Q}{Q_w} \tag{8–78}$$

where r = primary clarifier tank recycle flow ratio relative to influent flowrate
Q = influent flowrate to the PST, $\mathrm{m^3/d}$
Q_w = PST underflow waste sludge flowrate, $\mathrm{m^3/d}$
T_f = influent VSS thickening factor, PST underflow solids concentration to influent flow solids concentration
t_c = detention time of mixed contact tank based on rQ, d
f_d = fraction of PST sludge blanket depth
d = PST depth, m.
SOR = PST surface overflow rate, $\mathrm{m^3/m^2{\cdot}d}$

Operating issues of odors, mixing, and accumulation of rags in the fermenters must also be considered in design and operation requirements.

Exogenous Carbon. Exogenous carbon has been obtained by purchasing acetate or by obtaining wastes from food processing, including corn syrup, brewery and sugar containing beverage processing, fruit and vegetable canning, and molasses waste. Care must be used in adding these wastes so as not to develop an abundant GAO population that could later affect PAO EBPR efficiency during operational changes. Glycerol and ethanol have also been evaluated in bench-scale studies for addition to anaerobic contact zones to support EBPR. They are both proven feasible, but ethanol requires a lengthy acclimation time, presumably to develop ethanol fermenters (Guerrero et al., 2012), and glycerol requires a longer than commonly used anaerobic contact to facilitate glycerol fermentation to acetate and propionate (Puig et al., 2008).

Fermentation of Activated Sludge Mixed Liquor. Fermentation of activated sludge mixed liquor has also promoted EBPR, and was the basis of the Phostrip process proposed in 1965 (Levin and Shapiro, 1965). In that process, thickener supernatant was removed for chemical treatment of the released phosphorus, and the mixed liquor is returned to the mainstream treatment for phosphorus uptake in the aerobic zone. However, Barnard et al. (2011) have reported effective EBPR removals with activated sludge fermentation without the Phostrip process. Fermentation of about 7 percent of the return activated sludge flow in anaerobic reactors at 35 to 50 h retention times has resulted in effective EBPR in a number of facilities in Denmark and England.

Solids Retention Time. Enhanced biological phosphorus-removal efficiency is affected by the activated sludge process type, the design SRT, and the influent wastewater characteristics (Randall et al., 1992). A sufficient aerobic SRT is needed for P uptake for an effective EBPR system. An SRT of ≥ 2.5 d is needed at 20°C and ≥ 4.0 d at 10°C. Biological nutrient-removal systems with longer SRTs are less efficient for EBPR than shorter SRT designs. Two adverse effects on phosphorus removal efficiency are associated with lightly loaded, long SRT processes. First, at longer SRT values more endogenous decay occurs and the amount of PAO biomass produced and wasted is less, with a proportional reduction in P removal. Second, at long SRT values the PAOs are in a more extended endogenous phase, which will deplete more of their intracellular storage products. If the intracellular glycogen is depleted, less efficient acetate uptake and PHA storage will occur in the anaerobic contact zone, thus making the overall EBPR process less efficient (Stephens and Stensel, 1998). Operation at an SRT just past that needed for nitrification appears to be the most optimal SRT for best EBPR performance (Oldham and Stevens, 1985).

Aerobic Zone and Aeration Design. The aeration zone configuration and DO concentration affects EBPR phosphorus uptake efficiency and effluent soluble P concentrations. A DO concentration ≥ 1.5 mg/L is needed in the 1st stage of a staged aerobic zone or the P removal efficiency will be compromised (Narayanan et al., 2011). Higher phosphorus removal efficiency occurs with staged aerobic zones compared to a single aerobic reactor tank due to the first-order reaction kinetics of phosphorus uptake (Petersen et al., 1998). The phosphorus uptake rate is a function of the stored PHA concentration, bulk liquid DO and PO_4 concentrations, and PAO biomass concentration.

A staged aerobic reactor has higher stored PHA and PO_4 concentrations in the upstream stages which will then have faster phosphorus uptake rates leading to much lower PO_4 concentrations in the final stage. The rate of PO_4 uptake is typically modeled with an expression such as given by Eq. (8–79):

$$R_p = q_{pp}\left(\frac{S_{O_2}}{K_{O_2} + S_{O_2}}\right)\left(\frac{S_{PO_4}}{K_{PO_4} + S_{PO_4}}\right)\left[\frac{X_{PHA}/X_{PAO}}{K_{PHA} + (X_{PHA}/X_{PAO})}\right]\left[\frac{K_{max} - (X_{pp}/X_{PAO})}{K_{ipp} + K_{max} - (X_{pp}/X_{PAO})}\right]X_{PAO} \tag{8–79}$$

where R_p = rate of PO_4 uptake, g/m^3·d
q_{pp} = maximum PO_4 uptake rate, g/m^3·d
S_{O_2} = DO concentration, g/m^3
K_{O_2}, K_{PO_4}, K_{PHA} = half-velocity coefficients, g/m^3
S_{PO_4} = PO_4 concentration, g/m^3
X_{PHA} = stored PHA concentration, g/m^3
X_{PAO} = phosphorus accumulating organisms concentration, g/m^3
X_{pp} = stored phosphorus concentration in PAOs, g/m^3
K_{max} = maximum specific phosphorus storage in PAOs, g/g
K_{ipp} = unreleasable inert phosphorus in PAOs, g/g

Operational Factors That Affect Enhanced Biological Phosphorus Removal

In addition to the influent wastewater characteristics and the other factors discussed above, there are a number of operational factors that can affect the performance of EBPR processes including the impact of nitrate and oxygen addition to the contact zone, the sludge wasting process, and the process alkalinity and pH. These factors are considered in the following discussion.

Effect of Nitrate and Oxygen Addition to Anaerobic Contact Zone. Nitrate and DO in upstream and recycle flows to the anaerobic contact zone must be avoided where possible. Filter backwash recycle flows contain DO and should be sent to the aerobic zone instead of the anaerobic or anoxic zones. Recycle streams with significant concentrations of DO and nitrate can have an adverse impact on process performance. Other heterotrophic bacteria, as noted previously, can consume rbCOD in the anaerobic contact zone using DO or NO_3-N for electron acceptors, leaving less rbCOD to support growth of PAOs for effective EBPR performance.

The amount of rbCOD consumed by NO_3-N and DO entering the anaerobic contact zone can be determined from Eqs. (7–127) and (7–129), in which the synthesis yield is used in place of the net yield. The synthesis yield given in Table 8–14 is 0.45 g VSS/g COD with oxygen as the electron acceptor. With nitrate as the electron acceptor, it is estimated at 70 percent of that with oxygen (Muller et al., 2003) or 0.32 g VSS/g COD. Thus, the ratio of rbCOD consumed to nitrate-nitrogen or oxygen made available in the anaerobic contact zone is shown as follows:

Nitrate: (Eq. 7–127)

$$\frac{\text{g rbCOD}}{\text{g NO}_3\text{-N}} = \frac{2.86}{1 - 1.42(0.32 \text{ g VSS/g COD})} = 5.2$$

Oxygen: (Eq. 7–129)

$$\frac{\text{g rbCOD}}{\text{g O}_2} = \frac{1}{1 - 1.42(0.45 \text{ g VSS/g COD})} = 2.8$$

Based on the above rbCOD/NO_3-N and rbCOD/DO ratios, the impact of DO and nitrate fed into the anaerobic contact zone on the EBPR performance can be evaluated. The rbCOD in the influent wastewater added to the anaerobic zone will most likely be removed by bacteria using oxygen and nitrate before it is available for biological phosphorus removal.

Waste Sludge Processing. Because phosphorus is contained in the sludge wasted from EBPR processes, consideration must be given to the waste sludge processing methods and the potential to recycle excessive amounts of phosphorus back to the EBPR process. Further, it has been found that anaerobic digester biosolids from waste sludge from EBPR systems exhibit poorer dewatering properties including lower cake solids and higher polymer use. The cause of the dewatering problems may be related to an increase in the ratio of monovalent to divalent cations as reported by Murthy et al. (1998). In EBPR digester sludge the ratio of monovalent to divalent cations can increase because there is a higher proportion of potassium as compared to calcium and magnesium with PAO phosphorus release under anaerobic conditions.

Impact of Anaerobic Conditions. In the review of the EBPR mechanism in Chap. 7, it was noted that phosphorus is released when the bacteria that contain stored phosphorus are subject to anaerobic conditions. Thus, anaerobic conditions in thickening and/or digestion can result in the release of significant amounts of phosphorus. The recycle stream from these processes would, in essence, increase the influent phosphorus concentration so that a greater amount of influent rbCOD is needed to produce the same effluent phosphorus concentration that would have been possible without the recycle stream. An additional problem is that solids dewatering may occur on an intermittent schedule with the release of large slugs of phosphorus in the recycle stream. Strategies for controlling the effect of recycled streams on EBPR performance include (1) select waste sludge processing methods that have minimal phosphorus release, (2) manage the return flow loadings by flow and load equalization, (3) use chemicals for phosphorus removal by precipitation and (4) use a phosphorus recovery process on anaerobic digester centrate/filtrate (struvite recovery processes are discussed in Chaps. 6 and 15).

Minimizing Phosphorus Release. Thickening of waste sludge by dissolved air flotation, gravity belt thickeners, or rotary-drum thickeners is preferred over gravity thickening of waste sludge to minimize phosphorus release. Phosphorus release occurs as biological solids are destroyed in anaerobic and aerobic digestion processes but only 20 to 40 percent of the phosphorus contained in the waste sludge has been observed in return streams. Not all of the phosphorus taken up is released and the formation of phosphorus precipitates, such as struvite and brushnite, has been credited with keeping phosphorus at lower concentrations. Phosphorus recovery technology is of interest to not only minimize the phosphorus content of return flows but to provide for reuse of a finite resource. Direct land application of liquid, digested sludge or dewatered raw sludge followed by stabilization such as composting also minimizes recycled phosphorus loads.

Alkalinity and pH. As described in Chap. 7 (Sec. 7–13) pH values greater than 7.0 can favor PAO dominance in their competition with GAOs for the acetate provided by the influent wastewater and that produced in the anaerobic contact tank. To assure that a favorable pH is available for efficient EBPR performance, an alkalinity balance, accounting for the influent alkalinity concentration, alkalinity consumed by nitrification, and alkalinity produced by denitrification, should be done. Alkalinity addition may be considered, especially for operating temperatures between 20 and 30°C, where GAOs are more competitive.

Enhanced Biological Phosphorus Removal Process Design

Key elements of process design for EBPR beyond what is involved for nitrogen removal are the anaerobic contact time, the aerobic SRT, configuration, DO concentration, and the amount of rbCOD available phosphorus uptake and removal by the PAOs. The first two items have been addressed above and in Sec. 8–7 for nitrogen removal. The importance of rbCOD and the effect of NO_3-N on phosphorus removal are illustrated in Example 8–13.

EXAMPLE 8–13 **Effect of Nitrate on Enhanced Biological Phosphorus Removal** An A^2O biological nutrient-removal process receives wastewater with the characteristics shown below. The system is operated at an 8-d SRT. The RAS recycle ratio, R, is 0.5. The anaerobic contact detention time is 0.75 h. Estimate the effluent soluble phosphorus concentration and the percent phosphorus content of the waste sludge if (a) the RAS contains 6.0 mg/L NO_3-N and (b) if a JHB EBPR process configuration is used and the RAS contains only 0.30 mg/L NO_3-N.

Design conditions and assumptions:

1. Wastewater characteristics:

Item	Unit	Value
Flowrate	m^3/d	4000
Total BOD	g/m^3	160
bCOD	g/m^3	250
rbCOD	g/m^3	75
Acetate	g/m^3	15
nbVSS	g/m^3	20
Inorganic inert matter	g/m^3	10
TKN	g/m^3	35
Phosphorus	g/m^3	6
Temperature	°C	12

Note: g/m^3 = mg/L.

2. rbCOD/ NO_3-N ratio = 5.2 g rbCOD/g NO_3-N
3. Phosphorus content of other heterotrophic biomass = 0.015 g P/g biomass
4. Nitrate oxidized (NO_x) = 28 g/m^3
5. Use coefficients from Table 8–14.

Solution, Part A—NO_3-N = 6.0 mg/L

1. Determine the rbCOD available for enhanced biological phosphorus removal.
   a. rbCOD in influent.

$$Q(\text{rbCOD}) = (4000\ \text{m}^3/\text{d})(75\ \text{g/m}^3) = 300{,}000\ \text{g/d}$$

   b. rbCOD consumed by nitrate.

   NO_3-N fed to the anaerobic contact zone

$$RQ(\text{NO}_3\text{-N}) = 0.50(4000\ \text{m}^3/\text{d})(6.0\ \text{g NO}_3\text{-N/m}^3) = 12{,}000\ \text{g NO}_3\text{-N/d}$$

$$\text{rbCOD used by NO}_3\text{-N} = (5.2\ \text{g rbCOD/g NO}_3\text{-N})(12{,}000\ \text{g NO}_3\text{-N/d})$$

$$= 62{,}400\ \text{g rbCOD/d}$$

   c. rbCOD available = (300,000 − 62,400) g rbCOD/d = 237,600 g/d
2. Determine phosphorus removal by EBPR.
   Use Fig. 8–38 to determine the rbCOD/P removal ratio.
   a. Determine the influent VFA/rbCOD ratio.

$$\frac{\text{VFA}}{\text{rbCOD}} = \frac{(15\ \text{g/m}^3)}{(75\ \text{g/m}^3)} = 0.20$$

   b. From Fig. 8–38 at VFA/rbCOD = 0.20, the rbCOD/P removal = 15.0
   c. P removal by EBPR.

$$\text{P removal} = \frac{\text{rbCOD}}{\text{rbCOD/P}}$$

   rbCOD available normalized to influent flow:

$$\text{rbCOD} = \frac{(237{,}600\ \text{g/d})}{(4000\ \text{m}^3/\text{d})} = 59.4\ \text{g/m}^3$$

$$\text{P removal} = \frac{(59.4\ \text{g rbCOD/m}^3)}{(15.0\ \text{g rbCOD/g P})} = 4.0\ \text{g/m}^3$$

3. Determine P removal by other heterotrophic bacteria for synthesis.
   a. Biomass production [Eq. (8–20), Table 10].

$$P_{x,\text{bio}} = \frac{QY_\text{H}(S_o - S)}{1 + b_\text{H}(\text{SRT})} + \frac{(f_d)(b_\text{H})QY_\text{H}(S_o - S)\text{SRT}}{1 + b_\text{H}(\text{SRT})} + \frac{Q(Y_n)(\text{NO}_x)}{1 + b_n\,(\text{SRT})}$$

   Assume $S_o - S \sim S_o$

   From Table 8–14,

   $Y_\text{H} = 0.45$ g VSS/g COD, $b_\text{H} = 0.12$ g/g·d at 20°C,
   $f_d = 0.15$ g/g, $Y_n = 0.15$ g VSS/g NO_x, $b_n = 0.17$ g/g·d at 20°C

Correct b for 12°C [Eq. 2–25, Table 8–10]

$$b_{\mathrm{H,12°C}} = b_{\mathrm{H,20}}(1.04)^{\mathrm{T-20}}$$

$$b_{\mathrm{H,12°C}} = 0.12(1.04)^{12-20} = 0.088\ \mathrm{g/g{\cdot}d}$$

$$b_{n,\mathrm{12°C}} = 0.17(1.029)^{12-20} = 0.135\ \mathrm{g/g{\cdot}d}$$

$$P_{x,\mathrm{bio}} = \frac{(4000\ \mathrm{m^3/d})(0.45\ \mathrm{g\ VSS/g\ COD})(250\ \mathrm{g\ COD/m^3})}{[1 + (0.088\ \mathrm{g/g{\cdot}d})(8\ \mathrm{d})]}$$

$$+ \frac{(0.15\ \mathrm{g/g})(0.088\ \mathrm{g/g{\cdot}d})(4000\ \mathrm{m^3/d})(0.45\ \mathrm{g\ VSS/g\ COD})(250\ \mathrm{g\ COD/m^3})(8\ \mathrm{d})}{[1 + (0.088\ \mathrm{g/g{\cdot}d})(8\ \mathrm{d})]}$$

$$+ \frac{(4000\ \mathrm{m^3/d})(0.15\ \mathrm{g\ VSS/g\ NO}_x\text{-N})(28\ \mathrm{g/m^3})}{[1 + (0.135\ \mathrm{g/g{\cdot}d})(8\ \mathrm{d})]}$$

$$P_{x,\mathrm{bio}} = 264{,}085\ \mathrm{g\ VSS/d} + 61{,}972\ \mathrm{g\ VSS/d} + 8077\ \mathrm{g\ VSS/d} = 334{,}134\ \mathrm{g\ VSS/d}$$

P removal (synthesis) = 0.015 $P_{x,\mathrm{bio}}$

P removal by synthesis = (0.015 g P/g VSS)(334,134 g VSS/d) = 5012 g P/d

$$\text{Normalized to } Q\text{, P removal} = \frac{(5012\ \mathrm{g\ P/d})}{(4000\ \mathrm{m^3/d})} = 1.2\ \mathrm{g/m^3}$$

4. Effluent P = Influent P − P_{EBPR} − $P_{\mathrm{synthesis}}$

   Effluent P = 6.0 g/m^3 − 4.0 g/m^3 − 1.2 g/m^3 = 0.80 g/m^3

5. Determine P content of waste sludge.
   a. Determine total sludge production using Eq. (8–21), Table 8–10.

$$P_{x,\mathrm{TSS}} = \frac{P_{x,\mathrm{bio}}}{0.85} + \frac{P_{x,\mathrm{AOB}}}{0.85} + Q(\mathrm{nbVSS}) + Q(\mathrm{TSS}_o - \mathrm{VSS}_o)$$

$$= \frac{(334{,}134\ \mathrm{g/d})}{0.85} + (4000\ \mathrm{m^3/d})(20\ \mathrm{g/m^3}) + (4000\ \mathrm{m^3/d})(10\ \mathrm{g/m^3})$$

$$= 433{,}099\mathrm{g/d}$$

   b. P removal = (6.0 − 0.8) g/m^3 (4000 m^3/d) = 20,800 g/d

$$\text{c. P in waste sludge, \%} = \frac{(20{,}800\ \mathrm{g/d})(100)}{(433{,}099\ \mathrm{g/d})} = 4.8\%$$

Solution, Part B—
NO_3-N = 0.3 g/m^3

1. Determine rbCOD available for enhanced biological phosphorus removal.
   a. rbCOD used by NO_3-N (proportion amount of rbCOD used for 0.30 g/m^3 to that for 6.0 g/m^3)

$$\text{rbCOD used by NO}_3\text{-N} = \frac{(0.3\ \mathrm{g/m^3})}{(6.0\ \mathrm{g/m^3})}(62{,}400\ \mathrm{g\ rbCOD/d}) = 3120\ \mathrm{g\ rbCOD/d}$$

   b. rbCOD available for enhanced biological phosphorus removal

   rbCOD available = (300,000 − 3120)g/d = 296,880 g rbCOD/d

2. Determine phosphorus removal by EBPR.
   a. rbCOD : P ratio = 15.0

   b. $$\text{rbCOD available} = \frac{(296{,}880 \text{ g rbCOD/d})}{(4000 \text{ m}^3\text{/d})} = 74.2 \text{ g rbCOD/m}^3$$

   c. P removal by EBPR

   $$P_{\text{removal}} = \frac{(74.2 \text{ g rbCOD/m}^3)}{(15.0 \text{ g rbCOD/g P})} = 4.9 \text{ g/m}^3$$

3. Estimated total P removal by EBPR + Synthesis.

   $$P_{\text{removal}} = 4.9 \text{ g/m}^3 + 1.2 \text{ g/m}^3 = 6.1 \text{ g/m}^3$$

   Note: The computed value exceeds the influent P concentration. The EBPR process will be kinetically limited for P uptake in the aerobic zone at a low P concentration that will occur. Depending on the aerobic tank design the effluent P concentration could be in the range of 0.10 to 0.30 mg/L.

Provision for Chemical Addition

Facility designs for EBPR should include provisions for phosphorus removal by chemical precipitation with alum or iron salts (See Chap. 6) in addition to that by PAOs. Chemical addition may be necessary (1) to meet strict effluent discharge phosphorus limits below that possible by EBPR, (2) to provide process reliability in the event of expected or unexpected conditions that reduce EBPR performance, and (3) for applications where the influent wastewater rbCOD/P ratio is not sufficient to provide the amount of phosphorus removal required. For the latter case, the cost of using chemical precipitation, primary sludge fermentation, return activated sludge fermentation or purchase of external carbon should be compared.

Metal Salt Addition. Extremely low effluent phosphorus concentrations of less than 0.05 mg/L have been achieved for EBPR processes with the addition of metal salts. Metal salts can be added to anaerobic, anoxic or aerobic tanks within an EBPR system, but over dosing can result in a less efficient EBPR performance. Lower EBPR removal could lead to incremental increases in the chemical dose, such that eventually most of the P removal is by chemical precipitation. If too much phosphorus is removed in the mixed liquor by chemical precipitation, less phosphorus is taken up by PAOs in the aerobic zone, which then decreases the amount of stored polyphosphates available for VFA uptake in the anaerobic zone and results in less PAO growth and removal by EBPR. To reach very low effluent P concentrations (i.e., less than 0.10 mg/L) metal salts should be added in a polishing final separate stage after the anaerobic release zone and aerobic P uptake zone. For activated sludge/secondary clarifier systems it can be added just before the clarifier step or in tertiary filtration. For an MBR system it should be added to the membrane separation zone or in a contact tank just before that zone. The addition of alum to an EBPR MBR system can result in less membrane fouling (Johannessen et al., 2005).

Chemical Addition to Primary Sedimentation. Alum or iron salts may be added to remove phosphorus in primary sedimentation prior to the EBPR system, so that minimal effluent P concentrations can be achieved by having a higher rbCOD/P ratio for the EBPR process. However, this approach has the potential of removing too much phosphorus in the primary treatment step which will result in poor performance for nitrogen and phosphorus removal in the secondary treatment step, and thus requires careful operation and control. In some situations, iron salts may be preferred over alum salts for primary treatment applications because they have the additional advantage of removing sulfide to help reduce odors.

Process Control and Performance Optimization

Process performance is affected by a number of operating conditions including (1) process SRT, (2) nitrate-removal efficiency in processes in which nitrification occurs, (3) control of dissolved oxygen and nitrate entering the anaerobic zone, (4) DO concentration in the aerobic zone, (5) phosphorus in recycle streams, (6) the amount of rbCOD and VFA available, and (7) the system effluent suspended solids concentration.

For nitrification systems, an SRT as close to the needed for nitrification will provide higher EBPR efficiency. The addition of DO and nitrate to the anaerobic contact zone must be avoided or minimized. In some cases, for activated sludge/secondary clarifier nitrification systems, it may be possible to control the secondary clarifier sludge blanket level to remove nitrate from the return activated sludge. It must be done with careful operation control and experience; if the sludge blanket is too high, secondary P release could follow the complete removal of nitrate or more solids may escape with the effluent.

Operating methods to increase available rbCOD and VFA can improve EBPR performance. Internal VFA generation by activated sludge and influent particulate fermentation has been demonstrated with improved performance at the Pinery Water, CO and Henderson, NV EBPR facilities by turning off mixers in anaerobic contact zones to allow a greater solids residence time for fermentation. The mixers are turned on 10–20 min each day (Barnard et al., 2011). Effluent soluble P concentrations of less than 0.50 and 0.10, respectively, were reported.

As discussed under Process Design Considerations, recycle streams from sludge thickening or digestion processes may contain high phosphorus concentrations. Equalization and control of the recycle flow and phosphorus load with time may help to minimize the impact of the recycled phosphorus on effluent quality. By adding the recycle streams during times of the day when the influent wastewater strength is higher may allow for the removal of recycled phosphorus in the waste sludge. Recycle streams may also be treated separately with chemical addition to minimize the phosphorus load to the liquid treatment process (see Chap. 15).

Effluent Suspended Solids. The phosphorus content in the mixed-liquor solids is greater than that from the conventional activated sludge process due to the biological phosphorus storage. The phosphorus content, on a dry solids basis, may be in the range of 3 to 6 percent (Randall et al., 1992). Thus, the total phosphorus concentration in the effluent can be affected significantly by the system effluent TSS concentration. At 3 to 6 percent phosphorus in the solids, the phosphorus contribution in an effluent having a TSS concentration of 10 mg/L would be 0.3 to 0.6 mg/L. Fortunately, the biosolids from most EBPR processes settle well with secondary clarifier effluent TSS concentrations of 10 mg/L or less. To provide very low effluent phosphorus concentrations, effluent filtration or membrane separation is needed.

8–9 AERATION TANK DESIGN FOR ACTIVATED SLUDGE PROCESSES

The selection and design of the aeration equipment and aeration tank design is of critical importance in the implementation of the activated sludge processes used with secondary clarifiers or membrane separation systems. Aeration system and aeration tank and appurtenances design considerations are considered in this section.

Aeration System

The aeration system design for the activated sludge process must be adequate to (1) satisfy the oxygen demand for the biological oxidation of the bCOD in the wastewater, (2) satisfy the oxygen demand due to the endogenous respiration of the biomass, (3) meet the oxygen demand for biological nitrification, (4) provide adequate mixing within the reactor, and (5) maintain a minimum dissolved oxygen concentration throughout the aeration tank. If the oxygen transfer efficiency of the aeration system is known or can be estimated, the actual air requirements for diffused air aeration or installed power of mechanical surface aerators may be determined. The characteristics of air diffusers and the energy requirements for mixing for diffused air and mechanical aeration systems are discussed in Sec. 5–12 in Chap. 5. An important issue considered in this section is the effect of the activated sludge process design on the oxygen transfer efficiency in mixed liquor.

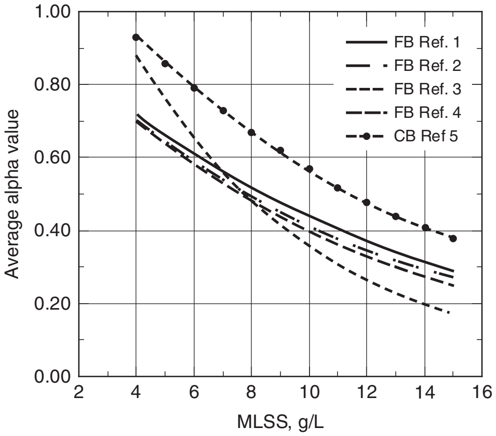
Alpha Factor for Activated Sludge Process with Clarifiers. Aeration design for activated sludge processes involves using clean water oxygen transfer performance data for aeration equipment and adjusting the oxygen transfer rates at the same diffuser air flow or mechanical aerator kW output for the effect of mixed liquor operating conditions. One of the most important factors in the mixed liquor correction is the effect that the mixed liquor has on the aeration design alpha factor. The alpha factor is defined as the ratio of the oxygen transfer rate in mixed liquor to that in clean water. In mixed liquor, the alpha is less than 1.0 due to the effect of surfactants and organic contaminants on gas-liquid mass transfer and the effects of viscosity. The surfactant and organic contaminant concentrations decrease as the SRT is increased due to biodegradation. A range of alpha values for activated sludge/secondary clarifier systems as a function of SRT has been presented by Rosso et al. (2005b) after evaluating oxygen transfer test data for 30 facilities in the United States for fine bubble aeration. Average alpha values increased from about 0.53 to 0.60 to 0.65 as the SRT was increased from 10 to 20 to 30 d.

Alpha Factor for Membrane Bioreactors. The alpha values for fine bubble aeration in MBR systems are further affected by the increased viscosity caused by the higher MLSS concentration. The effect of MLSS concentration on alpha values is shown on Fig. 8–40 for four reports with fine bubble diffused aeration and one report with coarse bubble diffused aeration. The references and correlations of alpha as a function of MLSS concentration are listed in Table 8–32. Approximate alpha values for fine bubble diffusers in MBR aeration tanks are 0.47 at an MLSS concentration of 8000 mg/L and 0.35 for an MLSS concentration of 12,000 mg/L.

Modeling Peak Oxygen Demand. Activated sludge simulation models can include the effects of diurnal changes in flowrate and influent bCOD and TKN concentrations in determining daily sustained peak oxygen demands for different reactor configurations. Experience and engineering judgment can also be used to estimate oxygen demand at peak load conditions as well as design for average oxygen demand conditions. A peaking

Figure 8–40

Effect of MLSS concentration on diffused aeration alpha values in MBR systems. References are given in Table 8–32.



factor of at least 1.5 to 2.0 times the average BOD and TKN load should be used. Aeration equipment may also be sized based on a residual dissolved oxygen (DO) of 2 mg/L in the aeration tank at the average load and 1.0 mg/L at peak load. The aeration equipment must be designed with enough flexibility to (1) meet minimum oxygen demands, (2) prevent excessive aeration and save energy, and (3) meet maximum oxygen demands. Consideration of using multiple smaller blowers to meet minimum oxygen demand is often needed so that the system is not over-aerated and energy wasted at low loads. Excessive aeration can harm biological nutrient removal process performance. The impact of the use of blowers with adjustable guide vanes and variable speed drives on the energy requirements for aeration is considered in Sec. 17–8 in Chap. 17.

Aeration Tanks and Appurtenances

After the activated sludge process and the aeration system have been selected and a preliminary design has been prepared, the next step is to design the aeration tanks and support facilities. The following design aspects are considered in the following discussion (1) aeration tanks, (2) flow distribution, and (3) froth control systems. Energy requirements for aeration tank mixing are discussed in Sec. 5–12 in Chap. 5.

Aeration Tanks. Aeration tanks usually are constructed of reinforced concrete and left open to the atmosphere. The use of rectangular or square shapes permits common-wall construction for multiple tanks. The total required volumetric capacity of the tank is

determined from the biological process design, as set forth in Secs. 8–6, 8–7, and 8–8. For plants in a capacity range of 0.22 to 0.44 m^3/s (5 to 10 Mgal/d), at least two tanks should be provided (a minimum of two tanks is preferred for smaller plants as well, for redundancy). In the range of 0.44 to 2.2 m^3/s (10 to 50 Mgal/d), four tanks are often provided to allow operational flexibility and ease of maintenance. Large plants, over 2.2 m^3/s (50 Mgal/d) in capacity, should contain six or more tanks. Some of the largest plants have from 30 to 40 tanks arranged in several groups or batteries. Although the air bubbles dispersed in the wastewater occupy perhaps 1 percent of the total volume, no allowance is made for this in tank sizing.

Use of Diffused Air Systems. If the wastewater is to be aerated with diffused air, the geometry of the tank may significantly affect the aeration efficiency and the amount of mixing obtained [see Fig. 8–41(a) and (b)]. The depth of wastewater in the tank should be between 4.5 and 7.5 m (~15 and 25 ft) to maximize the energy efficiency of diffuser systems. Freeboard from 0.3 to 0.6 m (1 to 2 ft) above the waterline should be provided. The width of the tank in relation to its depth is important if spiral-flow mixing is used in the plug-flow configuration. The width-to-depth ratio for such tanks may vary from 1.0/1 to 2.2/1, with 1.5/1 being the most common. In large plants, the channels become quite long and sometimes exceed 150 m (~500 ft) per tank. Tanks may consist of one to four channels with round-the-end flow in multiple-channel tanks. The length-to-width ratio of each channel should be at least 5/1. Where complete-mix diffused air systems are used, the length-to-width ratio may be reduced to save construction cost.

For tanks with diffusers on both sides or in a grid or panel pattern, greater widths are permissible. The important point is to restrict the width of the tank so that "dead spots" or zones of inadequate mixing are avoided. The dimensions and proportions of each independent unit should be such as to maintain adequate velocities so that deposition of solids will

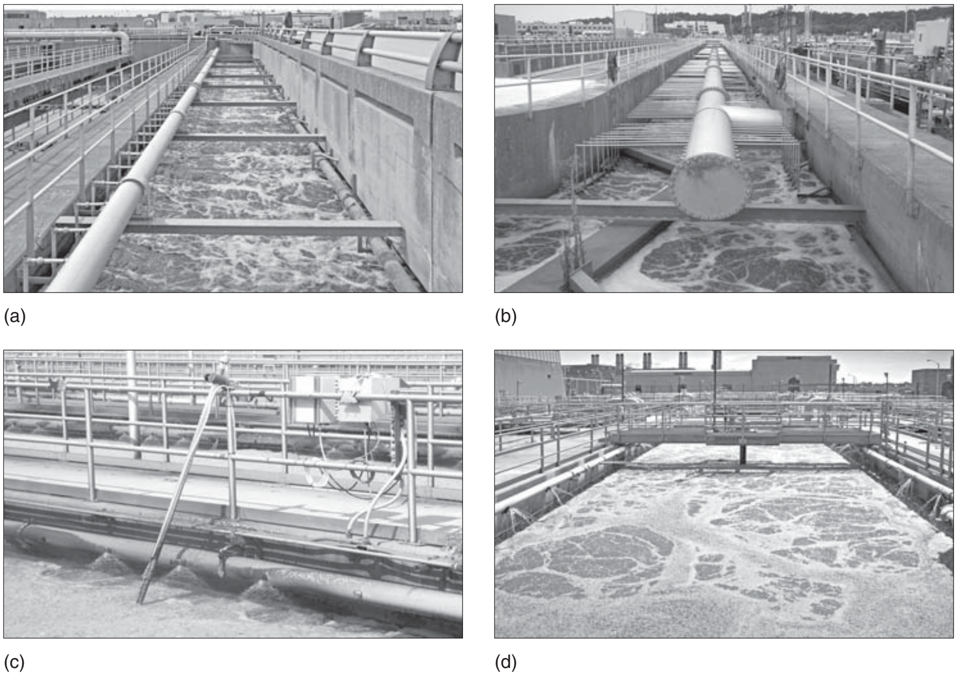
100	75	15–20	4.5–6	60–90	18–27

not occur. In spiral-flow tanks, triangular baffles or fillets may be placed longitudinally in the corners of the channels to eliminate dead spots and to deflect the spiral flow.

Use of Mechanical Aeration Systems. For mechanical aeration systems, the most efficient arrangement is one aerator per tank [see Fig. 8–41(c) and (d)]. Where multiple aerators are installed in the same tank for best efficiency, the length-to-width ratio of the tank should be in even multiples with the aerator centered in a square configuration to avoid interference at the hydraulic boundaries. The width and depth should be sized in accordance with the power rating of the aerator as illustrated in Table 8–33. Two-speed aerators are desirable to provide operating flexibility to cover a wide range of oxygen demand conditions. Freeboard of about 1 to 1.5 m (3.5 to 5 ft) should be provided for mechanical aeration systems.

Individual tanks should have inlet and outlet gates or valves so that they may be removed from service for inspection and repair. The common walls of multiple tanks must therefore be able to withstand the full hydrostatic pressure from either side. Aeration tanks must have adequate foundations to prevent settlement, and, in saturated soil, they must be designed to prevent flotation when the tanks are dewatered. Methods of preventing flotation include thickening the floor slab, installing hold-down piles, or installing hydrostatic pressure relief valves. Drains or sumps for aeration tanks are desirable for dewatering. In large plants where tank dewatering might be more common, it may be desirable to install mud valves in the bottoms of all tanks. The mud valves should be connected to a central dewatering pump or to a plant drain discharging to the wet well of the plant pumping station. Dewatering systems are commonly designed to empty a tank in 12 to 24 h.

Flow Distribution. For wastewater treatment plants containing multiple units of primary sedimentation basins and aeration tanks, consideration has to be given to equalizing the distribution of flow to the aeration tanks. In many designs, the wastewater from the primary sedimentation basins is collected in a common conduit or channel for transport to the aeration tanks. For efficient use of the aeration tanks, a method of splitting or controlling the flowrate to each of the individual tanks should be used. Methods commonly used are splitter boxes equipped with weirs or control valves or aeration tank influent control gates. Hydraulic balancing of the flow by equalizing the headloss from the primary sedimentation basins to the individual aeration tanks is also practiced. Flow regimes using a form of step feed particularly need a positive means of flow control. Where channels are used for aeration tank influent or effluent transport, they can be equipped with aeration devices to prevent deposition of solids [see Figs. 8–42(a) and (b)]. The air required ranges from 0.2 to 0.5 m^3/lin m·min (2 to 5 ft^3/lin ft·min) of channel.



(a) (b) (c) (d)

Figure 8–42

Aeration tank appurtenances: (a) and (b) views of activated sludge aerated mixed liquor transfer channels and (c) and (d) views of foam spay nozzles used to breakup and move foam to waste collection points.

Foam Control Systems. Spray nozzles are commonly mounted above the liquid surface along sides of aeration tanks to break up foaming and to help move foam into surface wasting collection points [see Figs. 8–42(c) and (d)]. During system start up or seasonal load changes foaming may develop and sprays can help move the foam back into the mixed liquor and to keep the level of foam down. Screened or filtered plant effluent is commonly pumped through the spray nozzles. Nocardioform froth is undesirable on aeration tanks and its prevention and control has been discussed previously in Sec. 8–3.

8–10 ANALYSIS OF LIQUID-SOLIDS SEPARATION FOR ACTIVATED SLUDGE PROCESSES WITH CLARIFIERS

Liquid-solids separation is critical to the operation and successful performance of the activated sludge process. Liquid-solids separation involves two very important functions (1) gravity settling to remove over 99.5 percent of the mixed liquor TSS from the treated effluent and (2) thickening of the settled activated sludge to reduce the volume before returning it to the process for mixing and treatment with the influent wastewater. In prior sections of this chapter, activated sludge treatment flow schemes for BOD removal and nitrification, biological nitrogen removal, and enhanced biological phosphorus removal have been shown using two different methods for liquid solids separation: gravity settling in secondary clarifiers and membrane separation. Liquid-solids separation by gravity settling is considered in this section. Design considerations for secondary clarifiers are considered in the following section. Membrane separation of solids is considered in Sec. 8–12.

Solids Separation by Secondary Clarifiers

The surface overflow rate and solids loading rate are the two principal parameters used for the analysis and design of secondary clarifiers. These two parameters are both dependent on the activated sludge system design and operation, which determines the mixed liquor floc characteristics and the amount of dispersed solids not captured in the floc particles during settling. Larger and denser floc particles, usually the result of having biological selectors in the activated sludge design, result in better settling and thickening and a more efficient clarifier performance.

Surface Overflow Rate. The surface overflow rate (SOR), defined as follows, is related to the time needed to allow particle separation from the effluent liquid flow.

$$\mathrm{SOR} = \frac{Q}{A} \tag{8–80}$$

where SOR = surface overflow rate, $\mathrm{m^3/m^2 \cdot d}$
Q = influent flowrate, $\mathrm{m^3/d}$
A = clarifier surface area, $\mathrm{m^2}$

Overflow rates are based on wastewater flowrates instead of on the mixed-liquor flowrates to the clarifier, which includes the influent and recycle sludge flowrates, because the overflow rate is equivalent to an upward flow velocity. The return sludge flow is drawn off the bottom of the tank and does not contribute to the upward flow velocity. Floc and small particles with settling velocities less than the SOR will be removed with the effluent from the clarifier. Floc and small particles settling velocities greater than the SOR will be removed by gravity settling.

Selection of a surface overflow rate is influenced by the effluent requirements and the need to provide consistent process performance. Typical surface overflow rates are given in Table 8–34 and range from 16 to 33 m/d (400 to 800 gal/$\mathrm{ft^2 \cdot d}$). Because steady-state

operations seldom occur due to fluctuations in wastewater flowrate, return activated sludge flowrate, and MLSS concentrations, attention to the occurrence of peak events and use of safety factors are important design considerations. If peak flowrates are of short duration, average 24-h overflow rate values may govern; if peaks are of long duration, peak overflow rate values that prevent the solids from overflowing the tank are assumed. Transient peak flows can be handled more effectively in deep clarifiers as more volume is available to accommodate the clarifier solids inventory due to the higher solids loading rate.

While the surface overflow rate has been the historical clarifier design parameter, the solids loading rate, as discussed below, is considered by some to be the limiting parameter that affects the effluent concentration. It has been shown that with proper hydraulic design and management of solids in the sedimentation tank, the overflow rate has little or no effect on the effluent quality over a wide range of overflow rates, and the design can be based on the solids loading rates (Parker et al., 2001). Based on the evaluation of secondary clarifier performance for a number of facilities, Wahlberg (1995) also found that no effect of using surface overflow rates up to 82 m/d.

Solids Loading Rate. Initially, as noted above, floc and small particles with settling velocities greater than the SOR will settle due to gravity, forming a clear water interface. As the particles continue to settle they begin to coalesce forming a thick suspension, sometimes identified as a sludge blanket. In turn, the sludge blanket undergoes thickening in the bottom portion of the clarifier. If thickening occurs at a slower rate, the amount of solids that can be applied per unit area of the clarifier is limited. The solids loading rate is a parameter used for the design of secondary clarifiers to account for thickening limitations of the secondary clarifier and is defined in Eq. (8–81). The SLR is normally expressed in SI units of kg/m^2·h and as lb/ft^2·d for English units.

$$\text{SLR} = \frac{(Q + Q_R)\text{MLSS}(1\ \text{kg}/10^3\ \text{g})}{A} \tag{8–81}$$

where SLR = solids loading rate, kg TSS/m^2·h

Q = secondary system influent flowrate, m^3/h

Q_R = return activated sludge flowrate, m^3/h

MLSS = mixed liquor suspended solids concentration in flow entering the secondary clarifier, g/m^3

A = clarifier surface area, m^2

The SLR is related to the SOR, mixed liquor suspended solids concentration and return activated sludge recycle ratio.

$$\text{SLR} = \frac{(Q + RQ)\text{MLSS}}{A} = (1 + R)(\text{SOR})(\text{MLSS}) \tag{8–82}$$

where R = return activated sludge recycle ratio = Q_R/Q

The ability to remove particulates is related to the SOR parameter and the ability to thicken the return sludge is related to the SLR parameter. The clarifier design is most often controlled by an allowable SLR, which is related to the sludge thickening properties. If sludge thickening properties decline, the SLR and MLSS concentration must be decreased. Typical SLR values as given in Table 8–34 range from 4 to 6 kg/m^2·h (0.8 to 1.2 lb/ ft^2·d).

Assessing Sludge Thickening Characteristics

At most WWTPs the thickening characteristics of activated sludge mixed liquor are monitored, on a routine basis, using the simple sludge volume index (SVI) test, introduced previously in Sec. 7–8 in Chap. 7, and by measurement of th depth of the sludge blanket in the secondary clarifier.

Sludge Volume Index (SVI). The SVI test is used to monitor any changes in mixed liquor properties as a function of operational, influent wastewater, or seasonal temperature changes. Lower SVI values are normally associated with more rapid thickening and more efficient clarifier performance. The SVI is the volume occupied by 1 g of sludge after 30 min of settling, expressed in milliliters per gram (mL/g). The SVI is determined by placing a mixed-liquor sample in a 1- to 2-L cylinder (see Fig. 8–10) and measuring the settled volume after 30 min and the corresponding sample MLSS concentration. The numerical value is computed using the following expression:

$$\text{SVI, mL/g} = \frac{(\text{settled volume of sludge, mL/L})(10^3 \text{ mg/1 g})}{(\text{suspended solids, mg/L})} \tag{8–83}$$

For example, a mixed-liquor sample with a 3000 mg/L TSS concentration that settles to a volume of 600 mL in 30 min in a 2-L cylinder would have an SVI of 100 mL/g. A value of 100 mL/g is considered a good settling sludge (SVI values below 120 are desired). SVI values above 150 are typically associated with filamentous growth (Parker et al., 2001). A 2-L settleometer is preferred over 1-L graduated cylinders to minimize wall effects on solids thickening (Keinath and Wahlberg, 1994). Alternatively a slow-speed stirring device (~ 1 rev/min) can be used in a small-diameter test apparatus (Wahlberg et al., 1988).

Because the SVI test is empirical, it is subject to significant errors. For example, if sludge with a concentration of 10,000 mg/L did not settle at all after 30 min, the SVI value would be 100. To avoid erroneous results and to allow for a meaningful comparison of SVI results for different sludges, the diluted SVI (DSVI) test has been used (Jenkins et al., 2004). In the diluted test, the sludge sample is diluted with process effluent until the settled volume after 30 min is 250 mL/L or less. The standard SVI test is then followed with this sample.

Depth of Sludge Blanket in Clarifier. Solids thickening occurs in the lower portion of a secondary clarifier before withdrawing return activated sludge. The thickening process results in a sludge depth of some distance from the bottom of the clarifier with a distinctive change in the solids concentration at the top of the thickening zone and water column. The distance from the top of the thickening zone to the bottom of the clarifier is termed the sludge blanket depth. The sludge blanket depth is affected by (1) the clarifier solids loading and sludge thickening properties, (2) rapid changes in the solids loading rate to the clarifier, (3) the return activated sludge recycle ratio, and (4) the solids wasting strategy used by the plant operator. Activated sludge with higher SVI values results in higher sludge blanket levels due to having a slower thickening flux as discussed in Sec. 8–10. Biological nutrient processes tend to have relatively low SVIs, and average sludge blanket depths of 0.30 to 0.60 m are common.

Variations in Blanket Depth. The sludge blanket depth varies with diurnal flow changes as a result of varying solids loading rates to the clarifier. Rapid increases in influent flowrates related to storm events can result in dramatic changes in solids loads to clarifiers and increases in the sludge blanket depth. Deeper clarifiers accommodate such changes better by having more depth and volume to handle a greater solids inventory, while maintaining an adequate water column depth above the sludge blanket so that the settled solids in the sludge blanket are not carried into the effluent. The use of a lower return activated sludge recycle ratio results in a thicker return sludge concentration, which requires more thickening time and a higher sludge blanket level. Higher sludge blanket levels may also be associated with an excess sludge wasting strategy that bases the sludge wasting rates on maintaining a certain sludge blanket level in the clarifier, in lieu of the more proactive SRT control methods recommended in Sec. 8–3. For facilities with multiple activated sludge/clarifier trains, a higher sludge blanket in the clarifier of one train may be indicative of uneven flow splitting between trains.

Measurement of Blanket Depth. Sludge blanket depth measurements are an important operational tool that is used to make changes in the plant operations to control the blanket as necessary to prevent solids carry over into the clarifier effluent. Adjustments in the return activated sludge recycle ratio and sludge wasting rates provide a means to control the sludge blanket depth. The clarifier sludge blanket depth is measured several times during a 24-hour period by automatic or manual methods. Automatic measurements use online instruments that are mounted in the clarifier and employ ultrasound or light techniques. The most common manual method, used at many wastewater facilities because of its simplicity and reliability, is referred to as the *Sludge Judge*. Many variations in sludge judge designs are provided by different suppliers, but in general it is a long, clear plastic tube (19- to 32-mm diameter) that is immersed into the clarifier perpendicular to the clarifier bottom (see Fig. 8–43). The bottom section of the tube has a ball valve that allows liquid in when the tube is lowered into the clarifier and seals the sample when the tube is raised from the clarifier. The tube has markings along its length, typically at 0.3 m increments, which provides a visual means of evaluating the sludge blanket depth by the operator.

Clarifier Design Based on Solids Flux Analysis

The *solids flux* and *state point* methods of analysis are now used commonly to determine clarifier sizing. Both methods of analysis are based on a consideration the sludge-settling properties and clarifier return sludge flowrate. The solids flux method is considered in the following discussion. The state point method is considered following the presentation of the solids flux method.

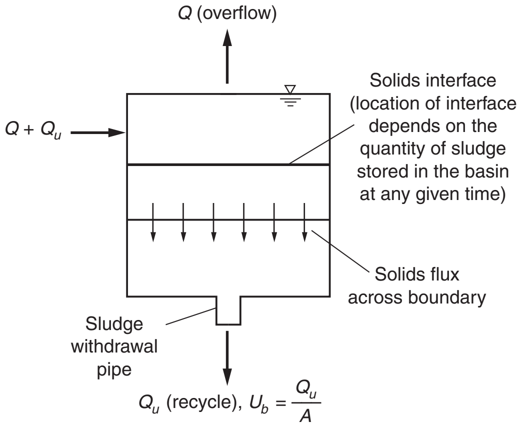
(a) (b) (c)

Figure 8–43

Views of treatment plant operators conducting sludge blanket depth measurements using a sludge judge.

Figure 8–44

Definition sketch for solids transport in a settling basin operating at steady state.



Definition of Solids Flux. Solids flux is defined as the rate of the solids mass moving downward across a unit area in the clarifier. In a settling basin that is operating at steady state, a constant flux of solids is moving downward, as shown on Fig. 8–44. Within the tank, the downward flux of solids is brought about by gravity (hindered) settling plus bulk transport due to the underflow that is being pumped out and recycled. As thickening occurs with depth, the flux due to each of these components changes. The area required for thickening of the applied mixed liquor depends on the limiting solids flux that can be transported to the bottom of the sedimentation basin. The depth of the thickening portion of the sedimentation tank must be sufficient to (1) ensure maintenance of an adequate sludge blanket depth so that unthickened solids are not recycled, and (2) temporarily store excess solids that may be applied.

Solids Flux Due to Gravity. The solids flux due to gravity is as follows:

$$\mathrm{SF_g} = C_i V_i (1\,\mathrm{kg}/10^3\,\mathrm{g}) \tag{8–84}$$

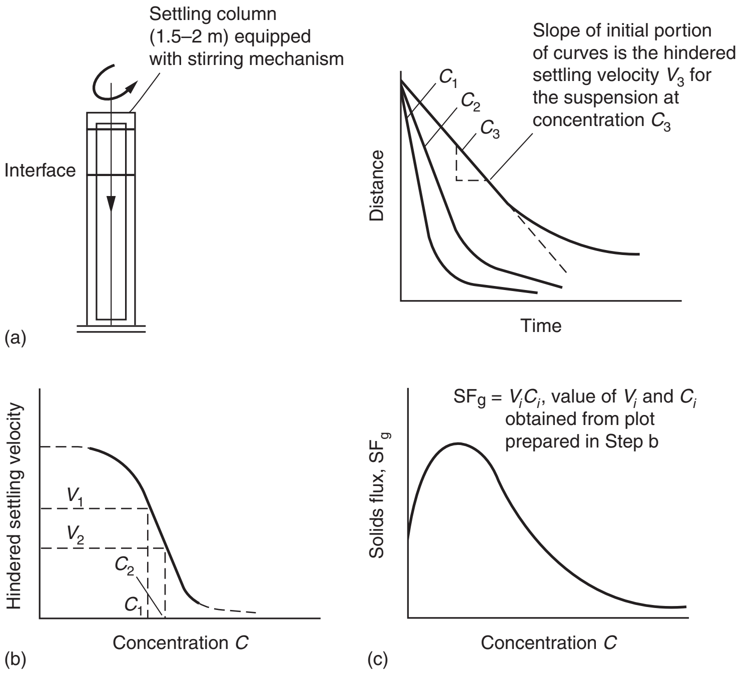
where $\mathrm{SF_g}$ = solids flux due to gravity, kg/m²·h
C_i = concentration of solids at the point in question, g/m³
V_i = initial settling velocity of the solids at concentration C_i, m/h

The flux of solids due to gravity settling depends on the concentration of solids (C_i) and the settling velocity (V_i) of the solids at that concentration. Because the solids flux due to gravity varies with the characteristics of the sludge, column settling tests are conducted to determine the relationship between the sludge concentration and the settling rate. The procedure used to develop a solids flux curve from column settling test data is illustrated on Fig. 8–45. First, a series of settling tests are done at different initial mixed liquor solids concentrations in which the initial settling velocity (V_i) is measured over a 5 to 10 min time period [see Fig. 8–45(a)]. Next, the settling velocity is plotted versus the MLSS concentration [see Fig. 8–45(b)]. The third step is to plot the solids flux as given by Eq. (8–84) versus the MLSS concentration [see Fig. 8–45(c)].

It should be noted that the initial settling velocity is also termed the *zone settling velocity* (ZSV) because an interface between a clear liquid above the sludge blanket occurs at some rate. At higher MLSS concentrations, the value for V_i will decrease. At low concentrations (below about 1000 mg/L), the movement of solids due to gravity is small, because the settling velocity of the solids is more or less independent of concentration. If the velocity remains essentially the same as the solids concentration increases, the flux due to gravity starts to increase as the solids concentration starts to increase. At higher solids concentrations, hindered settling occurs and the ZSV and gravity flux decreases. At some

Figure 8–45

Procedure for preparing a plot of solids flux due to gravity as a function of solids concentration: (a) hindered settling velocity is derived from column settling test for suspension at different concentrations, (b) plot of hindered settling velocity is obtained in step (c) versus corresponding concentration, and (d) plot of completed value of solids flux vs. corresponding concentration.



very high concentration the flux approaches zero. A typical gravity solids flux curve for an activated sludge MLSS is shown on Fig. 8–46.

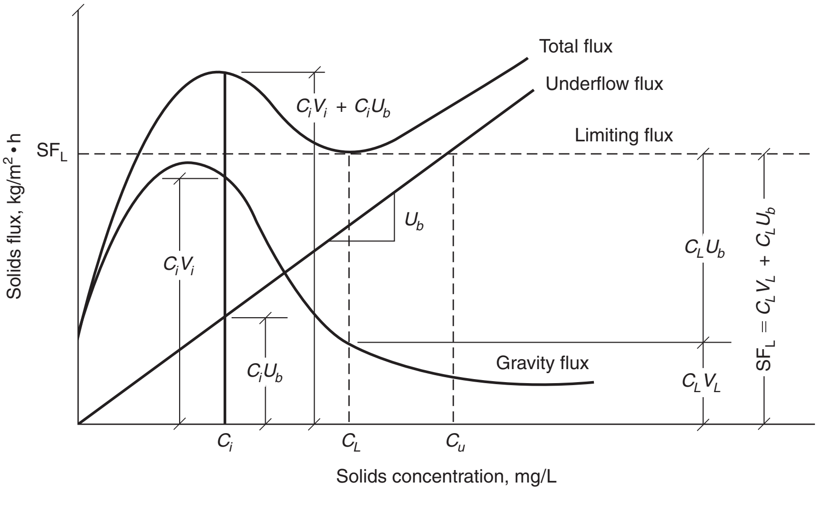
Zone Settling Velocity as a Function of MLSS and SVI. The zone settling velocity as a function of the mixed liquor concentration and SVI can be estimated using the following equation (Wilson and Lee, 1982; Wilson, 1996):

$$V_i = V_{\max} \exp[-(k/10^6)X] \qquad (8\text{–}85)$$

where V_i = settling velocity of interface, m/h
$V_{\max}$ = maximum settling velocity of interface, typically 7 m/h
K = constant, typically 600 L/mg for activated sludge mixed liquor with an SVI of 150
X = average MLSS concentration, mg/L

Figure 8–46

Definition sketch for applying the solids flux method with solids thickening data and a return sludge flowrate.



Correlations between V_i and the MLSS concentration have also been developed with SVI as an additional parameter using data from several facilities (Daigger, 1995; Wahlberg, 1995). The results of the correlations are given by the following equations in which lower zone settling velocities are computed with higher SVI values:

$$\text{In}(V_i) = 1.871 - (0.165 + 0.00159 \text{ SVI})X_T \tag{8–86}$$

$$\text{In}(V_i) = 2.082 - (0.103 + 0.00256 \text{ DSVI})X_T \tag{8–87}$$

where DSVI = diluted SVI, mL/g
X_T = MLSS concentration, g/L

The advantage of these correlations is that a solid flux analysis can be performed at a facility to estimate the clarifier capacity using easy to obtain SVI data in lieu of the extensive settling testing procedure.

Solids Flux Due to Bulk Movement. The solids flux due to the bulk movement of the suspension caused by the return sludge flow (see Fig. 8–44) is given by the following expression:

$$\text{SF}_\text{u} = C_i U_b (1\text{kg}/10^3 \text{ g}) = C_i \frac{Q_R}{A} (1 \text{ kg}/10^3 \text{ g}) \tag{8–88}$$

where SF_u = solids flux due to underflow, kg/m²·h
U_b = bulk downward velocity, m/h
Q_R = underflow flowrate, m³/h
A = cross-sectional area, m²

The solids flux due to bulk transport is a linear function of the concentration with slope equal to U_b, the underflow velocity, and is shown as the underflow flux on Fig. 8–46.

Total Solids Flux. The total solids flux SF_t, comprised of the gravity solids flux and the bulk solid flux, is given by the following expressions.

$$\text{SF}_\text{t} = \text{SF}_\text{g} + \text{SF}_\text{u} \tag{8–89}$$

$$\text{SF}_\text{t} = (C_i V_i + C_i U_b)(1 \text{ kg}/10^3 \text{ g}) \tag{8–90}$$

The total flux, as shown on Fig. 8–46, is the sum of the gravity and the underflow flux. The shape of the total flux curve follows the pattern for the gravity flux curve and decreases when hindered settling occurs as the solids get thicker. The total flux reaches a minimum value or *limiting flux* at a certain solids concentration, before increasing as the solids continue to thicken to higher concentrations. The limiting flux value is determined by drawing a horizontal line from the minimum point of the total flux curve extending to the vertical axis. The clarifier solids loading must not exceed the limiting flux or the solids will accumulate and increase the sludge blanket depth, with solids eventually spilling over into the clarifier effluent flow. The maximum allowable clarifier SLR in Eq. (8–81) is equal to the limiting solids flux.

$$\text{SLR} = \frac{(Q + Q_R)\text{MLSS}(1 \text{ kg}/10^3 \text{ g})}{A} = \text{SF}_\text{L} \tag{8–91}$$

where SF_L = limiting solid flux, kg TSS/m²·h

Using the limiting solids-flux value, the required clarifier area derived from a materials balance is given by

Based on flowrate, *Q*

$$A = \frac{(Q + Q_R)(\text{MLSS})}{\text{SF}_\text{L}}(1\ \text{kg}/10^3\ \text{g}) \qquad (8\text{–}92)$$

Based on the recycle ratio, *R*

$$A = \frac{(1 + R)(Q)(\text{MLSS})}{\text{SF}_\text{L}}(1\ \text{kg}/10^3\ \text{g}) \qquad (8\text{–}93)$$

where terms are as defined in Eqs. (8–81 and 8–82).

Return Flow Concentration. The corresponding underflow concentration (C_u) or return activated sludge concentration (X_R) is obtained by dropping a vertical line to the X axis from the intersection of the horizontal line and the underflow flux line assuming the gravity flux is negligible at the bottom of the settling basin and the solids are removed by bulk flow. The fact that the gravity flux is negligible at the bottom of the tank can be verified by performing a materials balance around the portion of the settling tank that lies below the depth where the limiting solids flux occurs and comparing the gravity settling velocity of the sludge to the velocity in the sludge withdrawal pipe.

Aeration Tank MLSS. The MLSS concentration in the aeration tank is governed by the underflow concentration which is related to the limiting solids flux and the return sludge recycle ratio. Because the sludge wasting flow is small compared to the recycle sludge flowrate, it can be ignored for the simple mass balance around the clarifier to estimate the aeration tank MLSS concentration:

$$X(Q + Q_R) = Q_R(X_R), \text{ where } X_R = C_u \qquad (8\text{–}94)$$

and

$$X = \left(\frac{R}{1 + R}\right)(X_R), \text{ where } R = \frac{Q}{Q_R} \qquad (8\text{–}95)$$

If a thicker underflow concentration is required, the slope of the underflow flux line shown on Fig. 8–46 must be reduced. The reduced slope, in turn, will lower the value of the limiting flux and increase the required settling area. In an actual design, the use of several different flowrates for the underflow should be evaluated.

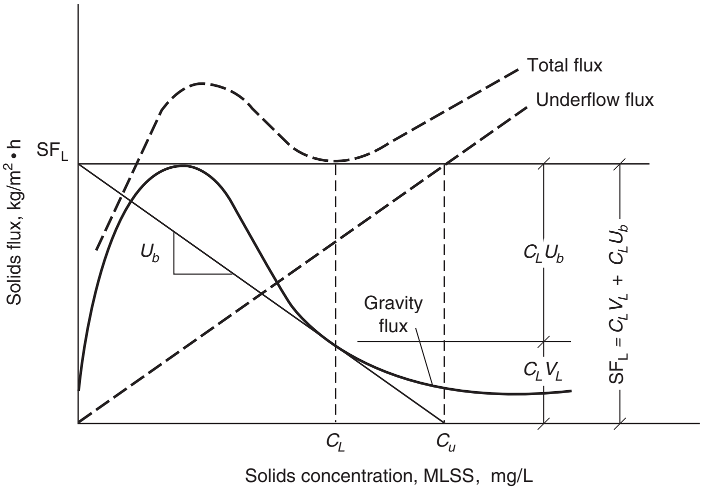
Graphical Analysis of Solid Flux. An alternative graphical method of analysis to that presented on Fig. 8–46 for determining the limiting solids flux is shown on Fig. 8–47. The graphical analysis is derived from Eq. (8–90) in which the minimal SF_t is defined where its derivative with respect to C_i equals zero:

$$\frac{\partial \text{SF}_\text{t}}{\partial C_i} = 0 = V_i - U_b \qquad (8\text{–}96)$$

Thus, as shown on Fig. 8–47, the solids concentration at the limiting solids flux is C_L and from Eq. (8–96) $C_L V_i = C_L U_b$. The value of the limiting flux on the ordinate is obtained by drawing a line tangent to the flux curve passing through the desired underflow and intersecting the ordinate. The geometric relationship of this method to that given on Fig. 8–46 is shown by the line for U_b on Fig. 8–47. The method detailed on Fig. 8–47 is especially useful where the effect of the use of various underflow concentrations on the size of the

Figure 8–47

Alternative definition sketch for determining the limiting solids flux in the solids flux method of analysis.



treatment facilities (aerator and sedimentation basin) is to be evaluated. Because the underflow velocity (return sludge flowrate) can be controlled, it is used for process control. Application of the solids flux method of analysis is illustrated in Example 8–14.

EXAMPLE 8–14 **Application of Solids Flux Analysis** Given the following settling data for a mixed liquor, derived from an anoxic/aerobic activated sludge pilot plant, estimate the maximum mixed-liquor suspended solids concentration that can be maintained in the aeration tank if the secondary clarifier surface overflow rate, Q/A, has been fixed at 24 m^3/m^2•d and the return sludge recycle rate, Q_R is equal to 75 percent of Q. The definition sketch for this problem is shown on Fig. 8–11(b). As shown, settled and thickened activated sludge from the secondary clarifier are returned to the aeration tank to maintain the desired level of mixed liquor solids. Assume that the solids wasting rate Q_w is negligible in this example.

MLSS, g/m^3	Initial settling velocity, m/h
1000	6.246
2000	3.203
3000	1.642
4000	0.842
5000	0.432
6000	0.221
7000	0.113
8000	0.058
9000	0.030
10,000	0.015
11,000	0.008
12,000	0.004
13,000	0.002
14,000	0.001

Note: g/m^3 = mg/L.

Solution

1. Set up a computation table to determine the gravity, underflow, and total solids-flux values corresponding to the given solids concentrations. Sample calculations for the required table entries are as follows.
   a. Determine the gravity solids flux as a function of the MLSS using the following relationship.

      Solids flux $= X(\text{g/m}^3)V(\text{m/h})\ (1\ \text{kg}/10^3\ \text{g})$

      For example, at $X_i = 2000\ \text{g/m}^3$,

      Solids flux $= (2000\ \text{g/m}^3)(3.203\ \text{m/h})(1\ \text{kg}/10^3\ \text{g}) = 6.41\ \text{kg/m}^2\cdot\text{h}$

   b. Determine the underflow bulk velocity.
      i. The surface loading rate on the clarifiers equals (Q/A), 24 $\text{m}^3/\text{m}^2\cdot\text{d}$ or 1.0 m/h.
      ii. The underflow velocity U_b is therefore equal to $(0.75)(24\ \text{m/h}) = 0.75\ \text{m/h}$.
   c. The underflow solids-flux is determined using the following relationship:

      $\text{SF}_\text{u} = X_i U_b (1\ \text{kg}/10^3\ \text{g})$

      where X_i = MLSS concentration, g/m^3
      U_b = bulk underflow velocity, m/h

      For example, at $X_i = 2000\ \text{g/m}^3$,

      $\text{SF}_\text{u} = (2000\ \text{g/m}^3)(0.75\ \text{m/h})(1\ \text{kg}/10^3\ \text{g}) = 1.5\ \text{kg/m}^2\cdot\text{d}$

   d. Determine the total solids-flux using Eq. (8–89).

      $\text{SF}_\text{t} = \text{SF}_\text{g} + \text{SF}_\text{u}$

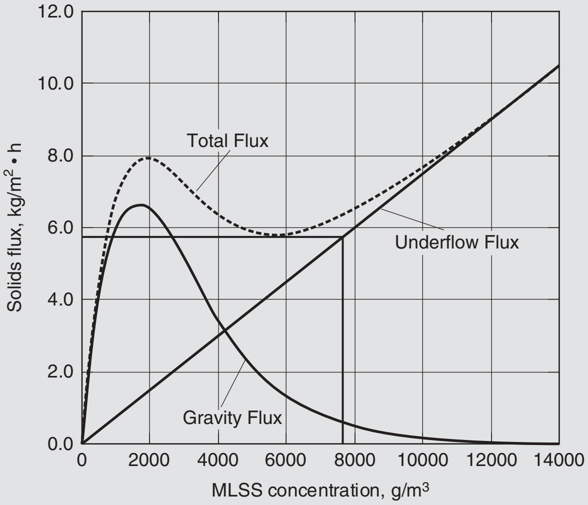
      For example, at $X_i = 2000\ \text{g/m}^3$,

      $\text{SF}_\text{t} = 6.41 + 1.50 = 7.91\ \text{kg/m}^2\cdot\text{h}$

   e. Prepare summary table of the gravity, underflow, and total solids-flux.

MLSS, g/m^3	Gravity solids flux, kg/m$^2\cdot$h	Underflow solids flux, kg/m$^2\cdot$h	Total solids flux, kg/m$^2\cdot$h
1000	6.25	0.75	7.00
2000	6.41	1.50	7.91
3000	4.93	2.25	7.18
4000	3.37	3.00	6.37
5000	2.16	3.75	5.91
6000	1.33	4.50	5.83
7000	0.79	5.25	6.04
8000	0.47	6.00	6.47
9000	0.27	6.75	7.02
10,000	0.15	7.50	7.65
11,000	0.09	8.25	8.34
12,000	0.05	9.00	9.05
13,000	0.03	9.75	9.78
14,000	0.01	10.50	10.51

2. Plot the flux curves (see following figure).



3. Determine the limiting solids flux and maximum underflow concentration.
   a. The limiting solids flux value is found by drawing a horizontal line extending to the underflow flux line, tangent to the total solids flux curve.

      From the plot in Step 2, the limiting flux at the point of tangency to the total flux curve is

      $SF_L = 5.8 \text{ kg/m}^2 \cdot \text{h}$

   b. The maximum underflow solids concentration at the intersection of the horizontal line and the underflow flux is equal to 7800 g/m^3.
4. Estimate the maximum solids concentration that can be maintained in the reactor.
   a. Write a mass balance for the system within the boundary, neglecting the rate of cell growth within the reactor. Let X_o = influent TSS to the aeration tank.

      $$QX_O + Q_R X_R = (Q + Q_R)X$$

   b. Assuming the $X_O = 0$ ($X_O << X_R$) and that $Q_R/Q = 0.75$, solve for the maximum MLSS concentration in the reactor.

      $$0.75Q(7800 \text{ g/m}^3) = (1 + 0.75)QX$$
      $$X = 3340 \text{ g/m}^3$$

Comment As shown in the above analysis, the concentration of the return solids will affect the maximum concentration of solids that can be maintained in the aeration tank. Thus, the secondary clarifier must be considered an integral part of the design of an activated sludge treatment process.

Clarifier Design Based on State Point Analysis

The state point analysis procedure extends the principles of the solids-flux analysis to provide a convenient means to assess different mixed-liquor concentrations and clarifier operating conditions relative to the limiting solids-flux operating condition (Keinath et al., 1977; Keinath, 1985).

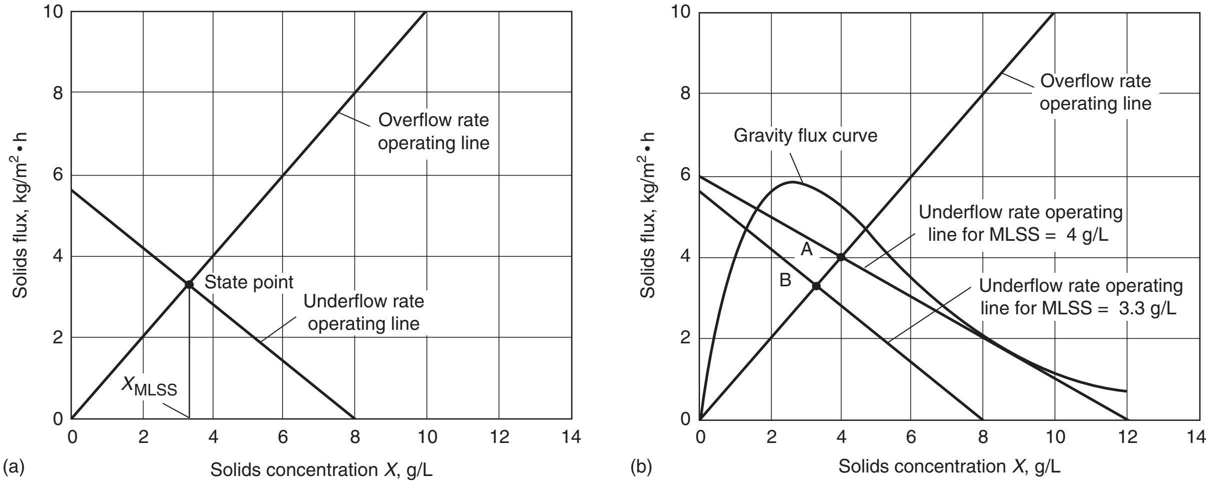


Figure 8–48

State point analysis for assessing clarifier operating conditions: (a) state point at intersection of overflow rate and underflow rate operating lines and (b) under loaded (B), and critically loaded (A) state points relative to settling flux curve.

The State Point. The state point, as shown on Fig. 8–48(a), is the intersection of the clarifier overflow solids-flux rate and underflow solids-flux rate lines. Thus, the analysis accounts for the actual mixed-liquor concentration, clarifier hydraulic application rate, return activated sludge recycle rate, and whether the combination of these operating parameters results in a condition that is within the clarifier solids-flux limitations for a sludge with specific thickening characteristics.

Overflow Solids Flux. The clarifier overflow solids flux as shown on Fig. 8–48(a) is

$$\mathrm{SF_Q} = \frac{Q(X)}{A} \tag{8–97}$$

where $\mathrm{SF_Q}$ = overflow solids-flux rate, kg/m²·d
Q = clarifier effluent flowrate, m³/d
A = clarifier cross-section area, m²
X = aeration tank MLSS concentration, g/L

The aeration tank MLSS concentration (X) at any point along the overflow solids-flux line is found by constructing a vertical line to the X axis.

Underflow Operating Line. The underflow operating line represents the negative slope of the clarifier underflow velocity as was also shown on Fig. 8–47. The intercept of the horizontal line drawn from the point of intersection of the vertical line and operating line is the total solids flux ($\mathrm{SF_X}$) to the clarifier. Evaluating the slope of the underflow flux rate line it can be shown that U_b, the bulk downward velocity, equals

$$U_b = \frac{\mathrm{SF_t} - \mathrm{SF_Q}}{0 - X_{\mathrm{MLSS}}} \tag{8–98}$$

$$U_b = \frac{[(Q + Q_R)X_{\mathrm{MLSS}}/A\,]}{-\,X_{\mathrm{MLSS}}} \tag{8–99}$$

$$U_b = -\frac{Q_R}{A} \tag{8–100}$$

The state point and underflow solids-flux line can be compared to the gravity flux curve to determine if the clarifier operation is within its solids-flux limitation [see Fig. 8–48(b)]. The underflow line at state point A is tangent to the gravity flux curve, which, as shown on Fig. 8–47, represents the limiting solids-flux condition. Thus, the clarifier is loaded critically for this underflow velocity and the MLSS concentration at the state point is equal to 4.0 g/L. If the operation is changed to obtain a higher MLSS concentration, and the underflow line crosses the lower limb of the gravity flux curve, the limiting solids flux will be exceeded and the clarifier blanket will rise to the effluent weir. At state point B on Fig. 8–48(b), a lower MLSS concentration is used and the underflow line is thus well below the lower limb of the gravity flux curve. An underloaded operation exists relative to the solids loading.

Use of the State Point Analysis. The state point analysis procedure provides a method to evaluate various clarifier overflow rates, and MLSS concentrations give a gravity flux curve that represents the activated sludge settling properties. The state point analysis technique can be used with settling tests on activated sludge mixed liquor at an existing facility to determine an optimal MLSS concentration and return sludge recycle ratio for a given influent flow condition. Application of state point analysis is illustrated in Example 8–15.

EXAMPLE 8–15 **Evaluate Secondary Clarifier Operating Conditions Using State Point Analysis** Determine acceptable operating conditions using the following solids-settling test results for one or two clarifiers in operation in an activated sludge system. The system is to be evaluated at a maximum month design flowrate of 15,070 m^3/d and the following design conditions.

Design conditions:

1. Two 20-m diameter clarifiers are to be used.
2. With both clarifiers in operation, the desired MLSS concentration is 3500 mg/L.
3. Evaluate the feasibility of operating the clarifier with underflow concentrations of 10, 12, and 14 g/L and determine the recycle ratios.
4. Determine the MLSS concentration with one clarifier in operation using an underflow solids concentration of 12 g/L.
5. Determine the solids loading to the clarifier for the 12 g/L underflow concentration and MLSS = 3500 g/m^3 for (a) two-clarifier operation and (b) one clarifier.
6. The solids settling results are:

Mixed-liquor solids concentration, g/m^3	Interfacial settling velocity, m/h
2000	2.90
3000	1.90
4000	1.30
5000	0.90
6000	0.60

(*continued*)

(*Continued*)

Mixed-liquor solids concentration, g/m^3	Interfacial settling velocity, m/h
8000	0.26
9000	0.17
10,000	0.12
12,000	0.05
16,000	0.01

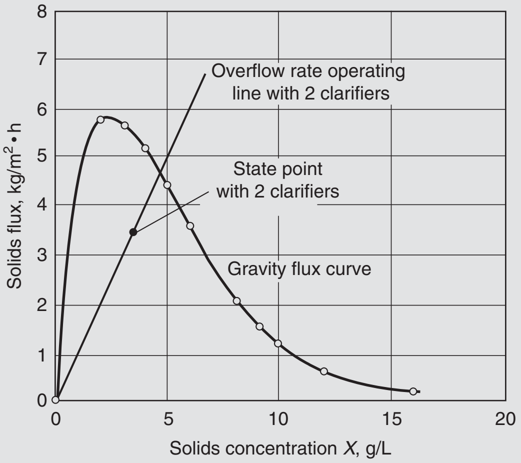
Note: g/m^3 = mg/L.

Solution

1. Develop gravity flux curve (shown below) using Eq. (8–84), $SF_g = C_iV_i$.
   a. Determine the SF_g values using the given data.

C_i, g/L	V_i, m/h	SF_g, kg/m^2·h
2.0	2.90	5.80
3.0	1.90	5.70
4.0	1.30	5.20
5.0	0.90	4.50
6.0	0.60	3.60
8.0	0.26	2.08
9.0	0.17	1.53
10.0	0.12	1.20
12.0	0.05	0.60
16.0	0.01	0.16

   b. Plot the gravity solids flux curve.



2. Add the overflow rate operating line and MLSS concentration state point at 3500 mg/L overflow solids flux rate.
   a. Determine the clarifier surface area.

$$A(\text{area/clarifier}) = \pi D^2 / 4 = \pi(20)^2 / 4 = 314\ \text{m}^2$$

$$\text{Total area (2 clarifiers)} = 2 \times 314 = 628\ \text{m}^2$$

   b. Determine the overflow rate, expressed as kg/m²·h, as a function of X using Eq. (8–97).

$$\text{SF}_\text{Q} = \frac{Q(X)}{A} = \frac{(15{,}070\ \text{m}^3/\text{d})(1\ \text{d}/24\ \text{h})(X)}{628\ \text{m}^2} = 1.0\ \text{m/h}(X)$$

For example at $X = 5000\ \text{g/m}^3$,

$$\text{SF}_\text{o} = (1.0\ \text{m/h})(5\ \text{kg/m}^3) = 5.0\ \text{kg/m}^2\cdot\text{h}$$

   c. Plot the overflow flux line on the graph developed in Part 1.
3. Plot the state point on the overflow flux line for an underflow concentration of 3500 mg/L (3.5 kg/m³).
   a. Determine the flux at the state point.

$$\text{SF}_\text{Q} = (1.0\ \text{m/h})(3.5\ \text{kg/m}^3) = 3.5\ \text{kg/m}^2\cdot\text{h}.$$

   b. Plot the state point on the overflow flux line graph (see Plot developed in Part 1).
4. Evaluate underflow conditions at 10, 12, and 14 g/L (see following figure).
   a. Analysis for an underflow concentration of 14 g/L. Draw a line that intercepts 14 g/L on the *x* axis and passes through the state point. The line intercepts the *y* axis at 4.67 kg/m²·h; however, this flux rate is not a feasible operating condition as the line crosses above the gravity flux curve. For 10 and 12 g/L underflow concentrations, the lines cross below the gravity flux curve; therefore, both concentrations are feasible.

   b. Calculate recycle ratio at 10 g/L (10 kg/m³) underflow concentration. Determine the slope of the underflow operating rate curve from the figure. The intercept on the x axis is 5.38 kg/m²·h and the slope is negative and is equal to the recycle velocity, m/h.

$$\text{Operating curve slope} = \frac{[(5.38 - 0)\text{kg/m}^2\cdot\text{h}]}{[(0 - 10)\text{g/m}^3]} = -0.538 \text{ m/h}$$

$$\text{Underflow velocity} = -(0.538 \text{ m/h}) = 0.538 \text{ m/h}$$

$$\text{Clarifier overflow rate} = \frac{(15{,}070 \text{ m}^3/\text{d})(1\text{d}/24 \text{ h})}{628 \text{ m}^2} = 1.0 \text{ m/h}$$

$$\text{Recycle ratio} = \frac{(0.538 \text{ m/h})}{(1\text{m/h})} = 0.538$$

c. Check recycle ratio at 10 g/L underflow concentration using solids balance.

$$X_R Q_R = (Q_R + Q)X$$

$$X_R R = (1 + R)X \text{ where } R = \text{recycle ratio}$$

$$R = \left(\frac{X_R}{X} - 1\right)^{-1} = \left[\frac{(10 \text{ g/L})}{(3.5 \text{ g/L})} - 1\right]^{-1}$$

$$R = 0.538$$

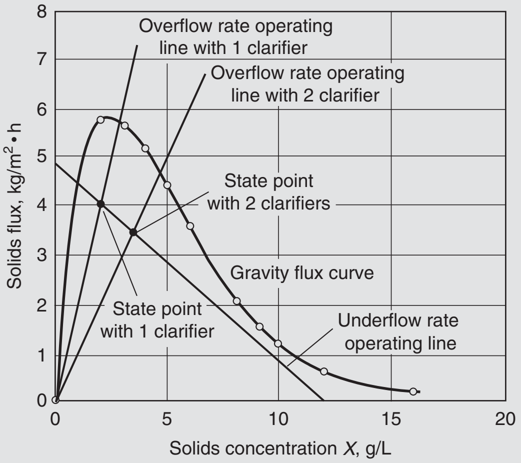
d. Calculate recycle ratio at 12 g/L (12 kg/m³) underflow concentration using the same procedure as above.

$$\text{Underflow velocity} = \frac{[(4.94 - 0) \text{ kg/m}^2\cdot\text{h}]}{[(0 - 12) \text{ g/m}^3]} = -0.4 \text{ m/h}$$

$$R = 0.41$$

5. Determine what MLSS concentration is possible with one clarifier operating and underflow solids concentration 12 g/L.

Using the gravity flux curve, draw an overflow operating rate line for one clarifier (see following figure).



For $A = 314\ \text{m}^3$ and $X = 2\ \text{g/L}$,

$$\text{SF}_Q = \frac{(15{,}070\ \text{m}^3/\text{d})(1\ \text{d}/24\ \text{h})(2\ \text{kg/m}^3)}{314\ \text{m}^2} = 4\ \text{kg/m}^2\cdot\text{h}$$

The MLSS concentration possible is the "state point" where the overflow rate operating line intersects the underflow rate operating line. In the above figure, the state point is approximately 2.1 g/L (2100 mg/L) MLSS concentration.

6. Determine clarifier solids loading.
   a. For 2 clarifiers: $A = 628\ \text{m}^2$; MLSS $= 3.5$ g/L, and $R = 0.41$

   Solids loading $= Q(1 + R)(X)/A$

   $$= \frac{(15{,}70\ \text{m}^3/\text{d})(1 + 0.41)(3.5\ \text{kg/m}^3)}{(314\ \text{m}^2)(24\ \text{h/d})} = 4.93\ \text{kg/m}^2\cdot\text{h}$$

   b. For one clarifier: $A = 314\ \text{m}^2$

   $$\text{Clarifier overflow rate} = \frac{(15{,}070\ \text{m}^3/\text{d})(1\ \text{d}/24\ \text{h})}{314\ \text{m}^2} = 2.0\ \text{m/h}$$

   Underflow velocity (from step 3d) $= 0.41$ m/h

   $R = (0.41\ \text{m/h})/(2.0\ \text{m/h}) = 0.205$

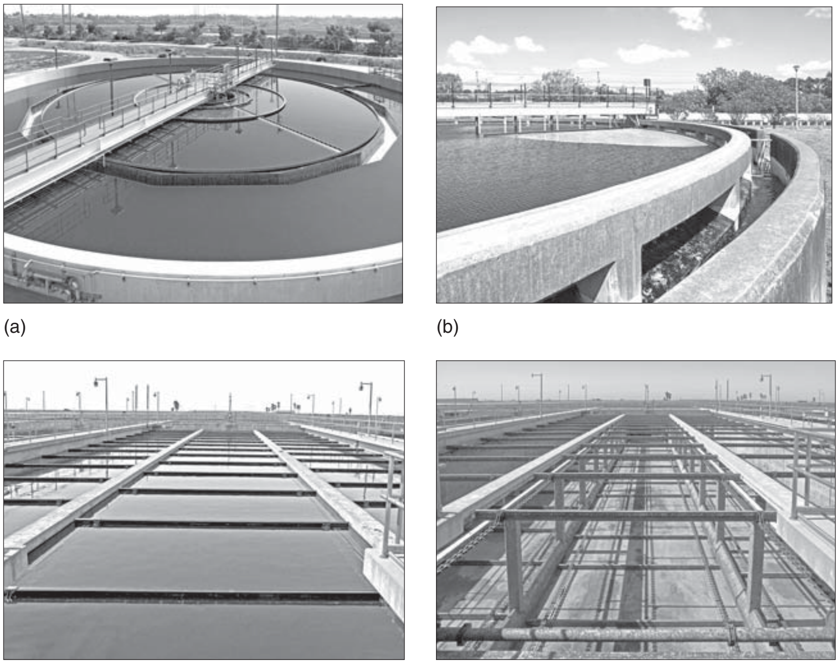
   $$\text{Solids loading} = \frac{(15{,}070\ \text{m}^3/\text{d})(1 + 0.205)(2.1\ \text{kg/m}^3)}{(314\ \text{m}^2)(24\ \text{h/d})} = 5.06\ \text{kg/m}^2\cdot\text{h}$$

8–11 DESIGN CONSIDERATIONS FOR SECONDARY CLARIFIERS

Solids separation is the final step in the production of a well-clarified, stable effluent low in BOD and TSS and, as such, represents a critical link in the operation of an activated sludge treatment process. Although much of the information presented in Chap. 5 for the design of primary sedimentation tanks is applicable, the presence of a large volume of flocculent solids in the mixed liquor requires that special consideration be given to the design of activated sludge settling tanks. As mentioned previously, these solids tend to form a sludge blanket in the bottom of the tank that will vary in thickness. The blanket may fill the entire depth of the tank and overflow the weirs at peak flowrates if the return sludge pumping capacity or the size of the settling tank is inadequate. Further, the mixed liquor, on entering the tank, has a tendency to flow as a density current, interfering with the separation of the solids and the thickening of the sludge. To cope successfully with these characteristics, the following factors must be considered in the design of secondary sedimentation tanks: (1) surface and solids loading rates, (2) tank types, (3) sidewater depth, (4) flow distribution, (5) inlet design, (6) weir placement and loading rates, and (7) scum removal. Surface and solids loading rates have been considered previously in Sec.8–10. The remaining factors are considered in this chapter.

Types of Sedimentation Tanks

The most commonly used types of activated sludge settling tanks are either circular [see Figs. 8–49(a) and (b)] or rectangular [see Figs. 8–49(c) and (d)]. Square tanks are used on occasion but they are not as effective in retaining separated solids as circular



(a) (b) (c) (d)

Figure 8–49

Typical views of secondary clarifiers: (a) circular clarifier with inboard effluent weirs, sludge collection mechanism is mounted in the center, (b) circular clarifier peripheral weir and rim drive bridge for the collection of sludge and surface skimming, (c) large rectangular clarifier shown full, and (d) tank shown on (c) empty. Note chain and flight sludge collection and skimming mechanism. Because of width of clarifier three chain and flight mechanisms are used.

or rectangular tanks. Solids accumulate in the corners of the square tanks and are frequently swept over the weirs by the agitation of the sludge collectors. Circular tanks have been constructed with diameters ranging from 3 to 60 m (10 to 200 ft), although the more common range is from 10 to 40 m (30 to 140 ft). The tank radius should preferably not exceed five to six times the sidewater depth.

Center and Rim Feed Circular Clarifiers. Two basic types of circular tanks are used for secondary sedimentation: center-feed and rim-feed (see Fig. 5–41 in Chap. 5). Both types use a revolving mechanism to transport and remove the sludge from the bottom of the clarifier. Mechanisms are of two types: those that scrape or plow the sludge to a center hopper similar to the types used in primary sedimentation tanks, and those that remove the sludge directly from the tank bottom through suction orifices that serve the entire bottom of the tank in each revolution. Of the latter, in one type the suction is maintained by reduced static head on the individual suction pipes [see Fig. 8–50(a)]. In another patented suction system, sludge is removed through a manifold either hydrostatically or by pumping. Spiral-type scrapers are also used to accelerate movement of settled solids from the tank periphery to the collection sump [see Fig. 8–50(b)].

Rectangular Clarifiers. Rectangular tanks must be proportioned to achieve proper distribution of incoming flow so that horizontal velocities are not excessive. The maximum length of rectangular tanks normally should not exceed 10 times the depth, but lengths up to 90 m (300 ft) have been used successfully in large plants. Where widths of rectangular tanks exceed 6 m (20 ft), multiple sludge collection mechanisms may be used to permit tank widths up to 24 m (80 ft). Regardless of tank shape, the sludge collector selected should be able to meet the following operational conditions: (1) the collector should have enough capacity so that when a high sludge-recirculation rate is desired, channeling of the overlying liquid through the sludge will not result, and (2) the mechanism

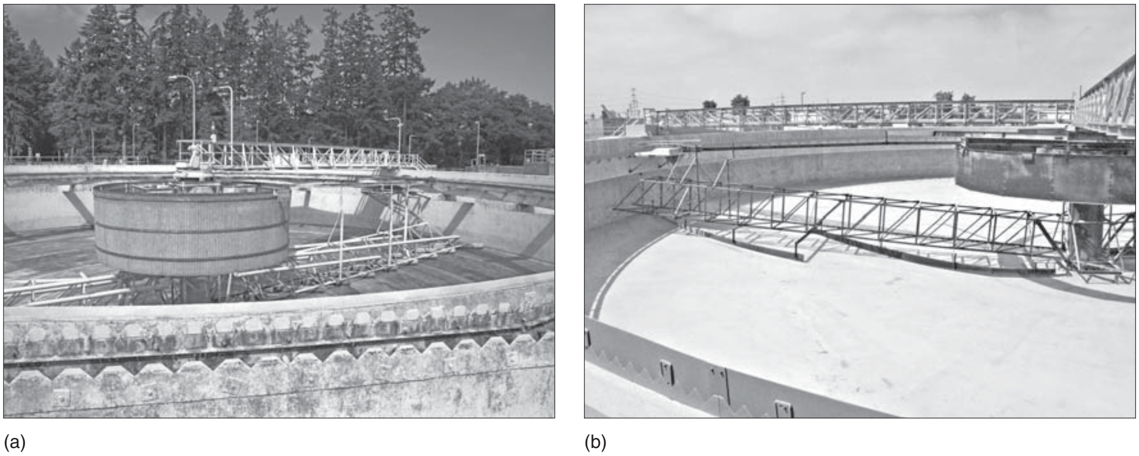


Figure 8–50

Typical circular sludge collection mechanisms: (a) suction-type and (b) spiral-type scrapers.

should be sufficiently rugged to transport and remove very dense sludges that could accumulate in the settling tank during periods of mechanical breakdown or power failure.

Two types of sludge collectors are commonly used in rectangular tanks: (1) traveling flights [see Fig. 8–51(a)] and (2) traveling bridges [see Fig. 8–51(b)]. Traveling flights are similar to those used for the removal of sludge in primary settling tanks. For very long tanks [see Fig. 8–52(a)], it is desirable to use two sets of chains and flights in tandem with a central hopper to receive the sludge to minimize the sludge transport distance [see Fig. 8–52(b)]. Sludge may be collected at the influent or effluent end of the tank. The traveling bridge, which is similar to a traveling overhead crane, travels along the sides of the sedimentation tank or on a support structure if several bridges are used. The bridge serves as the support for the sludge-removal system, which usually consists of a scraper or a suction manifold from which the sludge is pumped. The sludge is discharged to a collection trough that runs the length of the tank.

Other Types for Clarifiers. Other types of settling tanks that are used include stacked clarifiers, and tube and plate settlers (see Chap. 5). Stacked clarifiers (see Fig. 5–45 in Chap. 5) are used in installations where limited land area is available for clarifiers. Stacked clarifiers are used at the Deer Island Wastewater Treatment Plant in Boston, MA, for secondary sedimentation and were selected because of limited land area.

Clarification Tank Improvements. The efficiency of conventional or shallow clarifiers may be improved by the installation of tubes or parallel plates to establish laminar flow (see Fig. 5–25 in Chap. 5). Constructed of bundles of tubes or plates set at selected angles (usually 60°) from the horizontal, tube and plate settlers have a very short settling distance and circulation is dampened because of the small size of the tubes. Solids that collect in the tubes or on the plates tend to slide out due to gravitational forces. The major drawback in wastewater treatment is a tendency of the tubes and plates to clog because of the accumulation of biological growth, grease, and small objects that pass through coarse screens. Another drawback that can occur is if the characteristics of the MLSS change, the fixed angle of the plates or tubes may no longer be optimal.

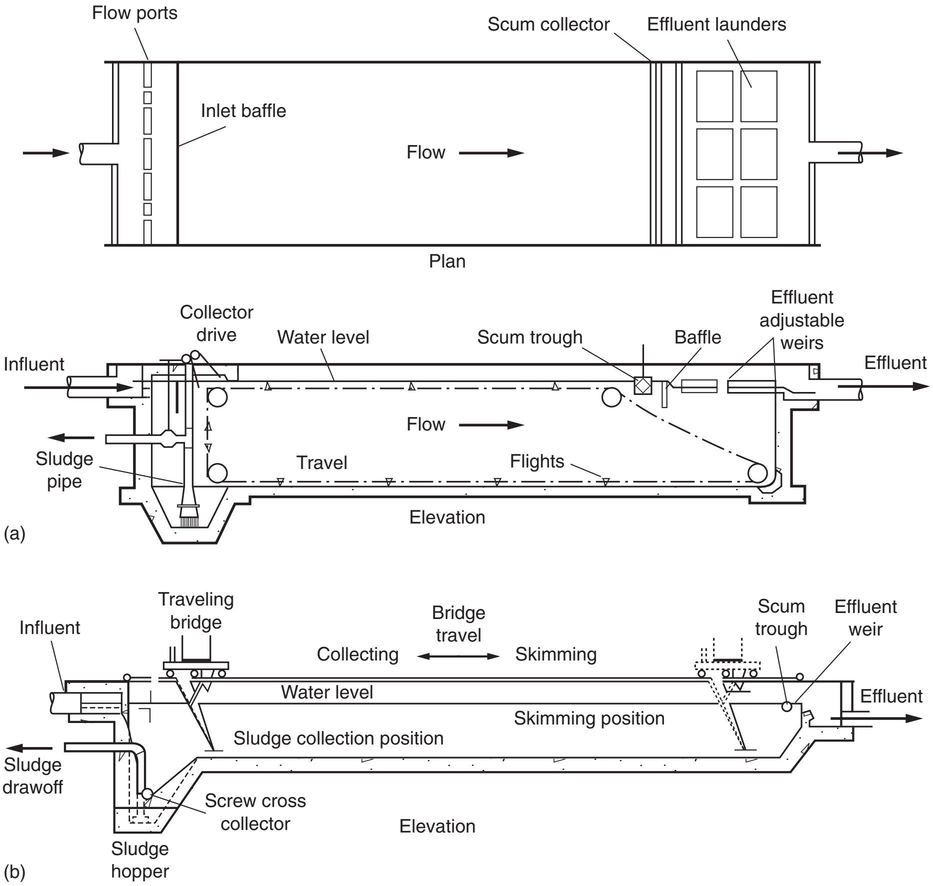

Figure 8–51

Typical rectangular sludge collection mechanisms: (a) chain and flight and (b) traveling bridge.

(a) (b)

Figure 8–52

Sludge-collection in long rectangular clarifiers: (a) chain and flight mechanisms are used to bring sludge to a central location from both ends of the clarifier where it is removed with a cross collector (coordinates 40.6430 N, 74.0343 W, view at altitude 750 m). The cross collector shown in (b) is located under central walkway dividing the clarifier. The flight mechanism on left side of divider also includes skimmers to collect floating material.

Sidewater Depth

Liquid depth in a secondary clarifier is normally measured at the sidewall in circular tanks and at the effluent end wall for rectangular tanks. The liquid depth is a factor in the effectiveness of suspended solids removal and in the concentration of the return sludge. Other factors such as inlet design, type of sludge-removal equipment, sludge blanket depth, and weir type and location also affect clarifier performance. In recent years, the trend has been toward increasing liquid depths to improve solids inventory capacity for periods of high flow variations and higher transient solids loading to the clarifier, which improves overall performance. Typical sidewater depths are presented in Table 8–34. Current practice favors a minimum sidewater depth of 4 to 5 m (13 to 16 ft) for large secondary clarifiers. Depths up to 6 m (20 ft) have been used. The cost of tank construction has to be considered in selecting a sidewater depth, especially in areas of high groundwater levels. Tanks with depths less than 3.5 m (~12 ft) often have difficulty containing the typically low-density activated sludge, and low-density sludge blankets are more easily disturbed by hydraulic fluctuations, especially morning diurnal variations. Deeper tanks therefore provide greater flexibility of operation and a larger margin of safety when changes in the activated sludge system occur.

Flow Distribution

Flow imbalance between multiple process units can cause under- or overloading of the individual units and affect overall system performance. In plants where parallel tanks of the same size are used, flow between the tanks should be equalized. In cases where the tanks are not of equal capacity, flows should be distributed in proportion to surface area. Methods of flow distribution to the secondary sedimentation tanks include weirs, flow distribution boxes, flow control valves, hydraulic distribution using hydraulic symmetry, and feed gate or inlet port control (see Fig. 8–53). Effluent weir control, although frequently used to effect flow splitting, is usually ineffective and should be used only where there are two tanks of equal size.

Tank Inlet Design

Poor distribution or jetting the influent to the clarifier can increase the formation of density currents and scouring of settled sludge, resulting in unsatisfactory tank performance. Clarifier inlets should be designed to dissipate the influent energy, distribute the flow evenly in horizontal and vertical directions, mitigate density currents, minimize sludge blanket disturbance, and promote flocculation. In circular center-feed clarifiers, a common design is to use small, solid-skirted, cylindrical baffles to dissipate the influent energy and distribute flow.

Figure 8–53

Alternative methods of flow splitting: (a) hydraulic symmetry, (b) flow measurement and feedback control, (c) hydraulic split with weirs, and (d) inlet feed gate control.

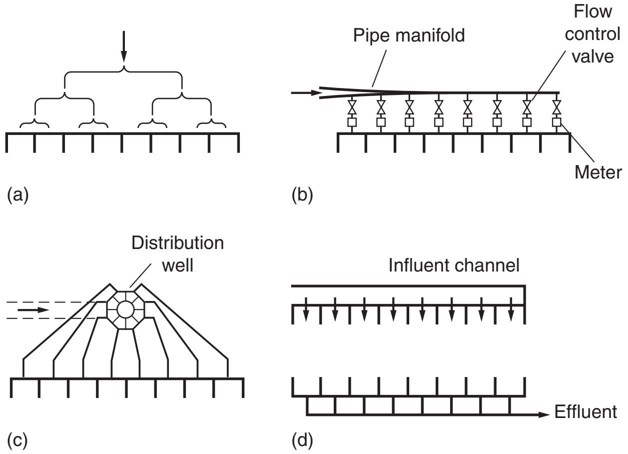

Figure 8–54

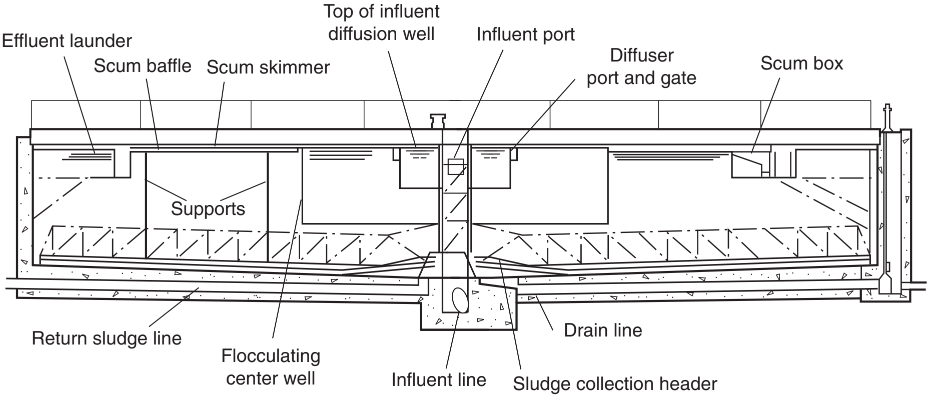
Typical secondary clarifier with a flocculating center feed well.



However, it has been found that a density current waterfall can be created in clarifiers using skirted baffles resulting in poor vertical flow distribution (Crosby and Bender, 1980). Methods to overcome these problems include the use of a large center diffusion well or a flocculating-type clarifier (see Fig. 8–54). The large center diffusion well, with a minimum diameter of 25 percent of the tank diameter, provides a greater area for dissipation of the influent energy and distribution of the incoming mixed liquor. The bottom of the feed well should end well above the sludge blanket interface to minimize turbulence and resuspension of the solids.

Flocculating center-feed clarifiers can incorporate an energy-dissipating inlet (EDI) and means to promote flocculation in the center-feed well [see Fig. 8–55(a)]. Typical flocculation feed wells have diameters of 30 to 35 percent of the tank diameter. An alternative device for dissipating energy, developed by the City of Los Angeles, is shown on Fig. 8–55(b). Operationally, the flow is discharged from a centerwell through a series of

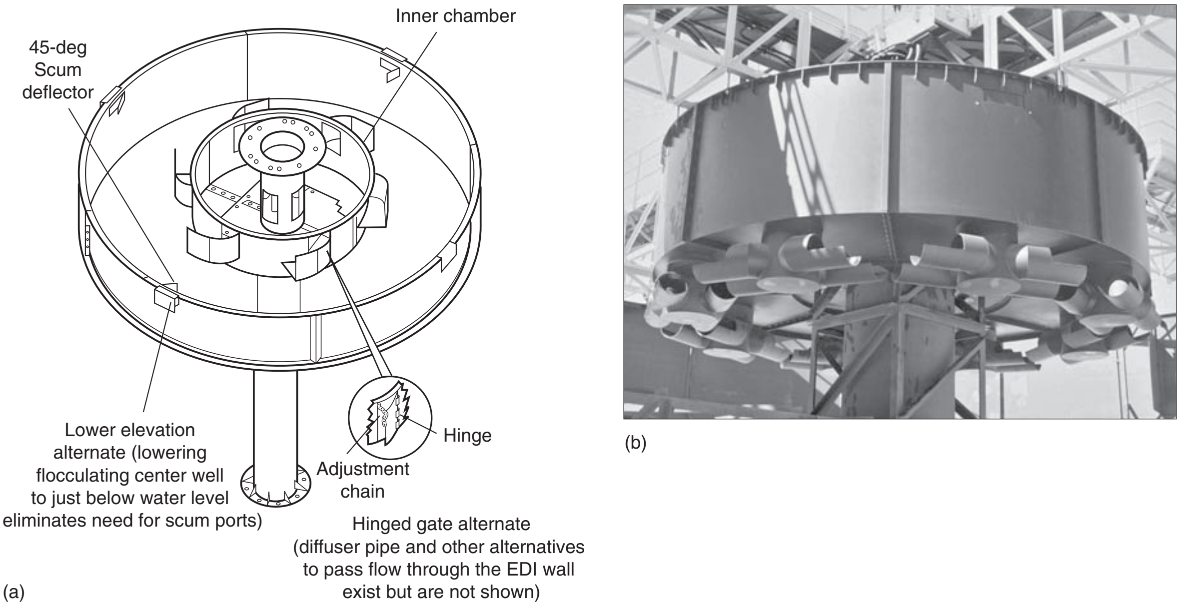


Figure 8–55

Energy-dissipating inlet devices used in circular clarifiers: (a) schematic of a center column energy-dissipating inlet and flocculating feed well (WEF, 1998) and (b) view of an energy-dissipating feed well (courtesy of the city of Los Angeles).

downward-facing discharge ports. By arranging the discharge ports so they discharge facing each other, the momentum energy is dissipated as the discharge streams impact each other. In rectangular tanks, inlet ports or baffles should be provided to achieve flow distribution. Inlet port velocities are typically 75 to 150 mm/s (15 to 30 ft/min) (WPCF, 1985).

Weir Placement and Loading

When density currents occur in a secondary clarifier, mixed liquor entering the tank flows along the tank bottom until it encounters a countercurrent pattern or an end wall. Unless density currents are considered in the design, solids may be discharged over the effluent weir. Experimental work performed by Anderson (1945) at Chicago on tanks approximately 38 m (126 ft) in diameter indicated that a circular weir trough placed at two-thirds to three-fourths of the radial distance from the center was in the optimum position to intercept well-clarified effluent. With low surface loadings and weir rates, the placement of the weirs in small tanks does not significantly affect the performance of the clarifier. Circular clarifiers are manufactured with overflow weirs located near both the center and the perimeter of the tank. If weirs are located at the tank perimeter or at end walls in rectangular tanks, a baffle should be provided to deflect the density currents toward the center of the tank and away from the effluent weir. Alternative baffle arrangements are shown on Fig. 8–56.

Weir loading rates are used commonly in the design of clarifiers, although they are less critical in clarifier design than hydraulic overflow rates. Weir loading rates used in large tanks should preferably not exceed 375 m^3/lin m·d (30,000 gal/lin ft·d) of weir at maximum flow when located away from the upturn zone of the density current, or 250 m^3/lin m·d (20,000 gal/lin ft·d) when located within the upturn zone. In small tanks, the weir loading rate should not exceed 125 m^3/lin m·d (10,000 gal/lin ft·d) at average flow or 250 m^3/lin m·d at maximum flow. The upflow velocity in the immediate vicinity of the weir should be limited to about 3.5 to 7 m/h (12 to 24 ft/h).

Scum Removal and Management

In many well-operating secondary plants, very little scum is formed in the secondary clarifiers. However, occasions arise when some floating material is present (see "Operating Problems" in Sec. 8–3), necessitating its removal.

Scum Removal by Skimming. Where primary settling tanks are not used, skimming of the final tanks is essential. Most designs in recent years provide scum removal for both circular and rectangular secondary clarifiers. Typical scum-removal equipment includes desert beach and scraper type, rotating pipe-through skimmer, and slotted pipes.

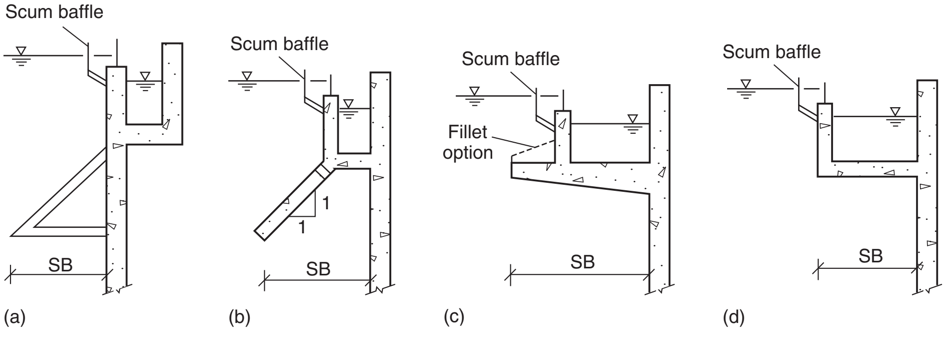

Figure 8–56

Alternative peripheral baffle arrangements: (a) Stamford, (b) unnamed, (c) McKinney (also known as the Lincoln baffle), and (d) Interior trough. (WEF, 1998.)

Note: SB will vary from 0.5 to 1.5 m, depending on the diameter of the clarifier

Scum Management. Scum should not be returned to the plant headworks because microorganisms responsible for foaming (typically *Nocardioform* such as *Gordonia amarae*) will be recycled, causing foaming problems to persist because of continuous seeding of the unwanted microorganisms. In some plants, scum is discharged to sludge-thickening facilities or is added directly to digester feed streams, as appropriate.

8–12 SOLIDS SEPARATION FOR MEMBRANE BIOREACTORS

In membrane separation, liquid-solids separation is accomplished by filtration or sieving. Water to be removed is withdrawn through a thin synthetic membrane which excludes colloidal and suspended solids because of the membrane pore sizes. In MBR systems the membranes are placed (immersed) in the activated sludge mixed liquor with a dedicated air supply system to provide a tangential flow across the membrane to prevent fouling by mixed liquor accumulation on the membrane surface. MBR technology background, applications, and advantages and disadvantages have been discussed previously in Sec. 8–1. Process configurations for biological nitrification and nitrogen removal, and enhanced biological phosphorus removal, with liquid solids separation using membranes in membrane bioreactors (MBRs) have been presented in Secs 8–6 and 8–7. The following topics are considered in this section: (1) design parameters for membrane separation in MBRs, (2) types of membranes and their characteristics, (3) membrane applications, (4) operating characteristics, (5) membrane fouling issues and (6) membrane fouling control methods.

Design Parameter

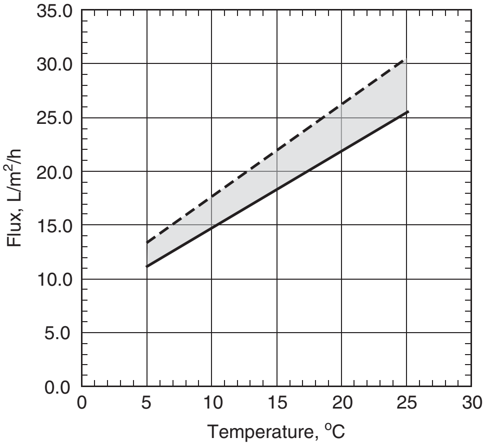
Key design and operating parameters for membrane separation are the membrane *flux* and *transmembrane pressure (TMP)*. The flux is the flowrate per unit area of membrane and is commonly expressed in $L/m^2 \cdot d$ or $gal/ft^2 \cdot d$. The higher the allowable flux, the lower is the membrane area required for a design flowrate. An acceptable pressure drop across the membrane or TMP is desired at the design flux. *Permeability* is a parameter used to reflect both flux and membrane pressure drop (TMP), and is the flux per unit of pressure driving force $[(L/m^2 \cdot h)/kPa]$. A decline in the permeability in a membrane system is typically due to membrane fouling.

The effluent from membrane separation is termed *permeate* and the remaining solids collected behind the membrane is called *retentate*. In the case of MBRs the retentate comprise solids in the return activated sludge flow and mixed liquor wasted. Recycle flowrates from the membrane separation zone are in the range of 4 to 6 times the influent flowrate to prevent excessive MLSS concentrations. Whereas solids thickening characteristics and the rate of solids and liquid applied per unit cross-section clarifier area (SOR and SLR) are key design parameters for the design of secondary clarifiers in activated sludge treatment, the liquid application rate across the membrane area (flux), pressure drop (TMP), and fouling issues apply to liquid-solids separation by membranes.

Membrane Flux. The membrane flux rate is a critical design parameter that is used to determine the required membrane surface area, membrane air scour supply requirements, and membrane tank volume. The flux is a function of the MBR MLSS concentration, temperature, TMP, and degree of membrane fouling. At a given TMP the flux is related inversely to viscosity, which increases at lower temperature and higher MLSS concentration (Trussell et al., 2007). There is, however, a tradeoff between using higher MLSS concentrations and smaller total tank volume for a given SRT, and having a greater membrane surface area.

Figure 8–57

Membrane flux decreases with decreasing temperature. The upper and lower lines represent flux values from low to high MLSS concentrations, respectively.



Although MBR systems can operate at very high MLSS concentrations (15,000 to 25,000 mg/L) (Cote et al., 1998), design MLSS concentrations in the range of 8000 to 12,000 mg/L appear to be most cost-effective when all factors are considered. A range of representative flux values is shown on Fig. 8–57 for average sustained design flows and at acceptable TMP settings. The bottom line with lower flux values applies to higher MLSS concentrations.

Because the MBR system must handle specified influent wastewater flowrates, the flux value is set for the expected controlling design condition of temperature, MLSS concentration, and acceptable TMPs, to determine the membrane available surface area. Typical operating TMPs are reported in Table 8–35 for hollow fiber and flat plate membranes. A higher pressure drop occurs for the membranes with smaller effective pore size.

In addition to the average design flux, the membrane suppliers set a peak allowable flux for 24 h or 6 h sustained peak flowrates. These higher transient flux values may be 1.5 to 2.0 times the average flux. Peak flow considerations affect the design and economics of MBR systems. In contrast to secondary clarifiers there is little economy of scale for higher flows. The required membrane area and tank volume is directly related to an average sustained flow or peak flow. Flow equalization basins are considered for handling high transient peak flowrates as an alternative to adding membrane surface area.

Membrane Properties

The types of membranes, membrane configurations, and membrane appurtenances are considered below.

Types of Membranes and Materials. Two types of membranes are used: (1) a hollow fiber membrane and (2) a flat sheet membrane or membrane plate. The membranes consist of a thin surface layer of a polymeric substance, with a high surface porosity and selected narrow pore size, over a thicker macro porous support structure, which provides structural strength and mechanical stability. The polymer materials used may be polyvinylidene difluoride (PVDF), polyethylene (PE), polyethylsulphone (PES), and polypropylene (PP), with proprietary manufacturing techniques and designs from different suppliers. The liquid flow through the membranes is termed *outside/in* with flow from the agitated mixed liquor on the surface of the membrane to the internal membrane structure from which the separated liquid is removed via a series of tubes or manifold system. The membrane pore sizes fall into either the range of microfiltration (MF) (0.01 to 0.40 μm) or ultrafiltration (UF) (0.01 to 0.10 μm). Microfiltration membranes can retain bacteria, while

Table 8–35

Design and operating characteristics of various proprietary MBR systems[a]

[a] Adapted in part from Yang et al. (2006), Babcock (2007), and Asano et al. (2007).

ultrafiltration can retain bacteria and viruses. However, permeate disinfection is normally employed for MBR applications, because the treated water is often used as reclaimed water and to also protect the effluent quality in case of a membrane failure or leak. The impact of fiber breakage is examined in Example 11–5 in Chap. 11.

Membrane Configurations. Individual membranes are contained in a *module* (also referred to as an *element*), which is a collection of membranes to be mounted as a unit. Another term to describe a membrane unit is a cassette, which is an assembly of membrane modules in a frame and with connections for permeate withdrawal and an air sparge system at opposite ends (WEF, 2006). The cassettes are standardized units with a set total membrane surface area. Membrane system manufacturers provide for air sparging at sufficient rates and locations to control fouling of the membranes by moving solids away from the membrane surface by a tangential flow while liquid is being drawn through the membrane. The distance between individual hollow fiber membranes or membrane plates is based on the flow needed across the membrane surface for fouling control and varies according to manufacturers' specifications. Hollow fiber and flat sheet membrane configurations are shown on Fig. 8–58.

The membrane specific surface relative to the cassette volume varies from 150 to 334 m^2/m^3 for different membrane designs, as reported in Table 8–35. The hollow fiber membranes have a greater specific surface area and thus require smaller membrane separation tank volumes. The additional volume needed to house the membrane cassettes varies with the membrane type and supplier designs, and may range from 3 to 10 m^3 tank volume/m^3 cassettes with the higher value used for hollow fiber membranes. On a membrane surface area basis the ratio ranges from 0.015 to 0.05 m^3 tank volume/m^2 of membrane surface area, with the smaller value applicable for hollow fiber membranes.

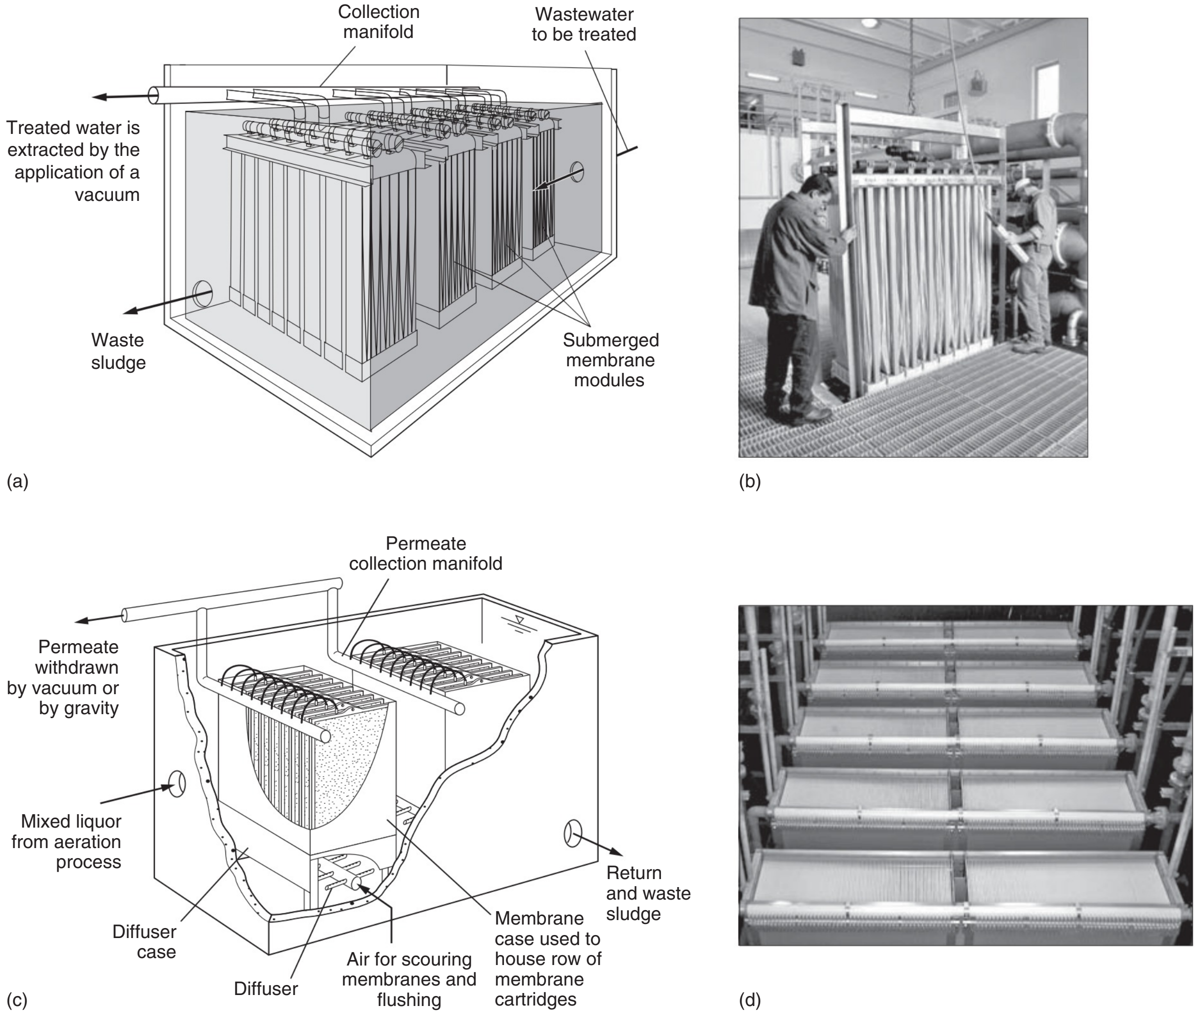

Figure 8–58

Example of membrane bioreactors: (a) schematic of placement of hollow fiber membrane bundles in an activated sludge reactor, (b) membrane bundle in position to be placed in a membrane bioreactor, (courtesy of Zenon environmental, Inc.), (c) schematic of placement of flat sheet membrane modules in an activated sludge reactor, and (d) flat sheet membrane modules in place with clear water.

Membrane Appurtenances. Because of the need to integrate the activated sludge system with the membrane flux and performance, and to provide proper membrane fouling control, the membrane suppliers provide other equipment items in addition to the membrane cassettes. Support facilities required include permeate pumps, chemical storage tanks, chemical feed pumps and all process controls for the membranes, including the motor control center for the membrane process. The membrane support equipment also includes an air-scour system and a back-pulse water-flushing system. The air-scour system consists of coarse bubble diffusers located in the aeration basin and provides continuous agitation on the outside of the membranes to minimize solids deposition. The air supply for the air-scour system is typically provided in addition to the activated sludge tank process air. Wastewater plant designers must first know the membrane system selected and design, before the final design of the activated sludge layout and configuration can be completed.

Membrane Design and Operating Characteristics

Design and operating characteristics for number of proprietary MBR systems representing most of the U.S. and world installations are summarized in Table 8–35. With the exception of the Mitsubishi designs, the membrane separation system may be contained in a separate tank or can be in a single aeration tank. The latter case is usually used for small facilities with coarse bubble aeration. When a separate tank is used for the membrane separation, coarse bubble aeration is only used in the membrane tank and fine bubble aeration is used in the preceding aerobic tank(s) for higher energy efficiency.

Membrane Usage

Currently (2012), the largest share of membrane installations utilize hollow fiber UF membranes, followed by the flat plate MF membranes (Yang et al., 2006). Hollow fiber membranes are typically about 2 m long with a 1.9 mm outer diameter, 0.8 mm inner diameter, and a spacing between membranes of about 3.0 mm. Some membranes are about 10 cm longer than the cassette height, which allows them to flex during air scour to provide further agitation against solids deposition. A typical UF cassette for a MBR system is shown on Fig. 8–58. The cassette shown on Fig. 8–58(b) is composed of hollow fiber membranes and has overall dimensions of 0.91 m wide by 2.13 m long, and approximately 2.44 m high (3 ft by 7 ft by 8 ft). Flat plate membranes [see Fig. 8–58(c) and (d)] consist of panels of 1.5 m wide by 0.55 mm high, a panel thickness of a 8 mm, and spacing between panels of 7 to 8 mm. A common application is to stack to panels, which reduces the tank area required and air flowrate for membrane fouling control (Judd, 2008b).

Membrane Fouling Issues

Membrane fouling is the reduction or loss of membrane performance due to the deposition of particulate or dissolved substance on the membrane surface or within the membrane pore structure (Koros et al., 1996). The effect of fouling is observed by an increase in TMP and thus decreased permeability for a give membrane flux. TMP is an important monitoring parameter to indicate when fouling exceeds acceptable levels in MBR systems to signal the need for special cleaning procedures to recover membrane performance. TMP values may remain stable and only slowly increase with time, but after some critical fouling point, they can increase rapidly (Gulglielmi et al., 2007). It appears this observed phenomenon is a two-step process in which gradual deposition occurs due to extracellular polymeric substances (EPS) substances, followed by cake formation and further headloss after fouling reaches a critical point. Note that fouling is different than membrane clogging or membranes becoming “sludged up,” which is the result of attempting to operate with excessive MLSS concentrations beyond the air scour hydrodynamic capacity to move mixed liquor off the membrane surface as permeate moves through it. Clogged membranes may need to be replaced or removed for special cleaning procedures.

Causes of Fouling. Fouling can be caused by physical, chemical and biological mechanisms as shown in Table 8–36. Some of the fouling agents are in the influent wastewater, such as hair and fibrous material, high alkalinity, soluble iron, and oil and grease. Oil and grease are very hydrophobic and can coat membrane material, but normally are not at levels of concern for most domestic wastewater flows. However, for smaller flows, where cooking oil is frequently used, or for systems receiving a high proportion of restaurant wastewaters without grease trap controls, it can be of great concern. Biofouling is a constant concern for MBR operations, but has been shown to be controllable in domestic wastewater treatment by operating within specified SRT and flux ranges, and maintaining the supplier's fouling control methods.

While there are conflicting literature reports on the effect of different microbial components contributing to fouling, it is generally agreed that macromolecules, colloids and soluble microbial products from bacteria growth and decay are major contributors to membrane fouling. Microbial fouling substances have in general been referred to as extracellular polymeric substances, which is a general term including autochthonous macromolecules, which include cell polymeric substances found outside bacteria cells and soluble material secreted by cells, such as proteins and polysaccharides (Judd, 2008a). Higher EPS production and increased fouling occurs at SRT values below 10 d (Trussell et al., 2006; Ke and Junxin, 2009). Less fouling was found at higher SRTs with good membrane performance at 30 and 50 day SRTs (Van den Broeck et al., 2012). MBR systems are generally designed with SRTs ≥ 10 d.

Table 8–36

Constituents that affect MBR membrane fouling and control methods[a]

Fouling type	Specific constituent	Control method
Physical	Hair, fibrous material, colloidal inorganic constituents, MLSS	Fine screening Air scour Relax operation Backpulse Chlorine
Chemical	High alkalinity,	Citric acid
	soluble iron,	Citric acid
	oil and grease	Chlorine Hypochlorite
Biological	Extracellular polymeric material	SRT control Air scour Chlorine Citric Acid
Biological	Colloidal organic matter	SRT control Backpulse Chlorine Citric Acid

[a] Refer to Table 11–25 for a broader range of fouling constituents and control methods.

Membrane Fouling Control Methods. The three principal methods used to control membrane fouling (see Table 8–35) are (1) pretreatment with fine screens, (2) operational fouling control procedures, and (3) recovery cleaning methods. Pretreatment by fine screening with sieve sizes in the range of 0.8 to 2 mm are needed to protect the membrane system from failure. If there is inadequate screening, hair and fibrous material can collect on membranes and on the air scouring diffusers to prevent proper cleaning and to cause a decline in the membrane flux capacity.

Operational Control of Fouling. Procedures to control fouling are provided by the membrane suppliers. Air scour by coarse bubble aeration systems that are designed specifically for each type of membrane by the respective supplier is critical to preventing solids accumulation on the membrane surface and fouling. Air scour rates are in the range of 3 to 12 L air/min·m^2 of membrane surface area. Some membrane systems do not require continuous air scour, but use a series of valves to alternate the air scour every 10 sec between two sets of membranes fed with a common blower (Palowski et al., 2007).

In addition to air scour, other fouling control methods are referred to as relax, backpulsing, maintenance cleaning, and recovery cleaning. Almost all of the membrane suppliers use a *relax* period in which the permeate withdrawal is stopped so that the air scour can wash solids off of the membrane surface during a period without solids application. A common relax strategy shown in Table 8–35 is 1 min of no permeate removal every 10 min. Some of the hollow fiber membrane suppliers reverse the flow through the membrane by a backpulse with permeate for about 0.50 min every 12 min to flush solids from the membrane.

Maintenance and Recovery Cleaning. Two types of cleaning regimens are used: (1) maintenance cleaning and (2) recovery cleaning. A maintenance cleaning involves back flushing the membrane with a sodium hypochlorite solution (200 mg/L) and/or citric acid (2000 mg/L) about 1 to 2 times per week. These are done in a series of repetitive alternative flushing with the chemical and permeate over a 60 to 75 min period. The combination of air scour, backflushing, and maintenance cleaning is not completely effective in controlling membrane fouling, and the pressure drop across the membrane increases with time. A recovery cleaning is done 2 to 4 times per year, or as needed, depending on the membrane type. It is required when TMP values remain elevated above the desired operating conditions. Recovery cleaning involves extensive chemical contact time, in the range of 4–6 h, and is done with chlorine (1000 mg/L) and citric acid (2000 mg/L), if needed for inorganic fouling. Some of the membrane systems have the recovery cleaning in place without draining the tank, while others drain the tank of mixed liquor and allow a soaking period with the chemical solutions.

PROBLEMS AND DISCUSSION TOPICS

8–1 Given the following laboratory test BOD and UBOD test results for one of the following wastewaters (to be selected by the instructor), determine the biodegradable COD (bCOD) concentration. Assume that values for f_d and Y_H are 0.15 g/g and 0.40 g VSS/g COD, respectively.

		Wastewater		
Test Parameter	Unit	1	2	3
BOD	mg/L	120	200	200
UBOD	mg/L	180	300	340

8–2 An influent wastewater sample is evaluated in a laboratory respirometer test to determine its readily biodegradable COD (rbCOD) concentration. The respirometer bottle is prepared by adding 500 mL of the influent sample with 500 mL of activated sludge mixed liquor. The respirometer records the accumulative oxygen consumption with time. The oxygen consumption occurs at a relatively constant rate initially (Phase A-total oxygen demand), and then the rate declines to another relatively constant rate (Phase B-oxygen demand for nitrification, slowly degradable COD, and endogenous decay), which continues for a number of hours. Finally, the oxygen consumption rate declines dramatically again and continues at a relatively constant rate (Phase C-oxygen demand for endogenous decay). The respirometer data are summarized in the following table for three different samples (to be selected by instructor). For the selected sample, determine the rbCOD concentration of the wastewater in mg/L, assuming the biomass yield for the heterotrophic bacteria is 0.45 g VSS/g COD and the oxygen equivalent of the biomass is 1.42 g COD/g VSS.

Phase	Duration of phase, h	Respirometer accumulative oxygen consumption for each phase, mg Wastewater 1	2	3
A	0.8	64	100	70
B	3.2	192	288	192
C	2.0	40	50	46

8–3 Primary effluent 24-h, flow proportioned composite samples are analyzed to determine its readily biodegradable COD concentration by using the flocculation-filtration COD (ffCOD) test method. The ffCOD is also measured for secondary effluent samples from the activated sludge treatment system, which has an aerobic SRT of 8 d. The average ffCOD values from 10 sampling days are shown in the table below. Determine the readily biodegradable concentration for one of the following wastewater plants (to be selected by the instructor).

Sample source	Unit	Wastewater 1	2	3
Primary effluent	mg/L	90	110	60
Secondary effluent	mg/L	30	20	30

8–4 For one of the following wastewater samples (to be selected by instructor) shown in the following table, with values for conventional wastewater characterization parameters, determine (a) the biodegradable COD concentration, (b) the slowly biodegradable COD concentration (c) the non-biodegradable volatile suspended solids (nbVSS) concentration, (d) the inert total suspended solids (iTSS) concentration, and (e) the average COD/VSS ratio. Assume that the bCOD/BOD ratio equals 1.6 and the activated sludge treatment effluent sCOD equals 30.0 mg/L.

Parameter	Unit	Wastewater 1	2	3
TSS	mg/L	220	170	90
VSS	mg/L	200	140	70
BOD	mg/L	200	160	120
rbCOD	mg/L	100	40	80
TCOD	mg/L	500	400	280
sCOD	mg/L	160	200	180

8–5 Given the following wastewater characteristics (to be selected by instructor), determine (a) the organic nitrogen, (b) the nonbiodegradable particulate organic nitrogen (nbpON), and (c) the biodegradable organic nitrogen (bON) concentrations.

		Wastewater		
Parameter	Unit	1	2	3
TKN	mg/L	40	45	50
NH_4-N	mg/L	25	30	35
Soluble organic nitrogen	mg/L	5.0	2.0	3.0
Nonbiodegradable soluble organic nitrogen	mg/L	1.0	1.0	1.0
VSS	mg/L	180	180	190
Nonbiodegradable VSS fraction	Percent	40	40	40

8–6 Using an observed yield value from Fig. 8–11, and Eqs. (8–19) and (7–56) (see Table 8–10), determine (a) the aeration tank volume in m^3 and (b) the amount of sludge wasted daily in kg TSS/d for an activated sludge system designed to treat a 6000 m^3/d wastewater flow with an influent BOD concentration of 120, 140, or 160 mg/L (as selected by instructor). The SRT is 6 d, the mixed-liquor temperature is 10°C, and primary treatment is used. What is the aeration tank volume and amount of daily sludge production if the SRT is increased to 12 d? Assume that the MLVSS and MLSS concentrations are 2500 mg/L and 3000 mg/L, respectively.

8–7 The following information is given for an activated sludge system design:

Parameter	Unit	Value
Flowrate	m^3/d	10,000
Influent BOD	mg/L	150
Effluent BOD	mg/L	2
τ	h	4
SRT	d	6
Synthesis yield, Y_H	g VSS/g bCOD	
Wastewater 1		0.40
Wastewater 2		0.50
Wastewater 3		0.30
Cell debris yield, f_d	g VSS/g VSS	0.15
Endogenous decay, b_H	g VSS/g VSS·d	0.08
nbVSS	mg/L	40
Temperature	°C	10

Note: Wastewater 1, 2, or 3 to be selected by instructor.

Assume no nitrification occurs due to the SRT selected and low temperature. Determine (a) the aeration tank oxygen requirements in kg/d, (b) the aeration tank oxygen uptake rate in mg/L·h, and (c) the aeration tank biomass concentration (mg/L). Assume bCOD = 1.6(BOD).

8–8 The following information is given for an activated sludge system designed with a long enough SRT to provide complete nitrification:

Parameter	Unit	Value
Flowrate	m^3/d	10,000
Influent BOD	mg/L	150
Effluent BOD	mg/L	2
Influent TKN	mg/L	35
Effluent NH_4-N	mg/L	1.0
τ	h	8.0
SRT	d	15
Temperature	°C	10
Cell debris yield, f_d	g VSS/g VSS	0.10
Synthesis yield, Y_H	g VSS/g bCOD	
Wastewater 1		0.40
Wastewater 2		0.50
Wastewater 3		0.30
Endogenous decay, b_H	g VSS/g VSS·d	0.08
Nitrifier yield, Y_n	g VSS/g NH_4-N	0.18
Nitrifier decay, b_n	g VSS/g VSS·d	0.12

Note: Wastewater 1, 2, or 3 to be selected by instructor.

Determine (a) the aeration tank oxygen requirements in kg/d, (b) the aeration tank oxygen uptake rate in mg/L·h, (c) the aeration tank biomass concentration (mg/L), and (d) the portion of the total oxygen required that is needed for nitrification.

8–9 Using Eqs. (8–20) and (8–21), compare the amount of sludge wasted daily as (a) VSS, (b) TSS, and (c) biomass for operation at an SRT of 10 and 20 d for the following wastewater and design conditions. Assume all of the influent TKN is biodegradable and complete nitrification to NO_3-N with no significant NO_2-N present (less than 0.10 mg/L). Repeat the calculation without accounting for cell debris. How much error is introduced?

Parameter	Unit	Value
Flowrate	m^3/d	15,000
Influent BOD	mg/L	200
Effluent BOD	mg/L	2
Influent TKN	mg/L	35
Effluent NH_4-N	mg/L	0.5
Heterotrophic yield, Y_H	g VSS/g bCOD	0.4
Heterotrophic decay, b_H	g VSS/g VSS·d	0.10
Cell debris yield, f_d	g VSS/g VSS	0.15
Nitrifier yield, Y_n	g VSS/g NH_4-N	0.18
Nitrifier decay, b_n	g VSS/g VSS·d	0.12
nbVSS	mg/L	
Wastewater 1		100
Wastewater 2		120
Wastewater 3		80
Temperature	°C	15

Note: Wastewater 1, 2, or 3 to be selected by instructor.

8–10 An activated sludge system consists of three completely-mixed reactors in series. The dissolved oxygen concentration in each reactor is 2.0 mg/L. Use the information given below for the biodegradable COD (bCOD) and NH_4-N concentrations in each stage for wastewaters 1 and 2. Determine the total oxygen transfer rate required for bCOD removal, nitrification, and endogenous decay. Prepare a table of the total oxygen transfer rate required and the amount for each of these 3 components in each stage in kg/h. Compare the percent of the total oxygen required for stages 1, 2, and 3. Assume that in Stage 3 the bCOD concentration is mainly as dissolved bCOD. Ignore the NH_4-N used for synthesis as this has already been accounted in determining the influent NH_4-N concentration available for nitrification. Assume that nitrification is complete to NO_3-N (i.e., NO_2-N concentration is insignificant).

		Wastewater	
Parameter	Unit	1	2
Flowrate	m^3/d	15,000	5,000
Recycle sludge ratio	unitless	1.0	0.5
Influent bCOD	mg/L	320	200
Influent available NH_4-N for nitrification	mg/L	30	35
Volume per stage	m^3	2300	500
Synthesis yield, Y_H	g VSS/g COD	0.45	0.45
Endogenous decay, b_H	g VSS/g VSS·d	0.10	0.10
STAGE 1			
bCOD	mg/L	30	50
NH_4-N	mg/L	8.0	17.0

biomass	mg VSS/L	1500	1200
Temperature	°C	15	

Note: Wastewater 1 or 2 to be selected by instructor.

8–11 An industrial wastewater from food processing is to be treated in an activated sludge process. The wastewater consists of soluble organics (no particulate degradable COD) with low nitrogen and phosphorus concentrations. For the summary of wastewater characteristics and design assumptions given in the following table, determine the amount of nitrogen and phosphorus that must be added to the influent flow as mg/L and in kg/d. Assume that residual effluent NH_4-N and soluble phosphorus concentrations of 0.10 mg/L are needed to prevent nutrient limitations, and no nitrification.

Parameter	Unit	Value
Flowrate	m^3/d	3000
Influent soluble bCOD	mg/L	
Wastewater 1		2000
Wastewater 2		3000
Wastewater 3		2500

(*continued*)

(*Continued*)

Parameter	Unit	Value
Effluent soluble bCOD	mg/L	5
Influent NH_4-N	mg/L	20
Influent phosphorus as P	mg/L	5
SRT	d	10
Synthesis yield, Y_H	g VSS/g bCOD	0.4
Heterotrophic decay, b_H	g VSS/g VSS·d	0.10
Cell debris yield, f_d	g VSS/g VSS	0.10

Note: Wastewater 1, 2, or 3 to be selected by instructor.

8–12 An activated sludge system is operating with the conditions described below for system 1, 2, or 3 to be selected by instructor. The conditions include the average influent flow, aeration tank volume and MLSS concentration, return activated sludge flow recycle ratio and TSS concentration, and the secondary clarifier effluent TSS concentration. Wasting is from the return activated sludge line leaving the bottom of the secondary clarifier.

(a) What should be the average daily waste sludge rate in m^3/d to maintain an SRT of 10 d?

(b) The plant operator decides to waste 1/10th of the aeration volume each day to maintain the SRT. What is the waste volume in m^3/d and what is the actual SRT?

		Activated sludge system		
Parameter	Unit	1	2	3
Flowrate	m^3/d	4000	10,000	5000
Aeration tank volume	m^3	2000	4000	5000
Aeration tank MLSS concentration	mg/L	3000	3500	3000
Clarifier effluent TSS concentration	mg/L	10.0	10.0	10.0
Return sludge recycle ratio	unitless	0.5	1.0	0.75
Return sludge TSS concentration	mg/L	9000	7000	7000

8–13 A membrane bioreactor consists of an anoxic tank followed by an aeration tank. The influent wastewater is added to the anoxic tank. The aeration tank is divided into two compartments. The first compartment is 75 percent of the total aerobic volume and is aerated with fine bubble diffusers, and the second compartment contains the membrane separation cassettes and is aerated with coarse bubble diffusers. The total aerobic volume is 4000 m^3. The return activated sludge flow is from the membrane separation compartment to the anoxic tank and is at six times the influent flowrate. The MLSS concentration in the membrane separation compartment is 12,000 mg/L. What is the daily waste sludge flowrate from the return activated sludge line, to maintain an SRT of 10 d?

8–14 A 2-L settleometer is used to perform an SVI test. The MLSS concentration for the test is 3500 mg/L and the settled sludge volume after 30 min is 840 mL. What is the sludge volume index in mL/g?

8–15 Using the ASM2d Model matrix described in Tables 8–12 and 8–13, write a mass balance equation for the second stage of a three stage aerobic activated sludge reactor for one or a combination of the following (1, 2, 3 or 4 or combination selected by instructor): (1) Heterotrophic bacteria (2) Autotrophic nitrifying bacteria (3) Slowly degradable substrate, and (4) Ammonia nitrogen.

8–16 A completely mixed activated sludge system treating domestic wastewater is operated at an SRT of 15 d at 12°C, such that complete nitrification occurs. The clarifier surface overflow rate is 1 m/h at average flow conditions, but the clarifier has a high sludge blanket with significant solids loss in the effluent. Describe (a) the specific steps you recommend to investigate the cause of the bulking sludge condition, (b) possible short-term immediate action to reduce the effluent TSS concentration, and (c) the selector alternatives that can be considered for bulking sludge control. Which one would you use and why?

8–17 Using the kinetic coefficients in Table 8–14 and assuming complete nitrification to NO_3-N (also ignore solids growth from nitrite oxidation), plot the following as a function of SRT (ranging from 3.0 to 20.0 d) for the municipal wastewater described in the table below. Assume that the MLSS concentration is 2500 mg/L and that all the TKN is biodegradable. The parameters to plot are (a) solids wasted as kg TSS/d, (b) aeration tank volume (m^3) and τ (h), (c) observed yield, as g TSS/g BOD, and g TSS/g $bCOD_r$, (d) effluent soluble bCOD concentration, (e) effluent NH_4-N concentration, and (f) oxygen requirements, kg/d.

Parameter	Unit	Value
Flowrate	m^3/d	20,000
BOD	mg/L	
Wastewater 1		220
Wastewater 2		250
Wastewater 3		180
bCOD/BOD	g/g	1.6

VSS	mg/L	200
nbVSS	mg/L	
Wastewater 1		100
Wastewater 2		120
Wastewater 3		80
TKN	mg/L	40
Temperature	°C	15
Aeration tank DO	mg/L	2.0

Note: Wastewater 1, 2, or 3 to be selected by instructor.

8–18 Solve Problem 8–17 for a MBR system, assuming that the aeration tank is divided into two compartments. The volume of the second compartment for the membrane separation cassettes is 25 percent of the total aerobic volume. Assume that the MLSS concentration in the membrane separation compartment is 12,000 mg/L and the return activated sludge ratio is 6.0.

8–19 Solve Problem 8–17 using primary clarification, assuming 35 percent BOD removal, 65 percent TSS and VSS removal, 10 percent TKN removal, and 80 percent nbVSS removal.

8–20 An activated sludge system is to be designed for nitrification to achieve an effluent NH_4-N concentration of 0.50, 0.80, or 1.0 mg/L (to be selected by the instructor) at a reactor DO concentration of 2.0 mg/L and 10°C temperature. The peak/average TKN load is 1.8. Determine the design SRT. Use coefficients from Table 8–14.

8–21 A completely mixed activated sludge system has a hydraulic retention time, τ, of 8.3, 10.8, or 13.1 h (to be selected by the instructor), an aeration tank DO concentration of 2.0 mg/L, and an MLSS concentration of 3000 mg/L. For the municipal wastewater characteristics given below determine (a) the aeration tank average SRT, (b) the effluent NH_4-N concentration and (c) the nitrification safety factor if the desired average effluent NH_4-N concentration is 1.0 mg/L. Use coefficients from Table 8–14.

Parameter	Unit	Value
Temperature	°C	10
Flowrate	m^3/d	15,000
BOD removed	mg/L	130
nbVSS	mg/L	30
TSS	mg/L	70
VSS	mg/L	60
TKN	mg/L	40

8–22 A 3000 m^3/d industrial wastewater with a soluble COD concentration of 1800 mg/L is to be treated in a completely mixed activated sludge process at 15°C and 2500 mg/L MLSS concentration. Using the kinetic coefficients and assumptions provided below determine (a) the aeration tank volume in m^3, and τ in h, (b) the oxygen required in kg/d, (c) the sludge production in kg TSS/d, (d) the effluent sBOD concentration from the secondary clarifiers in mg/L, (e) the clarifier diameter in m, assuming two clarifiers, and (f) the air flowrate for fine bubble diffused air aeration. Assume very little excess NH_4-N exists after cell synthesis needs are met so that nitrification is not significant.

Parameter	Unit	Value
bCOD/BOD	g/g	1.6
μ_{max}	g VSS/g VSS·d	3.0
K_s	mg bCOD/L	60.0

Aeration tank liquid depth	m	5.0
Clean H_2O oxygen transfer efficiency	%	30

Note: Wastewater 1, 2, or 3 to be selected by instructor.

8–23 An oxidation ditch process is designed for the following wastewater using the conventional design approach of no primary treatment, a 24-h aeration tank detention time, and 3500 mg/L MLSS concentration. The lowest expected mixed-liquor temperature is 10°C and an average effluent NH_4-N concentration of 1.0 mg/L is required with a 1.5 safety factor for peak loads. Mechanical surface aerators are used to provide a DO concentration in the aeration zone of 2.0 mg/L. For one of the three wastewaters given below (to selected by instructor) determine (a) the SRT in d, (b) the sludge production in kg TSS/d, (c) the MLVSS concentration in mg/L, (d) the oxygen required in kg/d, (e) the total required aeration horsepower in kW, and (f) the ratio of the total volume provided to the necessary nitrification volume. Use coefficients from Table 8–14 and assume that all the TKN is biodegradable.

		Values		
Parameter	Unit	Wastewater 1	Wastewater 2	Wastewater 3
Flowrate	m^3/d	4000	4000	4000
BOD	mg/L	270	250	200

Alpha factor, α	Unitless	0.90	0.90	0.90
Beta factor, β	Unitless	0.98	0.98	0.98
Elevation	m	500	500	500

Note: Wastewater 1, 2, or 3 to be selected by instructor.

8–24 For the same wastewater characteristics and mixed-liquor temperature as in Problem 8–23 and assuming uniform continuous flow, two sequencing batch reactor tanks are operated under the following conditions:
Fraction of tank liquid depth used for decant depth = 0.20
Aeration time = 2 h
Settle time = 1 h
Decant time = 0.5 h
Determine (a) the fill time in h, (b) the total time/cycle in h, (c) the total full volume of each tank in m^3, (d) the SBR SRT in d assuming an MLSS concentration of 3500 mg/L, and (e) the decant pumping rate in m^3/min.

8–25 A sequencing batch reactor treating the following wastewater is operated under the following conditions:
Temperature = 15°C
Aeration time/cycle = 2.0 h
Fill volume/total SBR tank liquid volume per cycle = 0.20
SRT = 20 d
DO = 2.0 mg/L
Two SBR reactor tanks are used and the full volume for each SBR tank = 3000 m^3.

		Values		
Parameter	Unit	Wastewater 1	Wastewater 2	Wastewater 3
Flowrate	m^3/d	4,800	4,800	4,800
BOD	mg/L	250	250	200
TKN	mg/L	45	40	30

Note: Wastewater 1, 2, or 3 to be selected by instructor.

Determine the effluent NH_4-N concentration in mg/L. Use kinetic coefficients values from Table 8–14.

8–26 An SBR tank has a total liquid depth of 5.5 m when full. The desired operating MLSS concentration is 3500 mg/L. If the SVI is 150, 180, or 200 mL/g (to be selected by instructor), determine the possible fill volume to total liquid volume ratio, assuming a 0.6 m clear liquid depth above the settled sludge blanket.

8–27 Repeat computations for Example 8–6 using the same design conditions and assumptions, but for an effluent NH_4-N concentration of 1.0, 2.0, and 4.0 mg/L (to be selected by instructor). How do the advantages of the staged system compare to the single-stage nitrification system as the desired effluent NH_4-N concentration is increased?

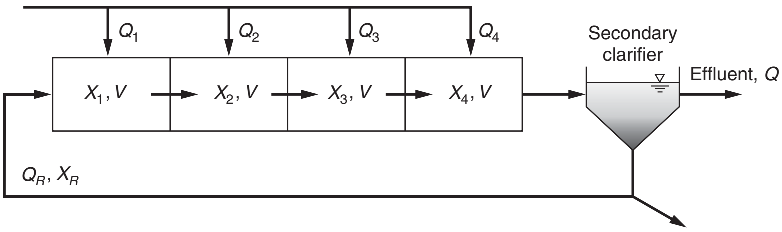
8–28 A four-stage activated sludge system with equal tank volumes of 240 m^3/stage is used to treat an industrial wastewater with a soluble BOD concentration of 300 mg/L. The influent flow is 4000 m^3/d and the RAS recycle ratio of 0.5. The active biomass concentration is 1600 mg/L. For the following biokinetic information determine: (a) the substrate concentration in each stage (mg/L as soluble bCOD), (b) the oxygen required per stage (kg/d), and (c) the percent of the total oxygen required per stage. Hint: to start the solution assume a 4th stage soluble bCOD concentration of 1.0 mg/L. (ignore nitrification).

Parameter	Unit	Value
Maximum specific substrate utilization rate, k	g COD/g VSS·d	1.2
Half velocity coefficient, K_s	mg bCOD/L	
Wastewater 1		50
Wastewater 2		75
Wastewater 3		100
Synthesis yield, Y_H	g VSS/g bCOD removed	0.35
b_H, endogenous decay	g VSS/g VSS·d	0.10

Note: Wastewater 1, 2, or 3 to be selected by instructor.

8–29 Compare the following activated sludge processes in terms of effluent quality, space requirements, complexity, energy requirements, operational requirements, and ability to handle variable flows and loads: completely mixed activated sludge, membrane bioreactor, contact stabilization, and oxidation ditch.

8–30 A four-pass step feed activated sludge system, shown in the figure below, has equal aeration tank volumes in each pass of 240 m^3. Using the design parameters given below, determine the MLVSS concentration in each tank.



Parameter	Unit	Value		
		Wastewater 1	Wastewater 2	Wastewater 3
X_R	mg VSS/L	10,000	10,000	10,000
Q_R	m^3/d	2000	4000	6000
Q	m^3/d	4000	4000	4000
Q_1	m^3/d	800	800	800
Q_2	m^3/d	1200	1200	1200
Q_3	m^3/d	1000	1000	1000
Q_4	m^3/d	1000	1000	1000

Note: Wastewater 1, 2, or 3 to be selected by instructor.

8–31 The following operating conditions can be used to describe an anoxic/aerobic process such as shown in Example 8–7 for 85 percent nitrogen removal.

Parameter	Unit	Value
Flowrate	m^3/d	1000
BOD	mg/L	200
rbCOD	mg/L	
Wastewater 1		60
Wastewater 2		95
Wastewater 3		120
Alkalinity	mg/L as $CaCO_3$	200
TKN	mg/L	35
Temperature	°C	15
MLSS	mg/L	3500
Biomass (VSS)	mg/L	1620
RAS (TSS)	mg/L	10,000
Aerobic volume	m^3	460
Aerobic SRT	days	10.0
Biomass nitrogen content	g N/g VSS	0.12
Effluent NH_4-N	mg/L	1.0

Note: Wastewater 1, 2, or 3 to be selected by instructor.

Determine (a) the internal recycle ratio and flowrate (m^3/d), (b) the anoxic tank volume and τ for a single-stage anoxic reactor, (c) the final alkalinity concentration, and (d) the oxygen required (kg/d) for the anoxic/aerobic process versus the aerobic system without the preanoxic tank. Use coefficients in Table 8–14.

8–32 Solve problem 8–31 for an anoxic/aerobic MBR with a two compartment aeration tank; a preaeration zone followed by a membrane separation zone. Use a return sludge recycle ratio from the membrane separation tank to the anoxic tank of 6.0 (i.e., calculate the resulting effluent NO_3-N concentration). Assume that the MLSS concentration in the membrane separation compartment is 10,000 mg/L. From Figure 8–52 the membrane flux is 20 L/m^2•h. Assume that the membrane compartment tank volume to membrane area ratio is 0.025 m^3/m^2.

8–33 An existing activated sludge system is operated at a minimal temperature of 10°C. The system is to be modified to an anoxic/aerobic process with the anoxic tank accounting for

10 percent of its total volume. For the following design wastewater conditions and total tank volume, determine (a) the effluent NH_4-N and NO_3-N concentrations, and (b) the minimal internal recycle ratio needed to match the nitrate removal capacity of the anoxic tank. Use necessary coefficients from Table 8–14.

Parameter	Unit	Value
Flowrate	m^3/d	8000
bCOD	mg/L	240
rbCOD	mg/L	
Wastewater 1		25
Wastewater 2		50
Wastewater 3		75
nbVSS	mg/L	60
TSS	mg/L	80
VSS	mg/L	70
TKN	mg/L	40
MLSS	mg/L	3500
Tank volume	m^3	3600
RAS ratio	Unitless	0.50
Biomass nitrogen content	g N/g VSS	0.12
Aeration tank DO	mg/L	2.0

Note: Wastewater 1, 2, or 3 to be selected by instructor.

8–34 An oxidation ditch system is operated with a single mechanical surface aerator such that one-half of the tank volume is aerobic with the DO concentration varying from 0 to 2.0 mg/L. For the information given below, determine the effluent NH_4-N (assuming 1.5 safety factor) and NO_3-N concentrations.

Parameter	Unit	Value
Ditch volume	m^3	4600
MLSS	mg/L	3500
Temperature	°C	10
BOD	mg/L	
Wastewater 1		250
Wastewater 2		220
Wastewater 3		200
nbVSS	mg/L	80
TKN	mg/L	40
TSS	mg/L	220
VSS	mg/L	210

Note: Wastewater 1, 2, or 3 to be selected by instructor.

8–35 Given the following wastewater characteristics, design an SBR system using two tanks, to produce an effluent NO_3-N and NH_4-N concentration of 6 mg/L and 1.0 mg/L, respectively. Assume that the aeration, settle, and decant times per cycle are 2.0, 1.0, and 0.5 h, respectively, and the MLSS concentration is 4000 mg/L. Determine (a) the fill volume fraction, (b) the volume of each SBR tank, (c) the decant pumping rate, and (d) the nitrification safety factor. Assume the aeration DO concentration is 2.0 mg/L and only anoxic mixing occurs during the fill period.

Parameter	Unit	Value
Flowrate	m^3/d	5000
BOD	mg/L	250
rbCOD	mg/L	50
nbVSS	mg/L	120
TKN	mg/L	
Wastewater 1		45
Wastewater 2		40
Wastewater 3		35
TSS	mg/L	220
VSS	mg/L	210
Temperature	°C	12

Note: Wastewater 1, 2, or 3 to be selected by instructor.

8–36 Exogenous carbon is to be added to a post anoxic tank in a Bardenpho process to remove 5 mg/L NO_3-N based on the influent flowrate to the tank. Compare the carbon dose needed in mg COD/L and mg/L of substrate for methanol, acetate, and ethanol. Assume a synthesis yield coefficient of 0.25, 0.40, and 0.36 g VSS/g COD removed under anoxic conditions for methanol, acetate, and ethanol, respectively. (Ignore the amount of exogenous carbon added that is contained in the effluent flow from the anoxic tank).

8–37 Acetate is to be added to a post anoxic tank in a Bardenpho process to decrease the NO_3-N concentration from an influent value of 6.0 mg/L to 0.30 mg/L in the anoxic tank effluent. For System 1, 2, or 3 below (to be selected by the instructor) determine (a) the acetate consumptive ratio in g COD/g NO_3-N removed, (b) the amount of NO_3-N reduced in mg/L (normalized to the tank influent flowrate) due to the substrate release and electron acceptor demand from endogenous decay, (c) the post anoxic tank effluent acetate concentration in mg/L, (d) the required acetate dose in mg COD/L and mg/L acetate (normalized to the influent flowrate), (e) the amount of acetate required per day in kg/d and the increase in NH_4-N concentration across the postanoxic tank.

Note: Wastewater 1, 2, or 3 to be selected by instructor.

Determine (a) the estimated effluent soluble phosphorus concentration for the biological phosphorus-removal process and (b) the phosphorus content (in percent on a dry weight basis) of the waste sludge. What process changes would you recommend to improve the amount of phosphorus removal?

8–39 An A^2O process is operated with a 12 d SRT and achieves the following effluent nutrient concentrations with internal and return activated sludge (RAS) recycle ratios of 3.0 and 0.5, respectively.
Effluent soluble P concentration = 0.50 mg/L
Effluent NO_3-N concentration = 5.0 mg/L
Assuming that the influent wastewater characteristics and SRT remain the same, determine (a) the change in effluent soluble phosphorus and NO_3-N concentrations if the internal recycle ratio is changed to 2.0, 2.5, or 2.8 (to be selected by instructor) and the RAS ratio is increased to 1.0 and (b) how much additional influent rbCOD is consumed by nitrate fed to the anaerobic zone.

8–40 Two 20-m diameter circular clarifiers are used for liquid-solids separation for an air activated sludge system. The MLSS concentration is 3000 mg/L and the return activated sludge recycle ratio is 50 percent. Assuming average solids loading rate values, within the range shown in Table 8–34, of 4, 5, or 6 kg/m^2·h (as selected by instructor), determine the allowable average influent flowrate in m^3/d and the return MLSS concentration.

8–41 State whether the effluent phosphorus concentration for an A^{2}O system will increase, decrease, or remain the same for each of the following changes in the wastewater characteristics or process operating conditions. Refer to basic process fundamentals to explain the basis for your answer.

a. The SRT is increased.

b. The influent rbCOD concentration increases.

c. The clarifier effluent suspended solids concentration increases.

d. A higher NO_3-N concentration exists in the return activated sludge recycle.

e. The influent particulate BOD concentration increases.

8–42 Given the settling data in the following table from tests with mixed liquor from an activated sludge plant, determine the percent RAS recycle rate if the clarifier overflow rate is 0.82, 1.0, or 1.2 m/h (to be selected by instructor) and the RAS MLSS concentration is 10,500 mg/L. What will the recycle rate be if the RAS MLSS concentration is 15,000 mg/L?

	Sludge liquid/solids interface depth in column test as a function of time and initial mixed-liquor concentration					
	MLSS concentration, mg/L					
Time, min	1000	2000	3000	5000	10,000	15,000
0	0	0	0	0	0	0
10	117.1	90.5	41.2	17.1	4.9	3.0
20	189.0	167.1	84.1	34.1	10.1	6.1
30	192.1	182.9	127.7	50.9	14.9	9.1
40	193.0	188.1	156.1	68.0	20.1	11.9
50	193.0	189.0	166.2	85.1	25.9	14.0
60	193.9	189.9	172.0	102.1	31.1	15.9

Note: Data in table corresponds to the distance from the top of the settling column to the sludge interface at indicated time, cm.

8–43 Two secondary clarifiers are operating with an overflow rate of 1 m/h and the activated sludge tank MLSS concentration is 4000 mg/L. Based on sludge thickening tests, the interfacial settling velocity can be described by the following relationship:

$$V_i = V_o(e^{-kX})$$

where V_i = interfacial settling velocity, m/d
X = MLSS concentration, g/L
V_o = 172 m/d
k = 0.4004 L/g

a. Plot the solids flux due to thickening as a function of the MLSS concentration in g/L.

b. On the same curve draw the overflow rate operating flux line and show the operating state point.

c. Determine the solids flux rate and recycle ratio for operating the clarifiers at an underflow concentration of 10, 11, or 12 g/L (as selected by instructor).

d. Determine the MLSS concentration possible with only one clarifier in operation using the above underflow concentration. Indicate the new overflow rate operating flux line and operating state point.

8–44 A conventional activated sludge process with an aeration tank volume of 4600 m^3 is operated with a 6-d SRT and 2500 mg/L MLSS concentration, when treating the following wastewater after primary treatment:

Parameter	Unit	Value
Flowrate	m^3/d	15,000
BOD	mg/L	150
nbVSS	mg/L	35
TSS	mg/L	80
VSS	mg/L	68
TKN	mg/L	35

The system must be upgraded to treat additional flow and to provide nitrification to produce an effluent NH_4-N concentration of 1.0 mg/L. A 12-d SRT is selected and membrane separation will replace the secondary clarifier operation, due to limited space for additional aeration tanks. Assuming the same wastewater characteristics, and using the same aeration tank volume with an MLSS concentration of 8000, 10,000, or 12,000 mg/L (to be selected by instructor), determine (a) the new wastewater treatment flowrate possible, (b) the previous and new volumetric BOD loadings (kg/m^3 d), and (c) the membrane surface area needed assuming a flux rate of 20.0 $L/m^2 \cdot h$.

Attached Growth and Combined Biological Treatment Processes

WORKING TERMINOLOGY

Term	**Definition**
Attached growth aerobic process	Aerobic treatment processes in which the biomass responsible for treatment is attached to some type of medium (packing material).
Biofilm	A layer of biomass that develops on the surface of media used in attached growth biological processes.
Biological aerated filter (BAF)	An aerobic downflow or upflow submerged growth process that uses an inert media to support the growth of a biofilm for the removal of dissolved organic matter. Filtration also occurs for suspended solids removal.
Denitrification filter	An anoxic packed bed reactor that contains granular or synthetic media to support a biofilm for nitrate and nitrite reduction and to filter effluent suspended solids.
Diffusion limited substrate removal	The substrate removal rate in a biofilm is limited by the rate of diffusion across a stagnant layer between the biofilm and mixed bulk liquid and diffusion into the unmixed biofilm layer.
Fluidized-bed bioreactor (FBBR)	A submerged attached growth process that can be used for either aerobic or anaerobic applications where wastewater is fed upward to a bed of sand or activated carbon; the fluid velocity causes the bed to expand and form a biofilm that removes soluble organic matter.
Hybrid processes	Those processes that use a combination of attached-growth and suspended-growth processes.
Integrated fixed film activated sludge (IFAS)	An activated sludge process in which a portion of the biomass is maintained on fixed or suspended media that is separated from the reactor effluent by screening. Return activated sludge is required.
Moving-bed bioreactor (MBBR)	A submerged attached growth biological process in which most of the biomass is maintained on suspended media, which is separated from the reactor effluent by screening. No return activated sludge is used.
Packed bed filter	A process that makes use of biofilm microbial communities attached to fixed packing materials.
Oxygen limited substrate removal	Rate of substrate removal in a biofilm may be limited by the rate that oxygen can be supplied by diffusion from the bulk liquid. Higher bulk liquid DO concentrations than used in suspended growth processes must be provided to realize the full removal rate potential of an attached growth biofilm.
Recirculation rate	The rate at which treated wastewater is returned to the process influent to dilute the organic concentration and to provide more optimal hydraulics to maintain the viability of the microorganisms in nonsubmerged attached growth processes.

Term	Definition
Rotating biological contactor (RBC)	A fixed-film biological treatment device in which microorganisms are grown on circular plastic disks mounted on a horizontal shaft that rotates slowly while partially immersed in wastewater.
Submerged attached growth processes	Aerobic submerged fixed film processes involving three phases: a support material, the attached biofilm, and liquid to be treated.
Trickling filter	A nonsubmerged aerobic fixed-film biological reactor that uses rock or a plastic packing over which wastewater is distributed for treatment.
Trickling filter/activated-sludge process (TF/AS)	A sequential combined attached and suspended growth biological process in which the influent wastewater is treated in a highly loaded trickling filter prior to activated sludge treatment for production of a high quality effluent.
Trickling filter/solids-contact process (TF/SC)	A sequential combined attached and suspended growth biological process. The main differences between the TF/SC and TF/AS processes are in the trickling filter loading and activated sludge SRT values.

The concept of attached growth processes was introduced in Chap. 7, along with the fundamental mechanisms of mass transfer of substrate and electron acceptors into the biofilms that develop in attached growth systems. In this chapter, various aerobic attached growth processes used for wastewater treatment are introduced and discussed. Following a brief introduction to the general characteristics of attached growth processes, separate sections are devoted to (1) nonsubmerged attached growth aerobic processes, (2) sequential combined trickling filter-activated sludge processes, (3) activated sludge processes with various media for attached growth, (4) submerged attached growth aerobic processes with suspended media, (5) submerged fixed bed attached growth processes, and (6) attached growth processes used for biological denitrification.

9–1 INTRODUCTION TO ATTACHED GROWTH PROCESSES

To introduce attached growth processes, it will be helpful to review briefly the types of processes and their evolution, and to consider the importance of mass transfer on their performance.

Types of Attached Growth Processes

Attached growth aerobic processes can be grouped into five general categories as illustrated on Fig. 9–1: (1) nonsubmerged attached growth aerobic processes, (2) partially submerged attached growth aerobic processes, (3) sequential nonsubmerged attached growth-activated sludge process (4) submerged attached growth aerobic processes, and (5) activated sludge processes with biofilm carriers. Features that are common to each of these processes include:

1. Growth of the biomass on a fixed media
2. Removal of excess solids by sedimentation after solids sloughing off the fixed film media or by backwashing of the media
3. Need to provide oxygen by either air movement through the void volume in nonsubmerged processes or by air sparging into fixed or moving submerged media, or oxygenation of recycle flow in a fluidized bed reactor
4. Need to provide distribution and contact of the influent flow with the media surface area
5. Need for an underdrain or other methods of collecting the treated effluent

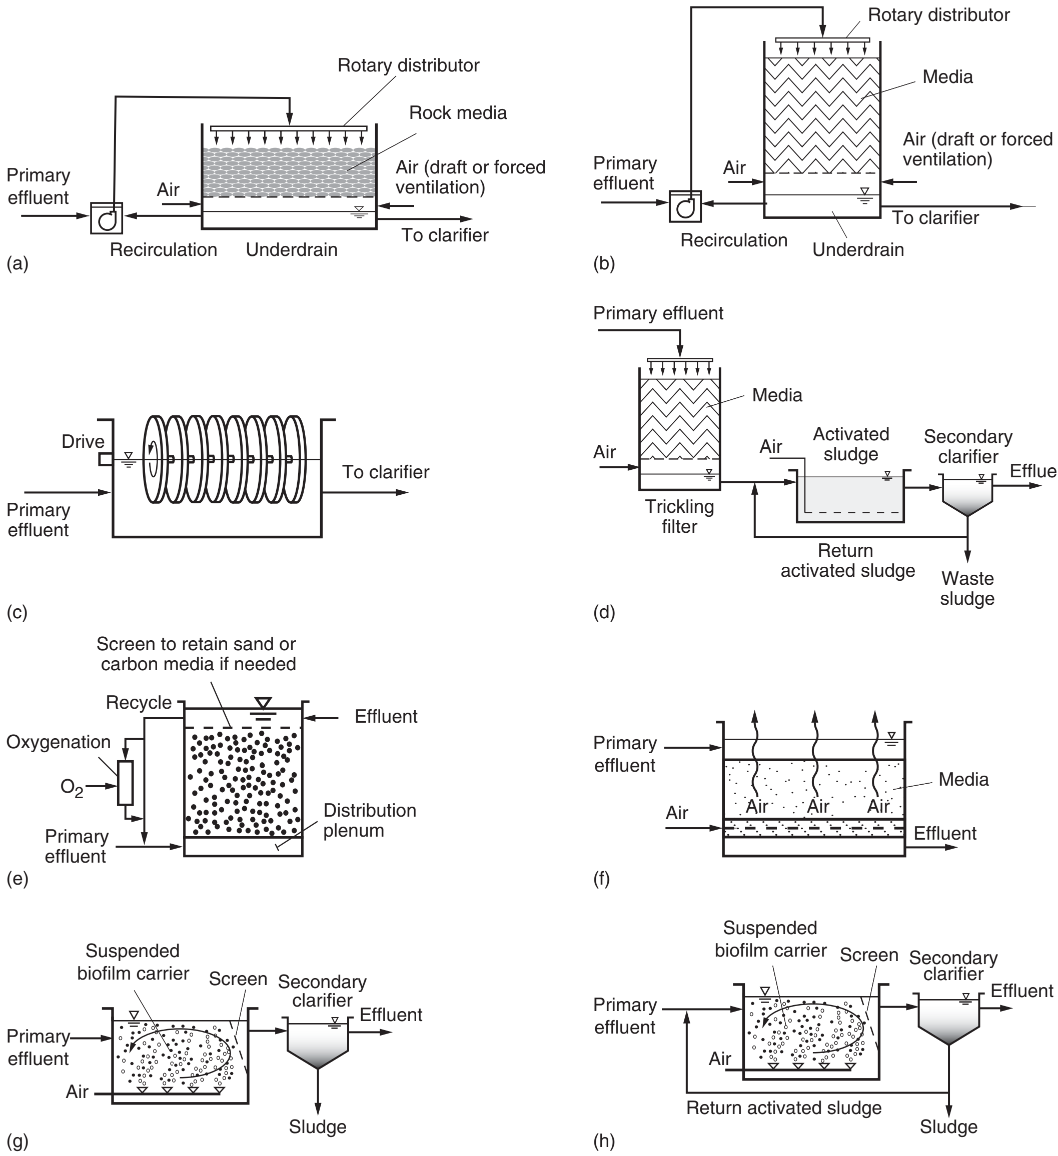

Figure 9–1

Schematics of common attached growth processes: (a) nonsubmerged attached growth shallow depth rock trickling filter, (b) nonsubmerged attached growth tower type trickling filter with plastic media, (c) nonsubmerged attached growth rotating biological contactor, (d) combined trickling filter/activated sludge process, (e) submerged upflow fixed media, (f) submerged downflow fixed media, (g) submerged moving bed attached growth bioreactor, and (h) combined submerged attached growth-activated sludge.

As the media size gets smaller, the area for biomass growth per unit of reactor volume increases and the reactor volume can become smaller. However, the oxygen transfer rate needed per unit volume increases, which cannot be supplied by forced air ventilation or natural draft air flow. Thus, a submerged media with air sparging is used in systems with media that have high surface area to volume ratios. A brief historical background is provided below for these processes.

Nonsubmerged Attached Growth Processes. The principal processes considered under this heading are the many variations of the trickling filter process [see Figs. 9–1(a) and (b)]. Trickling filters with rock packing [see Fig. 9–1(a)] have been a common, simple, and low-energy process used for secondary treatment since the late 1800s. A trickling filter is a non-submerged fixed film biological reactor using rock or plastic packing over which wastewater is distributed continuously. Treatment occurs as the liquid flows over the attached biofilm. The concept of a trickling filter grew from research at the Lawrence Experimental Station in Massachusetts, established in 1887, and the use of contact filters in England in the early 1890s (Alleman, 1982). Work at Lawrence confirmed wastewater treatment in an intermittent dosed sand filter, while treatment in watertight basins filled with broken stones with a cyclic operating mode was demonstrated in England. The bed was filled with wastewater from the top, and the wastewater was allowed to contact the packing for a short time. The bed was then drained and allowed to rest before the cycle was repeated. A typical cycle required 12 h (6 h of operation and 6 h of resting). The limitations of the contact filter included a relatively high incidence of clogging, the long rest period required, and the relatively low loading that could be used. Because of the clogging problems, larger packing was used until a rock size 50 to 100 mm (2 to 4 in.) was reached. Rotary distributor designs driven by water jets were developed at the Lawrence Experimental Station in 1894 to allow continuous uniform distribution of wastewater to the trickling filter (WEF, 2011).

In the early 1950s, Dow Chemical developed a plastic packing media, termed *Surfpak*, that enabled the use of taller filters (also known as biotowers), higher void volume, and better ventilation with less land area needs and improved process efficiency [see Fig. 9–1(b)] (Bryan, 1955). In the United States, plastic media has essentially replaced rock media in nonsubmerged attached growth processes; however, rock is still used in many parts of the world.

Partially Submerged Attached Growth Processes. In the mid-1960s, Allis Chalmers Corporation started investigating the use of metal rotating discs for wastewater treatment at the Jones Island treatment plant in Milwaukee. Soon after, they licensed a similar process termed *Bio-Disc* from a German company, which used polystyrene discs. However, in 1972 the process was passed to Autotrol Corporation, which introduced a new rotating biological contactor (RBC) media made from corrugated sheets of polyethylene. In the RBC attached growth process the packing is rotated in the wastewater treatment tank in contrast to pumping and applying the wastewater over a vertical static packing [see Fig. 9–1(c)].

The first RBC unit in the United States was for a small cheese factory in 1969 and its application became widespread in the United States through the 1970s (Alleman, 1982). However, problems with lower performance at design loadings, excess biomass accumulations on the discs due to the development of an undesirable type of biological growth, shaft breakage, and media deterioration on the disks has resulted in very few new installations over the last 20 years. Because of their relatively infrequent application, RBCs are not considered further in this chapter. The use of RBCs for the treatment of return flows is considered in Chap. 15. A complete discussion of the RBC process including design equations and examples may be found in the fourth edition of this textbook (Tchobanoglous et al., 2003). Process design guidelines are also provided in a U.S. EPA report on RBCs (U.S. EPA 1984).

Sequential Nonsubmerged Combined Attached Growth-Activated Sludge Process. Trickling filters have also been used before activated sludge in a coupled process to utilize the benefits of both processes, in terms of energy savings and effluent quality [see Fig. 9–1(d)]. The first sequential *trickling filter/activated sludge* systems were applied for the treatment of industrial wastewaters or high strength combined domestic/industrial wastewaters. The nonsubmerged attached growth process was used for partial BOD removal without solids clarification followed by activated sludge treatment for final treatment. The upstream attached growth process greatly improved the activated sludge settling characteristics with low SVIs, and the energy needed for BOD removal in the attached growth process was 20 to 40 percent of that needed per kg of BOD removal in the activated sludge process (Biesinger et al., 1980). Other combined trickling filter processes are considered in Sec. 9–3.

Another sequential trickling filter and activated sludge system is the *trickling filter/solids contact process*, which was developed in the late 1970s from research in Corvallis, OR, aimed at a higher quality effluent after trickling filter treatment of domestic wastewater (Norris et al., 1982). In this case the trickling filter was designed to remove most of the soluble BOD, and was followed by an aerated solids contact channel also receiving return activated sludge from secondary clarifiers. The primary purpose of the aerated solids contact channel was to flocculate trickling filter effluent suspended solids in the activated sludge.

Submerged Attached Growth Aerobic Processes. Beginning in the 1970s and extending into the 1980s, a new class of aerobic attached growth processes became established alternatives for biological wastewater treatment. These are upflow, downflow, and fluidized bed reactors with fixed or moving media that do not use secondary clarification or sparged aeration reactors. Work by Jeris et al. (1977) developed an upflow fluidized bed reactor that was applied for BOD removal [see Fig. 9–1(e)] and also for denitrification in an anoxic reactor. The first downflow submerged fixed media bed system [see Fig. 9–1(f)] using a fired clay media was developed from research work in Paris, France (Leglise et al., 1980). Later, upflow submerged fixed media bed systems were developed. In the late 1980s a moving bed bioreactor (MBBR), containing a mixed and aerated high density polyethylene biofilm media in a submerged horizontal flow tank [see Fig. 9–1(g)] was developed in Norway (Ødegaard, 2006).

The unique advantage of the submerged attached growth system is the small footprint required with an area requirement that is a fraction (one-fifth to one-third) of that needed for activated sludge treatment. Other advantages compared to activated sludge are the ability to handle dilute wastewaters and the avoidance of activated sludge settling concerns. Though they are more compact, their capital costs are generally higher than that for activated sludge treatment. In addition to BOD removal, submerged attached growth processes have also been used for tertiary nitrification and denitrification following suspended or attached growth nitrification.

Activated Sludge Processes With Fixed Film Carriers. The placement of material for attached growth in the aeration tank of the activated sludge process dates back to the 1940s with the Hays and Griffith processes (WEF, 2011), in which cement asbestos or wood baffles were added to activated sludge aeration tanks. Present day designs use more engineered materials and include the use of synthetic media that are suspended in the aeration tank with the mixed liquor, fixed synthetic material placed in portions of the aeration tank, and submerged RBCs. This combined attached growth/activated sludge process [see Fig. 9–1(h)] has also been referred to as a *hybrid* process or *integrated fixed-film activated sludge* (IFAS) process. The advantages claimed for these activated sludge process enhancements are as follows:

1. Increased treatment capacity
2. Greater process stability

3. Reduced sludge production
4. Enhanced sludge settleability
5. Reduced solids loadings on secondary clarifier
6. No increase in operation and maintenance costs

Mass Transfer Limitations in Attached Growth Processes

A significant process feature of attached growth processes in contrast to activated sludge treatment is the fact that the performance of biofilm processes is often diffusion limited. Substrate removal and electron donor utilization occurs within the depth of the attached growth biofilm and subsequently the overall removal rates are a function of diffusion rates and the electron donor and electron acceptor concentrations at various locations in the biofilm. By comparison, the process kinetics for the activated sludge process are generally characterized by the bulk liquid concentrations.

The diffusion-limited concept is especially important when considering the measurable bulk liquid DO concentrations on attached growth process biological reaction rates. Where a DO concentration of 2 to 3 g/m^3 is generally considered satisfactory for most suspended growth aerobic processes, such low DO concentrations can be limiting for attached growth processes. For uninhibited nitrification in the biofilm a much higher DO concentration may be required, as shown in Sec. 7–7, depending on the ammonia-N concentration.

The concept of diffusion limitations on nitrification rates and the ability to develop anaerobic layers within the biofilm may be exploited to accomplish both nitrification and denitrification in attached growth processes with positive bulk liquid DO concentrations. Investigators have shown how aerobic and anaerobic layers can be developed in the biofilm to accomplish nitrogen removal by nitrification and denitrification (Chui et al., 1996, Richter et al., 1994, and Meaney et al., 1994).

9–2 NONSUBMERGED ATTACHED GROWTH PROCESSES

Trickling filters and variants are the principal nonsubmerged attached growth processes used for aerobic biological treatment of wastewater. The objective of this section is to consider the fundamentals of the trickling process, important design considerations, and the implementation of trickling filters for BOD removal and nitrification. Topics considered in this section include (1) general process description, (2) trickling filter classification and application, (3) advantages and disadvantages of trickling filters, (4) physical facilities for trickling filters, (5) operational considerations (6) process analysis for BOD removal, (7) process analysis for BOD removal and nitrification design, and (8) process analysis for tertiary nitrification design. The first series of topics (1 through 5) deal with a general description of the characteristics and physical features of trickling filters. The focus of the last three topics (6, 7, and 8) is with the important process analysis considerations for trickling filters and their application for the removal of BOD and nitrification with or following BOD removal.

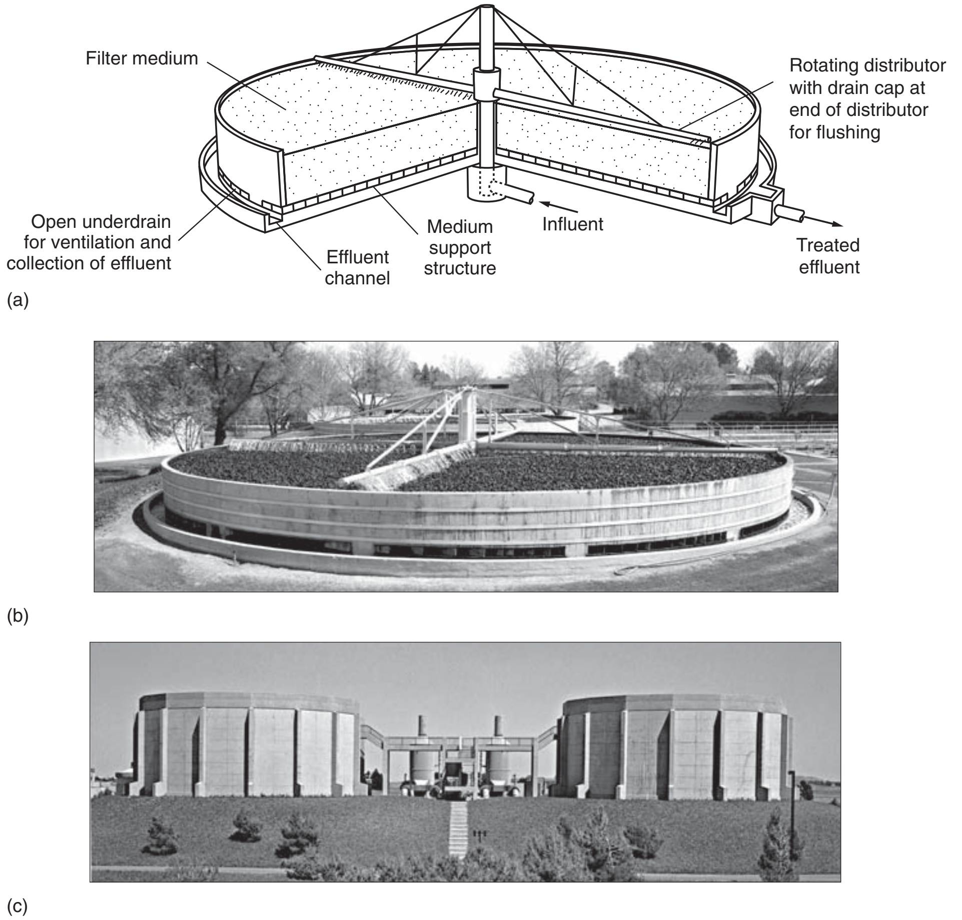
General Process Description

As noted previously, the trickling filter is a nonsubmerged fixed film biological reactor using rock or plastic packing over which wastewater is distributed continuously. The physical features and functional description of the trickling filter process are introduced in this section, and considered further subsequently.

Physical Features. The three principal features of trickling filters, as illustrated on Fig. 9–2(a), are (1) the filter media, (2) the wastewater distribution system, and (3) the underdrain system.

Figure 9–2

Typical trickling filters: (a) cutaway view of a rock trickling filter (b) view of conventional rock-filled trickling filter, and (c) view of tower trickling filters with plastic filter media.



Filter Media. The ideal filter packing is a material that has a high specific surface area (m^2 exposed surface/m^3 bulk volume), is low in cost, has a high durability, has a high enough porosity to avoid clogging, and allows good air ventilation by natural draft or low pressure blowers. The media serves as a structure for the attachment and growth of a biofilm. Treatment occurs as the liquid flows over the attached biofilm. Many conventional trickling filters using rock as the packing material [see Fig. 9–2(b)] have been converted to plastic packing to increase treatment capacity. Virtually all new trickling filters in the United States are now constructed with plastic packing in a tower arrangement [see Fig. 9–2(c)]. Primary clarification is used before application of wastewater to the trickling filter media to prevent clogging, although in some cases primary clarification has been omitted where fine screens are used.

Distribution System. The distributor is used to apply the wastewater to be treated uniformly over the surface of the filter media. The flow-driven rotary distributor for trickling filtration has become a standard for the process because it is reliable and easy to maintain. A distributor consists of two or more arms that are mounted on a pivot in the center of the filter and revolve in a horizontal plane [see Fig. 9–2(b)]. The arms are hollow and contain nozzles through which the wastewater is discharged over the filter bed. The distributor assembly may be driven either by the dynamic reaction of the wastewater discharging from the nozzles or by an electric motor.

Underdrain System. The functions of the underdrain system are twofold: (1) to collect wastewater that has passed through the filter, along with any biofilm that has sloughed off from the media, and (2) to provide an open area for the movement of air, either by natural draft or by forced air, needed for treatment of the applied wastewater.

Functional Description. Functionally, trickling filter media is covered with a very visible *biofilm* as a result of the BOD removal. In the literature, the biofilm is often identified as a *slime layer (*also a *zoogleal film)*, especially in those cases where an especially thick slimy biofilm layer develops. Soluble substrates and dissolved oxygen diffuse into the biofilm to support biomass growth. During the time when the wastewater flow is not applied or the *resting period*, oxygen continues to diffuse into the biofilm. Colloidal and particulate substances are removed by attachment and trapping in the biofilm. Effluent solids that become detached from the biofilm support are removed in a secondary clarifier, but clarifier underflow solids are not recycled to the trickling filter as they are in the activated sludge process. Recirculation of the trickling filter effluent to the trickling filter influent is done to maintain wetting of the media at low flows, and because it also enhances the supply of oxygen and treatment performance.

Biofilm Development. Depending on operating conditions, the thickness of the biofilm can reach 10 mm. In the outer portions of the biofilm (0.1 to 0.2 mm), the organic material is degraded by aerobic microorganisms. As the microorganisms grow and the biofilm thickness increases, oxygen is consumed before it can penetrate the full depth, and an anaerobic environment is established near the surface of the packing. As the biofilm thickness increases, the substrate in the wastewater is used before it can penetrate the inner depths of the biofilm, where the biofilm then enters an endogenous respiration state and lose their ability to cling to the packing surface.

Sloughing. When the microorganisms can no longer cling to the media, the applied liquid washes the biofilm off the packing, and a new biofilm layer starts to grow. The phenomenon of losing a portion of a biofilm layer is called *sloughing* and is primarily a function of the organic and hydraulic loading on the filter. The hydraulic loading affects the shear velocities, and the organic loading affects the rate of metabolism and rate of biofilm growth. Methods to control the hydraulic loading and sloughing are discussed subsequently.

Process Microbiology. The biological community in the biofilm is very diverse and includes aerobic and facultative bacteria, protozoan, fungi, and algae. Higher life forms, such as worms, insect larvae, and snails, are also present. Facultative bacteria are the predominating organisms in trickling filters, and decompose the organic material in the wastewater along with aerobic and anaerobic bacteria. *Achromobacter, Flavobacterium, Pseudomonas,* and *Alcaligenes* are among the bacterial species commonly associated with the trickling filter. The fungi present are also responsible for waste stabilization, but their role is usually important only under low-pH conditions or with certain industrial wastes. At times, their growth can be so rapid that the filter clogs and ventilation becomes restricted. Among the fungi species that have been identified are *Fusazium, Mucor, Pencillium, Geotrichum, Sporatichum*, and various yeasts (Hawkes, 1963; Higgins and Burns, 1975). For low-loaded trickling filters where little organic substrate remains nitrifying bacteria will be established on the media. At higher organic substrate concentrations the heterotrophic bacteria outcompete the nitrifying bacteria for growth on the media surface area due to their faster growth rates and higher biomass yields.

Filamentous Bacteria. When adverse dissolved oxygen conditions prevail within the biofilm due to high organic loading, the filamentous bacteria forms *Sphaerotilus natans* and *Beggiatoa* will be found. The *Beggiatoa* are favored due to their ability to oxidize hydrogen sulfide and other reduced organic substances that can be produced within anaerobic layers in the depth of the biofilm.

Presence of Higher Forms. Higher life forms, such as protozoa, worms, snails, and insects feed on the biological film. The protozoa in the filter are predominantly of the ciliate group, including *Vorticella, Opercularia*, and *Epistylis* (Hawkes, 1963; Higgins and Burns, 1975). Their function is to feed on the biological films and free bacteria to decrease effluent turbidity and help keep the film in a higher growth state. Snails are especially troublesome in trickling filters used mainly for nitrification, where they have been known to consume enough of the nitrifying bacteria to significantly reduce treatment efficiency (Timpany and Harrison, 1989).

Presence of Algae. Algae can grow only in the upper reaches of the filter where sunlight is available. *Phormidiun, Chlorella*. and *Ulothrix* are among the algae species commonly found in trickling filters (Hawkes, 1963; Higgins and Burns, 1975). Generally, algae do not take a direct part in waste degradation, but during the daylight hours they add oxygen to the percolating wastewater. From an operational standpoint, the algae may be troublesome because they can cause clogging of the media surface, which produces odors.

Trickling Filter Classification and Applications

Trickling filters are often classified according to the applied organic loading rates expressed as kg BOD applied/m^3 bulk media volume·d (in US Customary units as lb BOD/1000 ft^3·d). Trickling filter applications and loadings, based on historical terminology developed originally for rock filter designs, are summarized in Table 9–1. As shown in Table 9–1, trickling

Table 9–1

Trickling filter process applications and representative design parameter when treating primary effluent[a]

Design parameter	Unit	Low rate BOD removal	High rate BOD removal	High rate BOD removal	BOD removal and nitrification	Partial BOD removal
BOD removal efficiency	%	80–90	80–90	70–90	85–90	40–70
Type of packing		Rock	Rock	Plastic	Plastic (P)/rock (R)	Plastic
Ventilation	Type	Natural	Forced air	Forced air	Forced air	Forced air
Organic loading	kg BOD/m^3·d (lb BOD/10^3 ft^3·d)	0.08–0.3 (5–20)	0.6–1.6 (40–100)	0.6–2.4 (50–150)	0.08–0.4 (5–25)	1.6–3.5 (100–220)
Hydraulic loading	m^3/m^2·d (gal/ft^2·d)	1–4 (25–100)	4–40 (100–1000)	15–75 (350–1850)	5–16 (125–400)	40–100 (1000–2500)
Recirculation ratio	Q_R/Q	0–1	1–2	1–2	1–2	0–2
Depth	m (ft)	1–2.5[b] (3–8)	1–2.5[b] (3–8)	3–12 (8–40)	P, 3–12 (8–40) R, 1–2.5 (3–8)	0.9–6 (3–20)
Effluent quality	BOD, mg/L	<30	<30	<30	<20	>30
	NH_4-N, mg/L	<5	>5	>5	<3

[b] Depth is limited due the weight of the rock.

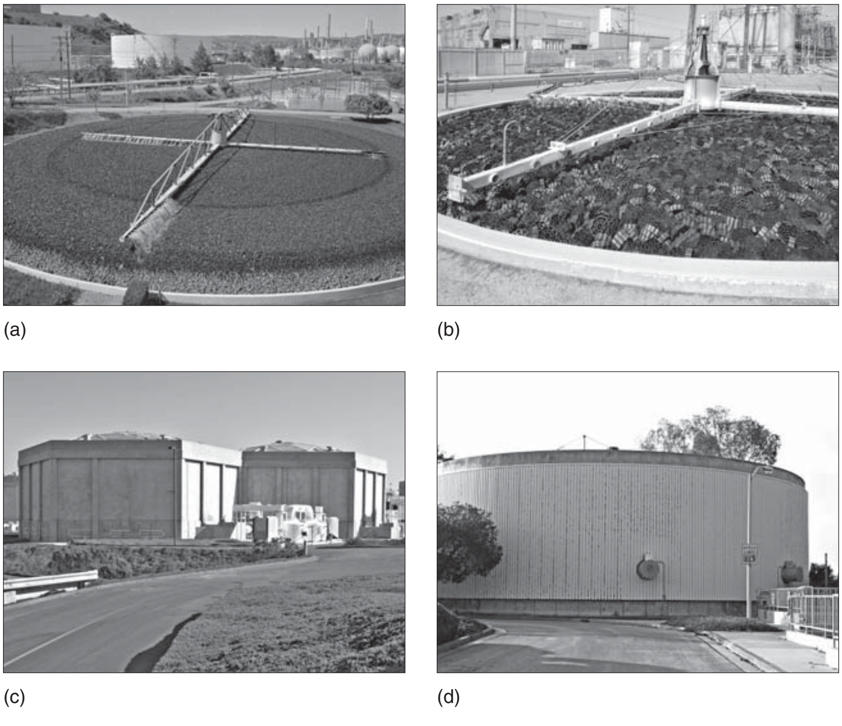
Note: kg/m^3·d × 62.4280 = lb/10^3 ft^3·d

m^3/m^2·d × 24.5424 = gal/ft^2·d

filter applications and the corresponding loading rates will vary depending on whether the treatment objective is (a) BOD removal with natural draft aeration, (b) BOD removal with forced draft aeration, (c) BOD removal and nitrification with forced draft aeration, and (d) partial BOD removal, or *roughing* treatment with forced draft aeration. Each type of loading is considered briefly in the following discussion.

BOD Removal with Natural Draft Aeration. Historically, rock trickling filters have been designed and operated with natural draft aeration. Because of low air movement during parts of the day when the temperature of the wastewater and air are within 1.7°C (3°F) of each other, the organic loading rates were low. These filters are often identified in the literature as *low rate* filters. Although relatively simple, a low rate filter is a highly dependable device that produces an effluent of consistent quality with an influent of varying strength. Low-rate filters with rock as the filter medium are usually operated without recirculation, although some recirculation has been used to keep the filters moist during low flow periods. Circular filters are the most common shape but rectangular and polygonal shapes have been used. In some cases, filters have been constructed without a surrounding enclosure [see Fig. 9–3(a), see also Fig. 7–15 in Chap. 7]. Often rock is replaced with plastic packing material [see Fig. 9–3(b)].

At lower organic loading rates, in the range of 0.07–0.25 kg $\text{BOD/m}^3\cdot\text{d}$, secondary treatment is achieved with 85 to 90 percent BOD removal. In most low-rate filters, only the top 0.6 to 1.2 m (2 to 4 ft) of the filter packing will have appreciable biofilm. As a result, the lower portions of the filter may be populated by autotrophic nitrifying bacteria, which oxidize ammonia nitrogen to nitrite and nitrate forms. Heterotrophic bacteria, with higher yield coefficients and faster growth rates, are more competitive than nitrifying bacteria for space on the fixed film packing. Thus, significant nitrification only occurs after the BOD concentration is reduced appreciably. Based on soluble BOD, Harremöes (1982) concluded that a concentration of less than 20 mg/L is needed to initiate nitrification. Low rate filters are seldom used these days, primarily due to odor issues and space constraints.



(a) (b) (c) (d)

Figure 9–3

Typical examples of trickling filters: (a) conventional shallow-depth, rock trickling filter without containment structure (see also Fig. 7–15 in Chap. 7), (b) conventional shallow-depth filter in which the original rock media (see Table 9–2) has been replaced with random pack plastic media (see Table 9–2), (c) multisided tower trickling filter employing plastic media (air pollution control equipment shown in foreground), and (d) tower trickling filter with fans for forced air aeration located around periphery of the filter.

BOD Removal with Forced Draft Aeration. Significantly higher organic loading rates (see Table 9–1) can be achieved with forced draft aeration. Although either rock or plastic packing can be used, the current trend is to use a plastic packing material in tall circular towers [see Figs. 9–3(c) and (d)]. The use of plastic packing allows for the construction of deeper filters with less land area required. Recirculation of the trickling filter effluent permits higher organic loadings, provides higher dosing rates on the filter to improve the liquid distribution and better control of the biofilm thickness, provides more oxygen in the influent wastewater flow, and returns viable organisms [see Figs. 9–4(a) and (b)]. It should be noted that other recirculation patterns have been used (Tchobanoglous et al., 2003).

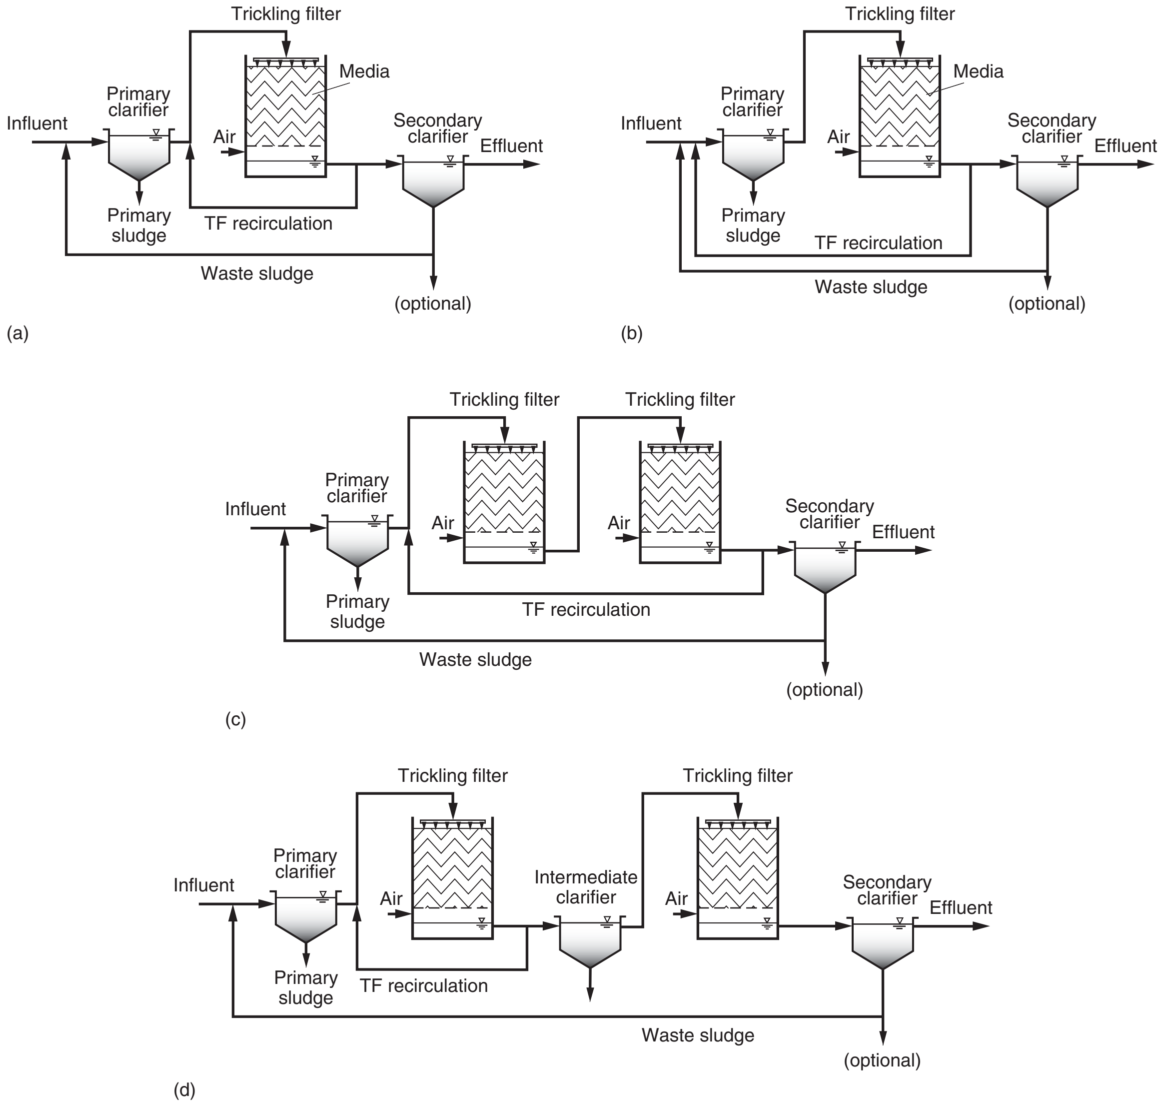


Figure 9–4

Typical trickling filter process schemes: (a) single trickling filter with waste sludge to the primary clarifier, (b) single trickling filter with recirculation and waste sludge to the primary clarifier, (c) two-stage trickling filter with waste sludge to the primary clarifier, and (d) two-stage trickling filter with intermediate clarifier. Note that many other flow schemes have been used (Tchobanoglous et al., 2003).

Recirculation also helps prevent ponding in the filter and to reduce the nuisance from odors and flies.

BOD Removal and Nitrification with Forced Draft Aeration. Both BOD removal and nitrification can be accomplished in rock or plastic packing trickling filters operated at reduced organic loading rates (Stenquist et al., 1974, Parker and Richards, 1986). As the BOD loading rate is decreased to what has been historically referred to as a *low-rate* trickling filter, as discussed above, nitrification also occurs in the same trickling filter or in the second stage of a system with two trickling filters in series [see Figs. 9–4(c) and (d)]. Plastic or rock media may be used in these trickling filters.

The hydraulic loading decreases with lower organic loadings. At very low hydraulic loading rates problems can occur due to improper media wetting and filter fly growth, unless the design adequately addresses filter effluent recirculation flows. Recirculation ratios (Q_R/Q) used range from 0.5 to 4.0. Vertical-flow media require an average total hydraulic loading exceeding 1.8 $m^3/m^2 \cdot h$ to maximize wetting and the BOD removal efficiency, and total hydraulic loadings in the range 0.4 to 1.1 $m^3/m^2 \cdot h$ have been used in shallow towers with cross-flow media.

Partial BOD Removal with Forced Draft Aeration. At organic loading rates typically greater than 1.6 kg $BOD/m^3 \cdot d$, trickling filters have been used to achieve partial BOD removal in the range of 50 to 70 percent. These highly loaded filters have been identified in the literature as *roughing* (or *high-rate*) filters. Most roughing filters are designed using plastic media (WEF, 2011). A roughing filter can be an attractive alternative for the pretreatment of modest to high strength industrial wastewaters. One of the advantages of roughing filters is the low energy requirement for BOD removal of higher strength wastewaters as compared to activated sludge aeration. Because the energy required is only for pumping the influent wastewater and recirculation flows, the amount of BOD removal per unit of energy input can increase as the wastewater strength increases until more recirculation is needed. The energy requirement for a roughing application may range from 2 to 5 kg BOD applied/kWh versus 1.2 to 2.4 kg BOD/kWh for activated sludge treatment.

Advantages and Disadvantages of Trickling Filters

Trickling filters, as noted above, have been used as aerobic attached growth processes for BOD removal only, combined BOD removal and nitrification, and for tertiary nitrification after secondary treatment by suspended growth or attached growth processes. The advantages and disadvantages of the use of trickling filters are as follows.

Advantages. The principal advantages claimed for trickling filters over the activated sludge process are as follows:

1. Less energy required
2. Simpler operation with no issues of mixed liquor inventory control and sludge wasting
3. No problems of bulking sludge in secondary clarifiers
4. Better sludge thickening properties
5. Less equipment maintenance needs
6. Better recovery from shock toxic loads

Disadvantages. Many disadvantages often cited for trickling filters, such as a poorer effluent quality in terms of BOD and TSS concentrations, greater sensitivity to lower temperatures, odor production, and uncontrolled solids sloughing events, are related more to the specific process and final clarifier designs than to the actual process capabilities

(WEF, 2011). In general, the actual limitations of the processes are the difficulty in accomplishing biological nitrogen and phosphorus removal compared to single-sludge biological nutrient removal suspended growth designs, and the production of an effluent with a higher suspended solids concentration than activated sludge treatment.

Physical Facilities for Trickling Filters

Factors that must be considered in the design of trickling filters include (1) type and physical characteristics of filter packing to be used, (2) type and dosing characteristics of the distribution system, and (3) configuration of the underdrain system. The dosing rate, the provision of adequate airflow (i.e., ventilation) by either natural or forced air and settling tank design are considered under design considerations.

Filter Packing Material. Typical trickling filter packing materials, including rock, random pack plastic media, and cross- and vertical-flow plastic bundles, are shown on Fig. 9–5. Redwood slates have also been used in the past, but are seldom used today. The physical characteristics of commonly used trickling filter packings, including those shown on Fig. 9–5, are reported in Table 9–2. Since the 1960s, plastic packing material, either cross-flow or vertical-flow, has become the packing of choice in the United States.

Rock. Where locally available and cost effective, rock media may be used. The most suitable material is rounded river rock or crushed stone, graded to a uniform size so that 95 percent is within the range of 75 to 100 mm (3 to 4 in.). The specification of size uniformity is a way of ensuring adequate pore space for wastewater flow and air circulation.

[b] C = BOD removal; N = tertiary nitrification; CN = combined BOD and nitrification.

Note: kg/m^3 × 0.06246 = lb/ft^3
m^2/m^3 × 0.305 = ft^2/ft^3

Plastic Packing. Plastic packing materials come in two forms: random pack and molded plastic bundles. A number of different random pack materials are available. Two different examples are illustrated on Figs. 9–5(b) and (c). The molded plastic packing bundles have the appearance of a honeycomb. Flat and corrugated sheets of polyvinyl-chloride are bonded together in rectangular modules. The sheets usually have a corrugated surface for enhancing slime growth and retention time. Each layer of modules is turned at right angles to the previous layer to further improve wastewater distribution. The two basic types of corrugated plastic sheet packing are cross- and vertical-flow [see Figs. 9–5(d), (e), and (f)].

Both types of plastic sheet packings are reported to be effective in BOD and TSS removal over a wide range of loadings (Harrison and Daigger, 1987; Aryan and Johnson, 1987). Biotowers as deep as 12 m (40 ft) have been constructed using plastic packing, with depths in the range of 6 m (20 ft) being more common. In biotowers with vertical plastic packing, cross-flow packing can be used for the upper-most layers to enhance the distribution across the top of the filter. The high hydraulic capacity, high void ratio, and resistance to plugging offered by these types of packing can best be used in a high-rate type filter.

Plastic packing has the advantage of requiring less land area for filter structure than rock due to the ability to use taller trickling filters. Grady et al. (1999) noted that when loaded at similar low organic loadings rates (less than 1.0 kg BOD/m^3·d), the performance of rock filters and plastic packing filters was similar. At higher organic loading rates, however, the performance of filters with plastic packing is superior. The higher porosity, which provides for better air circulation and biofilm sloughing, is a likely explanation for the improved performance.

Strength and Durability of Packing Materials. Other important characteristics of filter packing materials are strength and durability. Durability may be determined by the sodium sulfate test, which is used to test the soundness of concrete aggregates (U.S. EPA, 1974).

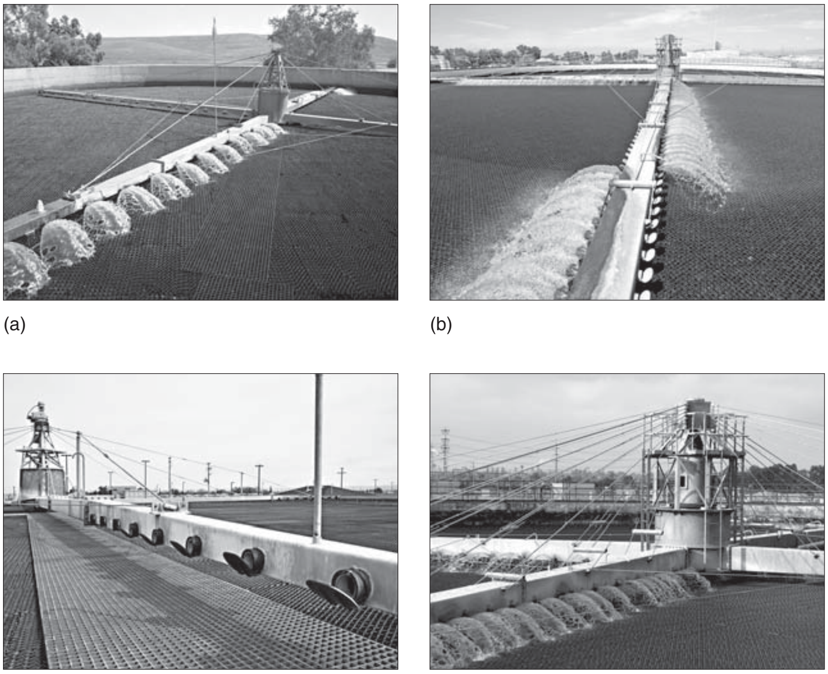
Because of the weight of the packing, the depth of rock filters is usually on the order of 2 m (6 ft). The low void volume of rock limits the space available for airflow and increases the potential for plugging and flow short-circuiting. Because of plugging, the organic loadings to rock filters are more commonly in the range of 0.3 to 1.0 kg BOD/m^3·d.

Distribution Systems. Distributors are manufactured for trickling filters with diameters up to 60 m (200 ft). Distributor arms may be of constant cross section for small units, or they may be tapered to maintain minimum transport velocity.

Flow Distribution Nozzles. Nozzles are spaced unevenly so that greater flow per unit of length is achieved with increasing length (and area) from the center. For uniform distribution over the area of the filter, the flowrate per unit of length should be proportional to the radius from the center [see Fig. 9–6(a)]. Headloss through the distributor is in the range of 0.6 to 1.5 m (2 to 5 ft). Forward-facing flow nozzles are also used to control the rotational speed of the rotary distributor [see Fig. 9–6(b) and (c)].

Fixed Nozzle Distribution Systems. Fixed-nozzle distribution systems consist of a series of spray nozzles located at the points of equilateral triangles covering the filter bed. A system of pipes placed in the filter is used to distribute the wastewater uniformly to the nozzles. Special nozzles having a flat spray pattern are used, and the pressure is varied systematically so that the spray falls first at a maximum distance from the nozzle and then at a decreasing distance as the head slowly drops. In this way, a uniform dose is applied over the whole area of the bed. Half-spray nozzles are used along the sides of the filter.

Distributor Drive Systems. Drive systems for trickling filter rotary distributors are of two types: (1) hydrostatic pressure and (2) a combination of hydrostatic pressure and electric



(a) (b) (c) (d)

Figure 9–6

Typical distributors used to supply wastewater to trickling filter packing: (a) view of two-arm tapered rectangular shaped rotary distributor for tower trickling filter, (b) view of top of tower trickling filter with four-arm rotary distributor (water jets on the left hand side are used to slow down the rotational speed of the distributor), (c) view of splash plates used to distribute water over media, and (d) view of variable speed electric motor drive for distributor arms.

motor drives. Historically, trickling filter distributor arms were driven with water pressure. One of the problems with the early pressure driven units was that a mercury seal was used around the distributor center column. Because mercury was released from seals that were occasionally blown out by excessive hydrostatic pressure, mechanical seals are now used on hydrostatic pressure driven distributor arms. Electric motor drives, both fixed and variable speed provide operational flexibility, and are almost always used with tower tricking filters with plastic packing [see Fig. 9–6(d)].

Other Important Features. Important features that should be considered in selecting a distributor are the ruggedness of construction, ease of cleaning, ability to handle large variations in flowrate while maintaining adequate rotational speed, and corrosion resistance of the material and its coating system. Drain caps should be provided at the end of the distribution arms for flushing, as needed. Clearance of 150 to 225 mm (6 to 9 in.) should be allowed between the bottom of the distributor arm and the top of the bed. This clearance permits the wastewater streams from the nozzles to spread out and cover the bed uniformly, and it prevents ice accumulations from interfering with the distributor motion during freezing weather.

Underdrains. The wastewater collection system in a trickling filter consists of underdrains that catch the treated wastewater and solids discharged from the filter packing for conveyance to the final sedimentation tank. The floor and underdrain slope to a central or peripheral drainage channel at a 1 to 5 percent grade. The effluent channels are sized to produce a minimum velocity of 0.6 m/s (2 ft/s) at the average daily flowrate (WPCF, 1988).

Underdrains for Rock Trickling Filter. Underdrains may be open at both ends, so that they may be inspected easily and flushed out if they become plugged. All underdrain channels should be designed to flow half full at the maximum anticipated hydraulic application rate. The underdrains also ventilate the filter, providing the air for the microorganisms that live in the filter slime, and they should at least be open to a circumferential channel for ventilation at the wall as well as to the central collection channel. All underdrain systems should be designed so that forced air ventilation can be added at a later date if filter operating conditions should change. The floor and underdrains must have sufficient strength to support the packing, slime growth, and the wastewater. The underdrain system for a rock filter usually has precast blocks of vitrified clay or fiberglass grating laid on a reinforced concrete subfloor [see Figs. 9–7(a), (b), and (c)]. The specific type of underdrain used will vary, depending on the location in the United States and from country to country.

Underdrains for Plastic Packing. The underdrain and support system for plastic packing consists of either a beam and column or grating. A typical underdrain system for a biotower filter is shown on Fig. 9–7(d). The beam and column system typically has precast concrete beams supported by columns or posts [see Fig. 9–7(e)]. The plastic packing is placed over the beams, which have channels in their tops to ensure free flow of wastewater and air. Air ventilation ports on a tower tricking filter are located around the periphery of the filter.

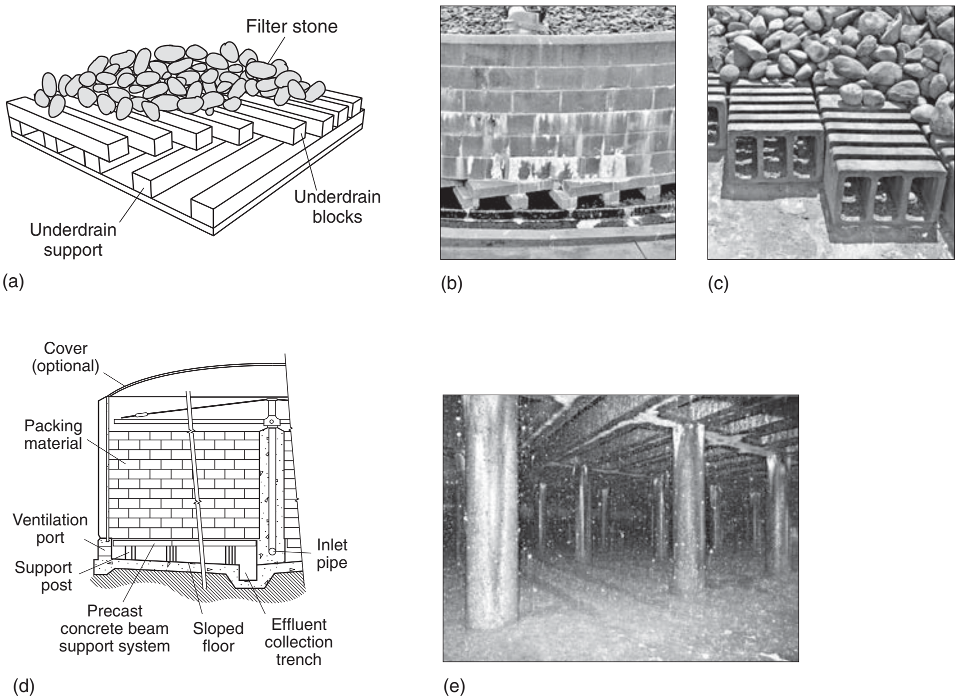
Design Considerations for Physical Facilities

Major design issues with trickling filters involve (1) providing an adequate dosing strategy and hydraulic load, (2) providing adequate airflow to meet oxygen requirements, (3) oxygen transfer, (4) pressure drop, (5) ponding, (6) odor control, and (7) control of predators. Each of these issues is considered below.

Hydraulic Application Rate. An adequate and uniform hydraulic application rate must be maintained to provide full wetting of the packing media, to promote efficient

Figure 9–7

Typical trickling filter underdrains: (a) schematic of underdrain for rock tricking filter, (b) view of concrete beam underdrain system for rock filter, (c) view of vitrified clay block underdrain system for rock trickling filter, (d) section through tower trickling filter (note ventilation port, media support sloped bottom, and effluent collection trench), and (e) view of underdrain plenum showing media support columns. [The crawl space between the media support and the floor is 1.25 m (4 ft) to allow for underdrain maintenance.]



treatment, to control the biofilm thickness, to minimize odors, and to minimize the nuisance *Psychoda* and *Anisopus* fly population. Sustained low hydraulic application rates and low dosing rates can result in excessive biofilm thickness that can lead to over weighting and collapse of plastic media packing and to excessive worm growth. The dosing rate is the depth of liquid discharged on top of the packing for each pass of the distributor. For higher distributor rotational speeds, the dosing rate is lower.

In the past, typical rotational speeds for distributors were about 0.5 to 2 min per revolution (WEF, 2000). With two to four arms, the trickling filter is dosed every 10 to 60 s. Based on the results from various investigators, it has been shown that reducing the distributor speed results in better filter performance. Hawkes (1963) found that rock trickling filters dosed every 30 to 55 min/rev outperformed a more conventional operation of 1 to 5 min/rev. Besides improved BOD removal, there were dramatic reductions in the *Psychoda* and *Anisopus* fly population, biofilm thickness, and odors. Similar advantages were found by Albertson and Davies (1984) from an investigation of reduced distributor speed. At a higher dosing rate, the larger water volume applied per revolution: (1) provides greater wetting efficiency, (2) results in greater agitation, which causes more solids to flush out of the packing, (3) results in a thinner biofilm, and (4) helps to wash away fly eggs. The thinner biofilm creates more surface area and results in a more aerobic biofilm.

Control of Biofilm Thickness. If the high dosing rate preferred to control the biofilm thickness is sustained the treatment efficiency may be decreased because the liquid contact time in the filter would be less. For low-loaded trickling filters, a daily intermittent high dose, referred to as a *flushing dose,* is used to control the biofilm thickness and solids inventory. A combination of a once per day high flushing rate and a lower daily sustained dosing rate is recommended as a function of the BOD loading as shown in Table 9–3 (WEF, 2011). The data in Table 9–3 can be used as guidance in establishing an appropriate

Table 9–3

A guideline for the trickling filter dosing rate as a function of BOD loading[a]

BOD loading, $kg/m^3 \cdot d$	Operating dose, mm/pass[b]	Flushing dose, mm/pass[b]
<0.4	25–75	100
0.8	50–150	150
1.2	75–225	220
1.6	100–300	300
2.4	150–450	450
3.2	200–600	600

[a] Adapted from WEF (2011).

[b] mm/pass represents the amount of liquid applied for each pass of each distributor arm.

dosing range. Optimization of the dosing rate and flushing rate and frequency is best determined from field operation. Flexibility in the distributor design is needed to provide a range of dosing rates to optimize the trickling filter performance.

Dosing Rate as a Function of the Hydraulic Loading Rate. The dosing rate is a function of the total hydraulic loading (influent flow plus recycle flow), the number of arms on the flow distributor, and the rotational speed of the distributor (WEF, 2011).

$$DR = \frac{(1 + R)(q)(10^3 \text{ mm/1 m})}{(N_A)(n)(60 \text{ min/h})} \tag{9–1}$$

where DR = dosing rate, mm/pass of distributor arm
n = rotational speed, rev/min
q = influent applied hydraulic loading rate, $m^3/m^2 \cdot h$
R = recirculation ratio
N_A = number of arms in rotary distributor assembly

The dosing rate has also been referred to as the SK value, which stands for *Spulkraft,* a term used in the German regulations to define dosing in the early 1980s. To achieve the suggested dosing rates, the speed of the rotary distributor can be controlled by: (1) reversing the location of some of the existing orifices to the front of the distributor arm [see Figs. 9–6(b) and (c)], (2) adding reversed deflectors to the existing orifice discharges, or (3) converting the rotary distributor to a variable-speed electric drive [see Fig. 9–6(d)] (Albertson, 1995). An advantage of the variable-speed electric drive is the wide range of operational flexibility it provides and the ease of controlling the dosing rate without having to change the distributor arm orifice discharge design.

Airflow. An adequate flow of air is of fundamental importance to maintaining aerobic conditions within the trickling filter biofilm to provide efficient treatment and to prevent odors. Natural draft has historically been the primary means of providing air flow for rock media filters, but it is not always adequate. Forced ventilation using low-head fans provides more reliable and controlled airflow.

Natural Draft. In the case of natural draft, the driving force for airflow is the temperature difference between the ambient air and the air inside the pores. If the wastewater is colder than the ambient air, the pore air will be cold and the direction of flow will be downward. If the ambient air is colder than the wastewater, the flow will be upward. The latter is less desirable from a mass transfer point of view because the partial pressure of oxygen (and thus the oxygen transfer rate) is lowest in the region of highest oxygen demand. In many areas in the United States, there are periods, especially during the summer, when essentially no airflow occurs through the trickling filter because temperature differentials are negligible.

Draft, which is the pressure head resulting from the temperature and moisture differences, may be determined from Eq. (9–2) (Schroeder and Tchobanoglous, 1976):

$$D_{\text{air}} = 353\left(\frac{1}{T_c} - \frac{1}{T_h}\right)Z \tag{9–2}$$

where D_{air} = natural air draft, mm of water
T_c = cold temperature, K
T_h = hot temperature, K
Z = height of the filter, m

A more conservative estimate of the average pore air temperature is obtained by using the log mean temperature, T_m for T_h in Eq. (9–2).

$$T_m = \frac{T_2 - T_1}{\ln (T_2/T_1)} \tag{9–3}$$

where T_2 = colder temperature, K
T_1 = warmer temperature, K

The volumetric air flowrate may be estimated by setting the draft equal to the sum of the headlosses that result from the passage of air through the filter and underdrain system (Albertson and Okey, 1988).

Where natural draft is used the following needs to be included in the design:

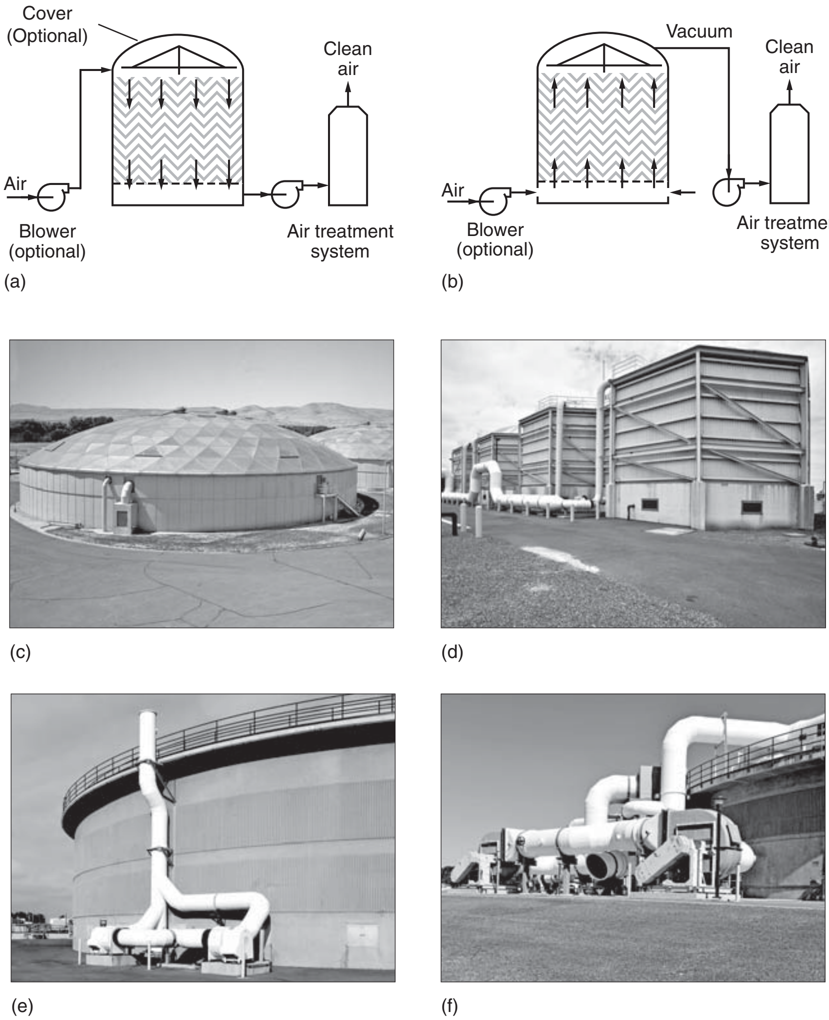
1. Underdrains and collecting channels should be designed to flow no more than half full to provide a passageway for the air.
2. Ventilating access ports with open grating types of covers should be installed at both ends of the central collection channel.
3. Large diameter filters should have branch collecting channels with ventilating manholes or vent stacks installed at the filter periphery.
4. The open area of the slots in the top of the underdrain blocks should be at least 15 percent of the area of the filter.
5. One square meter gross area of open grating in ventilating access ports and vent stacks should be provided for each 23 m^2 (250 ft^2) of filter area.

Forced Air. The use of forced or induced draft fans are recommended for trickling filter designs to provide a reliable supply of oxygen. As an approximation, an air flow of 0.3 $m^3/m^2 \cdot min$ (1 $ft^3/ft^2 \cdot min$) of filter area in either direction is recommended. The costs for a forced draft air supply are minimal compared to the benefits. For a 3800 m^3/d (1.0 Mgal/d) wastewater treatment flow the estimated power requirement is only about 0.15 kW (0.2 hp) (WEF, 2000). Both upflow and downflow forced-air aeration systems are used (see Fig. 9–8). A downflow direction is preferred as it provides contact time for treating odorous compounds released at the top of the filter and a richer air supply at the top where the oxygen demand is highest [see Figs. 9–8(a) and (c)]. If an upflow air direction is used, the trickling filter must be covered to collect odorous off gas [see Figs. 9–8(b) and (d)]. Covers also help to maintain water temperatures in the trickling filter. For applications with extremely low air temperature, it may be necessary to restrict the flow of air through the filter to keep it from freezing.

Forced air designs should provide multiple air distribution points by the use of fans around the periphery of the tower [see Figs. 9–3(d) and 9–8(e)] or the use of air openings

Figure 9–8

Examples of forced air aeration systems: (a) schematic of downflow forced-air aeration system, (b) schematic of upflow forced-air aeration system, (c) view of fan used to blow air into top of covered rock trickling filter, (d) view of covered tower trickling filter with air pulled up through filter by a vacuum withdrawal system leading to foul air treatment system, (e) view of large fans used to pull air through the tower trickling filter underdrain plenum and discharge it to the atmosphere, and (f) view of covered tower trickling filter with large fans used to blow air into the top of the filter and to withdraw air from the underdrain plenum for treatment.



below the packing material with suction from the top of the filter [see Fig. 9–8(d)]. The opening in the airflow distribution piping should be selected to provide equal airflow distribution. A pipe air flow velocity in the range of 1100 to 2200 m/h is typically used to further promote uniform airflow distribution (WEF, 2011).

Oxygen Transfer in Trickling Filters. Little has been done to quantify the amount of oxygen used in trickling filters and the actual oxygen transfer efficiency. The following formulations are based on earlier work by Dow Chemical during the development of plastic packing material for trickling filter applications. In developing these formulations for BOD removal applications, it was assumed that the oxygen transfer efficiency was about 5 percent. A more conservative transfer efficiency of 2.5 percent may be assumed as a higher dissolved oxygen concentration is desired in the gas-liquid interface to maximize nitrification efficiency (WEF, 2011). The required oxygen supply is given as follows:

BOD removal only:

$$R_o = (20\ \text{kg/kg})\,[0.80\,e^{-9L_B} + 1.2\,e^{-0.17L_B}](\text{PF}) \tag{9–4}$$

BOD removal and nitrification:

$$R_o = (40\,\text{kg/kg})[0.80e^{-9L_B} + 1.2e^{-0.17L_B} + 4.6N_{\text{ox}}/\text{BOD}](\text{PF}) \tag{9–5}$$

where R_o = oxygen supply, kg O_2/kg BOD applied
L_B = BOD loading to filter, kg BOD/m^3·d
N_{ox}/BOD = ratio of influent nitrogen oxidized to influent BOD, mg/mg
PF = Peaking factor, maximum to average load

The air application rate at 20°C and 1.0 atm is computed as follows. From Appendix B, the density of air at 20°C and 1.0 atm is 1.204 kg/m^3, and the percent of oxygen by weight in air is 23.18 percent. Thus, the volume of oxygen per kg of air is 3.58 m^3/kg {1/[(1.204 kg/m^3)(0.2318)]} and the required air flow is given by:

$$AR_{20} = \frac{(R_o)(Q)(S_o)(3.58\ \text{m}^3/\text{kg O}_2)}{(10^3\ \text{g}/1\ \text{kg})(1440\ \text{min/d})} \tag{9–6}$$

where AR$_{20}$ = air flowrate at 20°C and 1.0 atm, m^3/min
Q = wastewater flowrate, m^3/d
S_o = primary effluent BOD, g/m^3

The air flowrate is corrected for temperature and pressure according to the ideal gas law:

$$AR_T = AR_{20}\left(\frac{273.15 + T_A}{273.15}\right)\left(\frac{P_a}{P_b}\right) \tag{9–7}$$

where AR_T = air flowrate at ambient air temperature, °C
T_A = ambient air temperature, °C
P_a = atmospheric pressure, 1.0 atm (101.325 kPa)
P_b = atmospheric pressure at treatment plant site, atm (kPa)

A further correction to the calculated air flow is recommended for temperatures above 20°C to account for the lower oxygen saturation concentration at higher temperatures and the higher biological uptake rates in the filter. For each degree centigrade above 20°C the air flowrate is increase by 1 percent.

$$AR_{T>20°\text{C}} = AR_T\left(1 + \frac{T_A - 20}{100}\right) \tag{9–8}$$

Pressure Drop in Trickling Filters. The pressure drop through the packing is related to the superficial air velocity as follows:

$$\Delta P = N_p\left(\frac{v^2}{2g}\right) \tag{9–9}$$

where ΔP = total headlosses, kPa
g = acceleration of gravity, 9.81 m/s^2
v = superficial velocity, Q/A, m/s
N_P = tower resistance; number of velocity heads

The tower resistance term, N_p, is the sum of all the individual headlosses related to the air flow. Headloss occurs as air moves through the inlet, underdrain, and packing material. The packing loss in terms of number of velocity headlosses was developed by Dow Chemical for the original vertical packing:

$$N_p = 10.33(D)e^{(1.36 \times 10^{-5})(L/A)} \tag{9–10}$$

where N_p = packing headloss in terms of velocity heads
D = packing depth, m
L = liquid loading rate, kg/h
A = tower cross-section area, m^2

Table 9–4

Correction factors for computing headloss in nonvertical trickling filter packings based on Eq. (9–10)[a]

Packing	Specific surface, area, m^2/m^3	Correction factor
Rock	45	2.0
Plastic cross-flow	100	1.3
Plastic cross-flow	140	1.6
Plastic random	100	1.6

[a] Adapted from WEF (2010).

Although similar correlations have not been developed for other packing materials, recommended correction factors that can be used to obtain N_p values for other packing materials based on the value determined using Eq (9–10) are given in Table 9–4. To estimate the total headloss for the trickling filter, the value of N_p, computed using Eq. (9–10), is often multiplied by a factor of 1.3 to 1.5 to include inlet, underdrain, and other minor losses. The determination of airflow and pressure drop in trickling filters with forced aeration ventilation is illustrated in Example 9–1.

EXAMPLE 9–1 **Determine Trickling Filter Airflow Rate Requirements and Pressure Drop for Forced Ventilation** Determine the forced-ventilation air requirement and pressure drop in a trickling filter with cross-flow plastic packing designed for carbonaceous BOD removal, given the following design and operating information.

Wastewater characteristics:

1. Wastewater flowrate = 15,000 m^3/d (174 L/s)
2. Primary effluent BOD = 140 g/m^3
3. Warm month wastewater temperature = 20°C

Design assumptions:

1. BOD loading = 0.60 kg BOD/m^3·d (from Table 9–1)
2. Organic loading peaking factor = 1.4
3. Tower diameter = 20 m
4. Number of towers = 2
5. Depth of packing = 6.1 m
6. Headloss correction factor for inlet and other minor losses = 1.5
7. Headloss correction factor for cross-flow packing = 1.3 (see Table 9–4)
8. Air temperature = −7 to 28°C
9. Atmospheric pressure at treatment plant site = 1 atm

Solution

1. Determine the required oxygen supply rate using Eq. (9–4).

$$R_o = (20\text{ kg/kg})[0.80e^{-9L_B} + 1.2e^{-0.17L_B}](\text{PF})$$

$$L_B = 0.60\text{ kg BOD/m}^3\cdot\text{d}$$

$$\text{PF} = 1.4$$

$$R_o = 20[0.80e^{-9(0.60)} + 1.2e^{-0.17(0.60)}](1.4) = 41.6\text{ kg O}_2\text{/kg BOD applied}$$

2. Determine airflow rate for the given conditions.
   a. Using Eq. (9–6), determine the airflow rate at standard conditions

$$AR_{\mathrm{STD}} = \frac{R_o(Q)(S_o)(3.58\ \mathrm{m^3/kg\ O_2})}{(10^3\ \mathrm{g/1\ kg})(1440\ \mathrm{min/d})}$$

$$= \frac{(41.6\ \mathrm{kg/kg})(15{,}000\ \mathrm{m^3/d})(140\ \mathrm{g/m^3})(3.58\ \mathrm{m^3/kg\ O_2})}{(10^3\ \mathrm{g/1\ kg})(1440\ \mathrm{min/d})}$$

$$= 217\ \mathrm{m^3/min}$$

   b. Correct the air flowrate for temperature and pressure using Eq. (9–7).

$$AR_{TA} > AR_{\mathrm{STD}}\left(\frac{273.15 + T_A}{273.15}\right)\left(\frac{1\ \mathrm{atm}}{1\ \mathrm{atm}}\right)$$

$$T_A = 28°\mathrm{C}$$

$$AR_{28} = (217\ \mathrm{m^3/min})\left(\frac{273.15 + 28}{273.15}\right) = 239.2\ \mathrm{m^3/min}$$

   c. Correct the air flowrate for lower oxygen saturation using Eq. (9–8).

$$AR = AR_{TA}\left(1 + \frac{T_A - 20}{100}\right)$$

$$T_A = 28°\mathrm{C}$$

$$AR = (239.2)\left(1 + \frac{28 - 20}{100}\right) = 258.3\ \mathrm{m^3/min}$$

3. Determine pressure drop in the cross-flow packing.
   a. Determine the value of N_p using Eq. (9–10). The value of N_p will then be used to determine the pressure drop using Eq. (9–9).

$$N_p = 10.33(D)e^{(1.36\times 10^{-5})(L/A)}$$

Solve for L/A, kg/m²·h

Hydraulic loading $= q = Q/A$

$$Q = (15{,}000\ \mathrm{m^3/d})(1\ \mathrm{d/24\ h}) = 625\ \mathrm{m^3/h}$$

$$\text{Area of single tower } A = \frac{\pi D^2}{4} = \frac{3.14(20.0\ \mathrm{m})^2}{4} = 314\ \mathrm{m^2}$$

$$q = \frac{625}{314} = 1.99\ \mathrm{m^3/m^2{\cdot}h}$$

$$\frac{L}{A} = (1.99\ \mathrm{m^3/m^2{\cdot}h})(10^3\ \mathrm{L/1\ m^3})(1\ \mathrm{kg/L})$$

$$= 1990\ \mathrm{kg/m^2{\cdot}h}$$

Packing depth = 6.1 m

$$N_p = 10.33(6.1)e^{(1.36\times 10^{-5})(1990)}$$

$$= 64.7$$

Headloss correction factor for cross-flow packing = 1.3 (Table 9–4)

Headloss correction factor for inlet and other losses = 1.5

$N_P = (1.5)(1.3)(64.7) = 126.2$

b. Solve for the pressure drop using Eq. (9–9).

$$\Delta P = N_p\left(\frac{v^2}{2g}\right)$$

$$\text{Superficial velocity } v = \frac{\text{(air flowrate/tower)}}{\text{area of tower}}$$

$$v = \frac{(258.3/2)}{314.0} = 0.41\text{ m/min} = 0.0069\text{ m/s}$$

$N_P = 126.2$

$$\Delta P = 126.2\left(\frac{v^2}{2g}\right)$$

$$= \frac{(126.2)(0.0069\text{ m/s})^2}{2(9.8\text{ m/s}^2)} = 0.0003\text{ m}$$

Air density at 28°C = 1.175 kg/m^3 (see Appendix B)

$$\Delta P = 0.0003\text{ m }(1.175\text{ kg/m}^3)(9.8\text{ m/s}^2)$$

$$= 0.00346\text{ N/m}^2 = 0.00346\text{ Pa} = 3.46 \times 10^{-6}\text{ kPa}$$

4. Compare to natural draft pressure per Eqs. (9–2) and (9–3).

a. Determine log mean temperature using Eq. (9–3).

Wastewater temperature = 20°C

Air temperature = 28°C

$$T_m = \frac{T_2 - T_1}{\ln(T_2/T_1)} = \frac{28 - 20}{\ln(28/20)} = 23.8^\circ\text{C}$$

b. Determine draft using Eq. (9–2).

$$D_{\text{air}} = 353\left(\frac{1}{T_C} - \frac{1}{T_m}\right)Z$$

$T_C = 273.15 + 20 = 293.15\text{ K}$

$T_m = 273.15 + 23.8 = 296.95$

$$D_{\text{air}} = 353\left(\frac{1}{293.15} - \frac{1}{296.95}\right)6.1 = 0.094\text{ mm}$$

c. Compare draft to estimated headloss.
Convert mm of water to pressure expressed in Pa

$$\text{Draft} = (0.0094\text{ mm H}_2\text{O})\left(\frac{9.797\text{ Pa}}{\text{mm H}_2\text{O}}\right) = 0.0921\text{ Pa}$$

Thus, draft (0.0921 Pa) > headloss (0.00346 Pa)

Comment More draft is available for these temperature differences than is needed, but for periods where the wastewater and air temperatures are very close sufficient air flow and oxygen will not be available. Note that the pressure drop for the necessary airflow rate is very low and multiple air feed points are needed to assure uniform air distribution.

Ponding. On occasion, excessive growth and/or the presence of large suspended material in the influent wastewater can cause ponding to occur. Ponding occurs when a bridge is formed between the individual media particles or when the pore space between media particles is filled. Ponding is a more serious problem with rock filters, especially those with smaller rock sizes. Ponding can lead to poor air and water distribution within the filter which, in turn, can lead to reduced treatment performance, the breeding of mosquitoes, and the formation of odors.

Methods used to control ponding include (1) improved pretreatment (e.g. screening following primary sedimentation), (2) reducing the organic loading, (3) increasing the hydraulic loading to induce sloughing, (4) use of high pressure steam to breakup pond sites, (5) maintaining a chlorine residual of 1 to 2 mg/L to breakup the ponded sites, (6) shutting off the filter to allow the ponded sites to dry out so that they can be washed off, and (7) manually removing the material causing the ponding.

Odor Control. An extremely important consideration in the implementation of trickling filters is the control of odors, which can develop from time to time for a variety of reasons, in both natural and force draft filters, including the presence of odorous compounds and gases in the influent wastewater, excessive organic loading, unequal hydraulic distribution, inadequate air flow (draft through the filter), and ponding as described above.

Corrective measures that have been used include (1) temporarily increasing the hydraulic loading to flush the filter, (2) reducing the organic loading while increasing the hydraulic loading rate by increasing the rate of recirculation (use of temporary pumps may be necessary), (3) increasing the draft though the filter (if that option is available), (4) adding chemical oxidants, (5) switching from rock to plastic media, and (6) covering the filter and treating the odors through an odor scrubber. Although listed last, the covering of trickling filters is now common, especially where they are located near residential areas [see Figs. 9–3(c) and (d) and 9–8(c) and (d)]. Off gases from tower trickling filters are usually treated in either carbon absorbers, chemical scrubbers or biotrickling filters (see Fig. 9–9). Additional details on off-gas treatment are presented in Chap. 16.

Predator Problems. A significant problem for nitrifying filters is the development of a snail population, which may graze on the biofilm to reduce the nitrifying bacteria population and nitrification performance [see Figs. 9–10(a) and (b)]. In addition, snails can cause problems with plugging channels and pumps, accumulate in digesters, and cause wear and tear on equipment. A sump can be provided in an effluent collection chamber upstream of the secondary clarifiers to facilitate removal of snails from the effluent. Snail separation has also been done by passing the trickling filter clarifier underflow waste sludge through screens or a vortex classifier (Daigger and Boltz, 2011).

Methods to control snail growth involve the use of toxic chemicals or adverse environmental conditions. These include alkaline treatment, high ammonia concentration and pH, saline water dosing, chlorination, and copper sulfate at 0.4 g/L. The use of molluscicides such as metaldehyde, niclosamide and trifenmorph can also suppress snail growth (WEF, 2011). The use of toxic inhibitors must be short term and consider the effect on the

(a) (b) (c) (d)

nitrifying bacteria and WWTP effluent quality. It has been shown that at an aqueous free ammonia (NH_3) concentration in excess of 150 mg/L resulted in 100 percent snail mortality (Lacan et al., 2000). Successful snail control using this method at the Reno, Nevada Truckee Meadows Water Reclamation Facility was first reported by Gray et al. (2000). A tertiary nitrification trickling filter was contacted for 2 h with an ammonia-rich anaerobic digester centrate with sodium hydroxide addition to a pH of 9.2 to shift a high fraction of the total ammonia nitrogen concentration to free ammonia. Annual treatment of an isolated nitrifying trickling filter with a high ammonia concentration sludge dewatering liquor and sodium hydroxide additions was reported by Pearce and Jarvis (2011) to maintain successful snail growth control. Snail control by flooding at high pH (pH 9 to 10) was demonstrated by Parker et al. (1997) at the Littleton-Englewood WWTP in Colorado. Both of these methods require that the trickling filter tower tanks can be flooded fully and withstand hydrostatic pressures [see Fig. 9–10(c) and (d)].

Process Design Considerations for BOD Removal

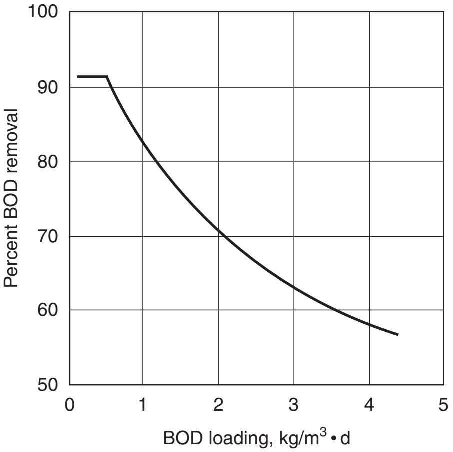
The trickling filter process appears simple, consisting of a bed of packing material through which wastewater flows and a clarifier. However, a trickling filter is a very complex system in terms of the physical characteristics of the attached growth and internal hydrodynamics. The biofilm thickness, surface contours, and degree of media coverage are difficult to predict. The attached growth is not uniformly distributed in the trickling filter (Hinton and Stensel, 1994), the biofilm thickness can vary, and the biofilm solids concentration may range from 40 to 100 g/L. The liquid flowrate through the media depth varies with time after dosing and does not uniformly flow over the entire packing surface area, which is referred to as the wetting efficiency. With the inability to quantify the biological and hydrodynamic properties of field trickling filter systems, broader parameters such as volumetric organic loading, unit area loading, and hydraulic loading have been used as design and operating parameters to relate to treatment efficiency. In view of these complexities, trickling filter designs and performance are based mainly on empirical relationships derived from pilot plant and full-scale plant experience. In this section, trickling filter performance for BOD removal and nitrification, factors that affect performance, and commonly used process design approaches are reviewed.

Effluent Characteristics. Historically, trickling filters have been considered to have major advantages of using less energy than activated sludge treatment and being easier to operate, but have disadvantages of more potential for odors and lower quality effluent. Some of these shortcomings, however, have been due more to inadequate ventilation, poor clarifier design, inadequate protection from cold temperatures, and the dosing operation. With proper design and within the volumetric loadings given in Table 9–1, trickling filters have successfully demonstrated the ability to produce effluent BOD concentrations of ≤ 30 mg/L for BOD removal designs and effluent BOD and ammonia-N concentrations of ≤ 20 mg/L and ≤ 3 mg/L, respectively, for combined BOD and ammonia removal designs. Tertiary nitrification systems have been designed to achieve effluent ammonia-N concentrations less than 1.0 mg/L.

Volumetric Loading Criteria. Volumetric BOD loading has been correlated well with treatment performance for both BOD removal and nitrification in combined BOD and nitrification trickling filter designs. Bruce and Merkens (1970 and 1973) found that the organic loading rate controlled trickling filter performance and not the hydraulic loading rate. The original design model for rock trickling filters was developed by the National Research Council (1946) from field data that correlated BOD removal efficiency with the

Figure 9–11

Example of trickling filter performance at 20°C. Effect of BOD loading on BOD removal efficiency for plastic media trickling filter.



volumetric organic loading rate. For combined BOD removal and nitrification systems, nitrification efficiency has also been related to the volumetric BOD loading (Stenquist and Kelly, 1980; U.S. EPA, 1975; and Daigger et al., 1993). An example of the effect of BOD loading on BOD removal efficiency is illustrated on Fig. 9–11. At low BOD loadings, BOD removal efficiency reaches a maximum plateau level of about 90 percent. In actual plant operations considerable scatter will exist around the curve due to variations in solids sloughing, wastewater characteristics (sBOD fraction), and clarification efficiency.

Trickling Filter Effluent Recirculation. Recirculation is an important aspect of trickling filter design that affects the wetting efficiency, controls the biofilm thickness, and helps maintain aerobic conditions at the upper, more highly-loaded section of the biotower. Wetting efficiency, defined as the ratio of the wetted area to the specific surface area, ranged from 0.2 to 0.6 with the lowest value for high density random pack media in the study by Crine et al. (1990). An increase in the total hydraulic loading to the trickling filter by recirculation flow reduces the liquid residence time, but increases the wetting efficiency. Recirculation flow also assures that a sufficient dosing rate, as shown in Table 9–3, is provided to control biofilm thickness. Insufficient dosing rates and a greater biofilm thickness can decrease the effective treatment area of trickling filter plastic packing (Daigger and Boltz, 2011).

Dilution of the influent BOD concentration of higher strength wastewaters by recirculation decreases the biological oxidation rates in the upper initial sections of a trickling filter to help maintain aerobic operating conditions. In addition, more oxygen to the tower is provided by the greater amount of flow leaving the distributor. A total hydraulic loading rate (influent flow plus recirculation flow) of greater than 0.5 $L/m^2 \cdot s$ is recommended for vertical-flow plastic media. Shallow cross-flow plastic media is able to provide improved spreading and wetting efficiency, and have been operated at about 0.25 $L/m^2 \cdot s$ in shallow trickling filter applications.

A trickling filter pumping station is designed to lift primary effluent and recirculated trickling filter effluent to the distributor system above the trickling filter packed media. Relatively low-head submersible or vertical turbine pumps are used. Variable frequency drives may be used on the pumps for operational flexibility.

Solids Production. Solids production from trickling filter processes will depend on the wastewater characteristics and the trickling filter loading. At lower organic loading rates, a greater amount of the particulate BOD is degraded, and because the biomass has a longer SRT, less biomass is produced. A procedure that can be used to evaluate the solids production for trickling filters is presented later in this chapter under in Sec. 9–4, which deals with combined trickling filter activated sludge processes.

Secondary Clarification. The function of clarifiers that follow trickling filters is to produce a clarified effluent. They differ from activated sludge settling tanks in that the clarifier has a much lower suspended solids content in the feed, and sludge thickening and recirculation is not necessary. The clarifier underflow is for the purpose of transporting waste sludge to the primary clarifier or sludge processing facilities.

Problems with Shallow Clarifiers. Trickling filter performance has historically suffered from poor clarifier designs. The use of shallow clarifiers (about 2.1 m depth) for trickling filter applications with relatively high surface overflow rates (about 1.7 m/h) was recommended in previous versions of the "Ten State Standards" (GLUMRB, 1997). Unfortunately, the use of shallow clarifiers typically resulted in poor clarification efficiency. Clarifier overflow rates recommended currently in the Ten State Standards are more inline with those used for the activated sludge process.

Use of Deep Clarifiers. Deeper clarifiers and lower surface overflow rates are now generally recommended with an interest in obtaining effluent TSS and BOD concentrations well below 20 mg/L. Surface overflow rates as a function of side water depth, as recommended in the WEF Biofilm Reactors MOP 35 (2011) are summarized in Table 9–5 and illustrated on Fig. 9–12. Clarifier designs for trickling filters should be similar to designs used for activated sludge process clarifiers (see Sec. 8–11 in Chap. 8), with appropriate feedwell size and depth and increased sidewater depth.

Mass-Transfer Limitations. One of the concerns in the process design for trickling filters is at what organic loading the filter performance becomes limited by oxygen transfer. When this condition occurs, treatment efficiency at the higher organic load is limited and odors may be produced due to anaerobic activity in the biofilm. Based on an evaluation of the data in the literature, for influent BOD concentrations in the range of 400 to 500 mg/L oxygen transfer may become limiting (Schroeder and Tchobanoglous, 1976). Hinton and Stensel (1994) reported that oxygen availability controlled organic substrate removal rates at soluble biodegradable COD loadings above 3.3 kg/m^3·d, which is on the upper end of BOD loadings for partial BOD removal applications as shown in Table 9–1. Note that recirculation flows can help reduce mass transfer limitations at the top of the trickling filter biotower.

Table 9–5

Recommended surface overflow rate (SOR) as a function of side water depth (SWD) for trickling filter and RBC secondary clarifiers with floor slope ≥1:1.2[a]

SWD, m	Average SOR, m/h	Maximum SOR, m/h
1.83 to 3.05	$\leq 0.092(\text{SWD})^2$	$\leq 0.182(\text{SWD})^2$
3.05 to 4.57	$\leq 0.278(\text{SWD})$	$\leq 0.556(\text{SWD})$

[a] Adapted from WEF (2011).

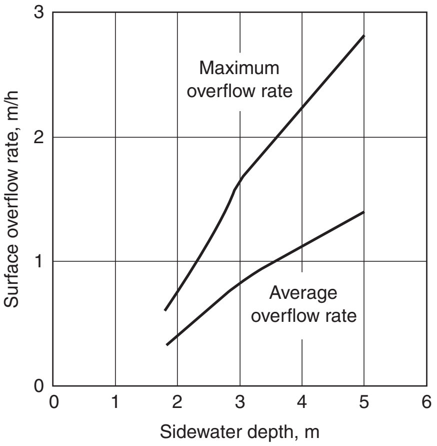


Figure 9–12

Typical secondary clarifier surface overflow rates as a function of clarifier sidewater depth.

EXAMPLE 9–2 **Trickling Filter Loadings** A 10-m diameter single stage trickling filter contains cross-flow plastic packing at a depth of 6.1 m. Primary effluent with the characteristics given below is applied to the filter. What is the volumetric BOD and TKN loading? What is the approximate BOD removal efficiency at 20°C? Can nitrification be expected?

Primary effluent wastewater characteristics:

Item	Unit	Value
Flowrate	m^3/d	4000
Temperature	°C	15
BOD	g/m^3	120
TSS	g/m^3	80
TKN	g/m^3	25

Solution

1. Determine the volume of the trickling filter packing material.

   Volume, $V = (A)(D)$

   $$A = \frac{\pi(10\text{ m}^2)}{4} = 78.5\text{ m}^2$$

   $$V = (78.5\text{ m}^2)(6.1\text{ m}) = 479\text{ m}^3$$

2. Determine the BOD Loading.

   BOD loading rate $= QS_O/V$

   $$= \frac{(4000\text{ m}^3/\text{d})(120\text{ g/m}^3)(1\text{ kg}/10^3\text{ g})}{479\text{ m}^3} = 1.0\text{ kg/m}^3\cdot\text{d}$$

3. Estimate the approximate BOD removal efficiency.

   From Fig. 9–11, at a loading of 1.0 kg BOD/m^2·d, the BOD removal efficiency is about 82 percent.

4. Can nitrification be expected?

   No. Based on the data given in Table 9–1, the BOD loading for combined BOD removal and nitrification is too high (1.0 $kg/m^3 \cdot d$, which is much greater than 0.25 $kg/m^3 \cdot d$). At the higher BOD loading, the heterotrophic bacteria outcompete the nitrifying bacteria for sites on the packing surface and, thus, control the slime biomass population.

Process Analysis for BOD Removal

The first empirical design equations were developed from field analyses of rock trickling filters. Later models were developed and applied for plastic packing trickling filters based on pilot plant and full scale plant operation and performance. The first empirical design equations for a rock trickling filter were developed by the National Research Council (1946) based on a data analysis on the performance of 34 systems in military installations treating domestic wastewater. These formulations can be found in a number of literature sources including WEF (2011) and Tchobanoglous et al. (2003). Because plastic media is used most often today the design equations for plastic media towers are the focus of this section.

Formulations for Plastic Packing. In the general equations developed for trickling filters with plastic packing, BOD removal was related to the hydraulic loading rate. The formulations are based on the early work of Velz (1948), who observed that the BOD remaining with depth in a trickling filter could be modeled as a first-order relationship, and Schulze (1960), who described the hydraulic detention time.

Schulze Equation. Schulze (1960) proposed that the liquid contact time with the biofilm is proportional to the filter depth and inversely proportional to the hydraulic loading rate as follows:

$$t = \frac{CD}{\text{THL}^n} \tag{9–11}$$

$$\text{THL} = \frac{Q(1 + R)}{A} = (1 + R)q \tag{9–12}$$

where THL = total hydraulic loading rate, $m^3/m^2 \cdot d$
t = liquid contact time, d
C = constant for packing used
D = depth of packing, m
n = hydraulic constant for the packing material used
R = recirculation ratio
q = hydraulic loading rate based on primary clarifier effluent flow, $m^3/m^2 \cdot d$

According to Eq. 9–11, as the influent flowrate to the trickling filter increases the detention time does not decrease in direct proportion to the flow, because the liquid film thickness increases.

The change in BOD concentration in the filter with time is described by a first-order reaction as follows:

$$\frac{dS}{dt} = -kS \tag{9–13}$$

where k = an experimentally determined rate constant
S = BOD concentration at time t

and using Eq. (9–11) to determine the time in the filter, Schulze derived the following equation:

$$\frac{S_e}{S_i} = \exp\frac{-kD}{(\text{THL})^n} \tag{9–14}$$

where S_e = BOD concentration of settled filter effluent, g/m^3
S_i = influent BOD concentration in total flow to trickling filter, g/m^3
k = an experimentally determined rate constant
D = packing depth, m

The values of k and n determined by Schulze at 20°C were 0.69/d and 0.67, respectively.

Germain Equation. Germain applied the Schulze equation in 1966 to trickling filters with plastic packing (WEF, 2000) as follows:

$$\frac{S_e}{S_i} = \exp\left\{\frac{-kD}{[(1 + R)q]^n}\right\} \tag{9–15}$$

where S_e = BOD concentration of settled filter effluent, g/m^3
S_i = influent BOD concentration in total flow to trickling filter, g/m^3
k = wastewater treatability and packing coefficient, (L/s)$^{0.5}$/m^2 (based on $n = 0.5$)
D = packing depth, m
n = constant characteristic of packing used

The value for n is normally assumed to be 0.50 and pilot plant or full-scale plant influent and effluent BOD concentration data are used to solve for k. Values for k were developed from more than 140 pilot plant studies by Dow Chemical Company with vertical plastic packing with a specific surface area of about 90 m^2/m^3. Similar tests have been done by other suppliers for a variety of packings. Most of these tests have been done with packing depths of 6.1 to 6.7 m (20 to 22 ft).

It should be noted that the clarifier design, solids loading, and dosing cycle and method can affect pilot plant results used to calculate a value for k (Harrison and Daigger, 1987). In summary, the value for k is affected by many factors including the wastewater characteristics, filter and clarifier design, and operating conditions.

The commonly accepted temperature correction for k is as follows:

$$k_T = k_{20}(1.035)^{T-20} \tag{9–16}$$

Other Formulations. Other formulations have been proposed (WEF, 2011) to describe the performance of plastic packing filters, including models by Eckenfelder (1961) and Eckenfelder and Barnhart (1963). One of the modified equations termed the modified Velz equation as given below in Eq. (9–19) relates the trickling filtered clarifier effluent BOD concentration as a function of the primary effluent BOD, the recirculation ratio, a factor for the specific area of the packing, and temperature. The equation is derived from Eq. (9–15) in which $(k_{20}A_s)$ equals k and S_e/S_o is used instead of S_e/S_i by developing a relationship between S_e/S_i and S_e/S_o from a BOD mass balance of the primary effluent and recirculation flows entering the trickling filter.

$$QS_o + Q_R S_e = (Q + Q_R)S_i \tag{9–17}$$

$$\frac{S_i}{S_e} = \frac{RS_e + S_o}{(1 + R)S_e} \tag{9–18}$$

Inverting Eq. (9–15) and substituting Eq. (9–18) for S_i/S_e relates the trickling filter clarifier effluent BOD concentration to the primary effluent BOD concentration and the recirculation ratio.

$$S_e = \frac{S_o}{(R + 1)\exp\left\{\dfrac{k_{20}A_s D\theta^{T-20}}{[q(R + 1)]^n}\right\} - R} \tag{9–19}$$

where S_o = influent BOD based on primary effluent flow, g/m^3
S_e = effluent BOD, g/m^3
k_{20} = filter treatability constant at 20°C, (L/s)$^{0.5}$/m
A_s = clean packing specific surface area, m^2/m^3
D = depth of packing, m
θ = temperature correction coefficient, 1.035
q = hydraulic loading rate based on primary effluent flow, L/m^2·s
R = ratio of recirculation flowrate to primary effluent flowrate
n = constant characteristic of packing used

Because the BOD removal is determined as a function of hydraulic loading rate, application of Eqs. (9–15) and (9–19) without regard to the fundamental effect of organic loading can lead to erroneous designs. For example, to achieve the same BOD removal efficiency, Eq. (9–15) would predict a smaller packing volume requirement by increasing the packing depth to greater than 6.1 m. However, as the volume is reduced, the organic loading increases and thus the treatment efficiency should decline. By assuming that the BOD removal efficiency is equal at the same organic loading, the value for k had to be adjusted for depth and influent BOD concentration. The k value is normalized to a specified depth and influent BOD concentration as follows (WEF, 2011):

$$k_2 = k_1\left(\frac{D_1}{D_2}\right)^{0.5}\left(\frac{S_1}{S_2}\right)^{0.5} \tag{9–20}$$

where k_2 = normalized value of k for the site-specific packing depth and influent BOD concentration
k_1 = k value at depth of 6.1 m (20 ft) and influent BOD of 150 g/m^3
S_1 = 150 g BOD/m^3
S_2 = site-specific influent BOD concentration, g BOD/m^3
D_1 = 6.1 m (20 ft) packing depth, m
D_2 = site-specific packing depth, m

Normalized values of k at 20°C determined from Dow Chemical Company pilot plant studies are summarized in Table 9–6. These are examples of pilot plant results and provide a rough approximation of treatability differences for different wastewaters. Wastewaters that would have the lowest degradation rates are from refineries, Kraft pulp mills, and textile mills.

Table 9–6

Normalized Germain equation $k_{20}A_S$ values [Eq. (9–19)] for plastic packing media (100 m^2/m^3) for different wastewaters

Type of wastewater	value, $(L/s)^{0.5}/m^2$
Domestic	0.210
Front canning	0.181
Kraft mill	0.108
Meat packing	0.216
Pharmaceutical	0.221
Potato processing	0.351
Refinery	0.059
Sugar processing	0.165
Synthetic dairy	0.170
Textile mill	0.107

Note: $[(L/s)^{0.5}/m^2] \times 0.3704 = (gal/min)^{0.5}/ft^2$.

EXAMPLE 9–3 **Design of Trickling Filter with Plastic Packing** Given the following design flowrates and primary effluent wastewater characteristics, determine the following design parameters for a trickling filter design assuming 2 towers at 6.1 m depth, cross-flow plastic packing with a specific surface area of 90 m^2/m^3, a packing coefficient n value of 0.5, a recirculation ratio of 1.0, and a 2-arm distributor system. The required minimum wetting rate = 0.5 $L/m^2 \cdot s$. Assume a secondary clarifier depth of 4.0 m.

Design Criteria:

Parameter	Unit	Primary effluent	Target effluent
Flow	m^3/d	15,140	
BOD	g/m^3	125	20
TSS	g/m^3	65	20
Minimum. temp.	°C	14	

Using the above information determine:

1. Diameter of tower trickling filter, m
2. Volume of packing required, m^3
3. Total pumping rate, m^3/h
4. Flushing and normal dose rate, mm/pass
5. Flushing and normal distributor speeds, min/rev
6. Clarifier diameter, m (Assume the ratio of the peak to average flowrate is 1.5)

Solution

1. Determine k_{20} for the design conditions using Eq. (9–20).

$$k_2 = k_1\left(\frac{D_1}{D_2}\right)^{0.5}\left(\frac{S_1}{S_2}\right)^{0.5}$$

   a. Solve for k_2.

   From Table 9–6, $k = 0.210\ (L/s)^{0.5}/m^2$ [Note: $k = k_{20}A_s$ in Eq. (9–19)]

Trickling filter depth = 6.1 m

$$= 0.210\left(\frac{6.1}{6.1}\right)^{0.5}\left(\frac{150}{125}\right)^{0.5} = 0.230\ (\text{L/s})^{0.5}/\text{m}^2$$

b. Correct k_2 for temperature effect using Eq. (9–16).

i. $k_T = k_{20}\ (1.035)^{T-20}$

ii. $k_{14} = 0.230(1.035)^{14-20} = 0.187\ (\text{L/s})^{0.5}/\text{m}^2$

2. Determine the hydraulic loading rate and the filter area, volume, and diameter.

a. Using Eq. (9–19) with $k_T = (k_{20}A_s)\theta^{T-20} = 0.187\ (\text{L/s})^{0.5}/\text{m}^2$ determine the hydraulic loading rate.

$$S_e = \frac{S_o}{(R+1)\exp\left\{\dfrac{k_T(D)}{[q(R+1)]^n}\right\} - R}$$

Rearrange to get following:

$$[q(1+R)] = \left\{\frac{k_T D}{\ln\left[\dfrac{S_o + RS_e}{S_e(1+R)}\right]}\right\}^{1/n}$$

$$[q(1+1)] = \left\{\frac{(0.187\ \text{L/m}^2\cdot\text{s})(6.1\ \text{m})}{\ln\left[\dfrac{(125\ \text{g/m}^3) + (1)(20\ \text{g/m}^3)}{(20\ \text{g/m}^3)(1+1)}\right]}\right\}^2$$

$$q = 0.443\ \text{L/m}^2?\text{s}$$

b. Determine the tower area.

$Q = 15{,}140\ \text{m}^3/\text{d} = 175.2\ \text{L/s}$

Filter area $= Q/q = 175/0.443 = 395.5\ \text{m}^2$

c. Determine the packing volume.

Packing volume $= (395.5\ \text{m}^2)\ (6.1\ \text{m}) = 2412\ \text{m}^3$

d. Determine the tower diameter.

Area/tower $= 395.5\ \text{m}^2/2 = 197.75\ \text{m}^2$

Diameter = 15.9 m each

Two towers each with a diameter of 16 m

3. Determine the pumping rate.

$q + q_r = (1+R)q = (1+1)0.443\ \text{L/m}^2\cdot\text{s} = 0.886\ \text{L/m}^2\cdot\text{s}$

Total pumping rate $= (0.886\ \text{L/m}^2\cdot\text{s})(\ 395.5\ \text{m}^2)$

$= 350.4\ \text{L/s} = 1261\ \text{m}^3/\text{h}$

4. Determine flushing and normal dose rate using the data given in Table 9–3.
   a. Determine BOD loading.

$$\text{BOD loading} = Q\,S_o/V$$

$$= \frac{(15{,}140\ \text{m}^3/\text{d})(125\ \text{mg/L})(1\ \text{kg}/10^3\ \text{g})}{2412\ \text{m}^3}$$

$$= 0.79\ \text{kg/m}^3\cdot\text{d}$$

   b. Determine the dosing rates.

   From Table 9–3, the estimated flushing and operation dose rates are:

   i. Flushing dose = 150 mm/pass

   ii. Operating dose = 75 mm/pass

5. Determine the distributor speed using Eq. (9–1).
   a. For normal operation:

$$n = \frac{(1 + R)\,q(1000\ \text{mm/min})}{(N_A)(DR)(60\ \text{min/h})},\ \text{where } q = \text{m}^3/\text{m}^2\cdot\text{h}$$

$$q = (0.443\ \text{L/m}^2\cdot\text{s})\left(\frac{3600\ \text{s}}{\text{h}}\right)\left(\frac{1\ \text{m}^3}{10^3\ \text{L}}\right) = 1.6\ \text{m}^3/\text{m}^2\cdot\text{h}$$

$$R = 1.0$$

$$n = \frac{(1 + 1)(1.6)(1000)}{(2)(75)(60)} = 0.36\ \text{rev/min (i.e. 2.8 min/rev)}$$

   b. For flushing operation:

$$n = \frac{(1 + 1)(1.6)(1000)}{(2)(150)(60)} = 0.18\ \text{rev/min (i.e. 5.6 min/rev)}$$

   Note because of the different speed requirements for normal and flushing operation, a distributor drive with variable speed capability should be used.

6. Determine clarifier diameter using the average curve from Fig. 9–12.

   Clarifier depth = 4.0 m

   From Fig. 9–12, the average SOR = 1.1 m/h

   The recommended ratio of the peak to average overflow rate from Table 9–5 is 2.0 (0.556/0.278). Because the ratio of the peak to average flowrate is 1.5, the average overflow rate controls the design.

   Flowrate = $(15{,}140\ \text{m}^3/\text{d})/(24\ \text{h/d}) = 630.8\ \text{m}^3/\text{h}$

   Clarifier area = $630.8/1.1 = 573.5\ \text{m}^2$

   Use 2 clarifiers

   Area for each = $573.5\ \text{m}^2/2 = 286.7\ \text{m}^2$

   Diameter of each = 14.1 m

7. Design Summary.

Parameter	Unit	Value
Number of filters	number	2
Diameter	m	16
Depth	m	6.1
Total packing volume	m^3	2412
BOD loading	$kg/m^3·d$	0.79
Hydraulic loading rate	$L/m^2·s$	0.886
Total pumping rate	m^3/h	1261
Recirculation ratio	unitless	1.0
Distributor arms	number	2
Normal distributor speed	min/rev	2.8
Flushing distributor speed	min/rev	5.6
Clarifiers	number	2
Clarifier depth	m	4.0
Clarifier diameter	m	14.1

Process Analysis for Nitrification

Two types of process design approaches have been used to accomplish biological nitrification in trickling filters, either in a combined system along with BOD removal or in a tertiary application following secondary treatment and clarification for BOD removal. Tertiary nitrification can be a low energy, cost-effective process for ammonia removal after secondary treatment by suspended growth or fixed-film processes. Empirical design approaches based on pilot plant and full-scale plant results are again used to guide nitrification designs in view of the difficulty in predicting the actual biofilm coverage area, wetting efficiency, and biofilm thickness and density. The nitrification efficiency in combined systems has been correlated with the BOD volumetric loading (kg BOD/m^3·d) and BOD surface area loading (kg BOD/1000 m^2·d) from full-scale and pilot plant results. For tertiary nitrification applications the ammonia surface loading is the common design parameter (g N/m^2·d).

Combined BOD Removal and Nitrification. In combined BOD removal and nitrification trickling filters, the heterotrophic bacteria will outcompete the nitrifying bacteria for media surface area due to their faster growth rate and higher biomass yield. Most of the nitrifying biomass growth occurs only after the soluble BOD is removed to below 5 to 10 mg/L (Harremoës, 1982; Figueroa and Silverstein, 1991; and Parker and Richards, 1986). Much lower BOD volumetric loading rates than that used for BOD removal only are used in combined BOD removal and nitrification trickling filters to provide additional media area for nitrifying bacteria.

For 90 percent nitrification efficiency, a BOD loading of less than 0.08 kg BOD/ m^3·d (5 lb BOD/1000 ft^3·d) is recommended (WEF, 2011) for rock media. At a loading of about 6.3 kg BOD/ m^3·d (14 lb BOD/1000 ft^3·d), about 50 percent nitrification efficiency could be expected. An evaluation of nitrification in a combined system using low-density, crossflow packing by Daigger et al. (1994) suggested a loading of less than 0.20 kg BOD/ m^3·d (12.5 lb BOD/1000 ft^3·d) for 90% nitrification efficiency.

Nitrification efficiency has also been related to the BOD loading based on the packing surface area. In comparing nitrification performance for both rock and cross-flow plastic packing, Parker and Richards (1986) found that the nitrification efficiency was similar at similar BOD surface loading rates (g BOD/m^2·d) for both packings. A surface loading rate as low as 2.0 kg BOD/ m^2·d (0.5 lb BOD/1000 ft^2·d) is necessary for ≥ 90 percent ammonia-N removal (Daigger and Boltz, 2011). Recirculation and a dosing rate strategy to control biofilm thickness improves nitrification performance (Parker et al., 1997).

Daigger et al. (1994) found that the oxidation of BOD and ammonia-N in trickling filters with plastic packing could be characterized by a volumetric oxidation rate defined as follows:

$$\text{VOR} = \frac{[S_o + 4.6(\text{NO}_\text{x})]Q}{(V)(10^3\ \text{g/1 kg})} \tag{9–21}$$

where VOR = volumetric oxidation rate, kg/m^3·d
S_O = influent BOD concentration, g/m^3
NO_x = amount of influent ammonia-N oxidized, g/m^3
Q = influent flowrate, m^3·d
V = packing volume, m^3

Using Eq. (9–21), the volumetric oxidation rate for three plants was determined and ranged from 0.4 to 1.3 kg/m^3·d. The amount of nitrification can then be estimated from an assumed VOR value and the influent BOD concentration.

Okey and Albertson (WEF, 2000) found a relationship between the specific nitrification rate (g/m^2·d) and the influent BOD/TKN ratio for combined systems based on data from four different studies.

$$R_n = 0.82\left(\frac{\text{BOD}}{\text{TKN}}\right)^{-0.44} \tag{9–22}$$

where R_n = specific nitrification rate, g/m^2·d
$\frac{\text{BOD}}{\text{TKN}}$ = influent BOD to TKN ratio, g/g

The data included in this correlation were for operation at temperatures ranging from 9 to 20°C. The authors concluded that the DO concentration had a greater effect on the nitrification rates than temperature. The effect of DO concentration is supported by fundamental mass transfer considerations in which it can be shown that a bulk liquid DO concentration of 2.8 mg/L is required for nitrification without oxygen diffusion limitations, at a liquid ammonia-N concentration of 1.0 mg/L.

Pearce and Edwards (2011) proposed a model for predicting the effluent ammonia-N concentration as a function of ammonia-N, BOD, and hydraulic loading rates relative to the packing surface area and temperatures.

$$\text{NH}_4\text{-N}_\text{e} = 20.81(\text{BOD}_\text{L})^{1.03}(\text{NH}_4\text{-N}_\text{L})^{1.52}(\text{Iv})^{-0.36}(\text{T})^{-0.12} \tag{9–23}$$

Where, $\text{NH}_4\text{-N}_\text{e}$ = average effluent ammonia-N concentration, mg/L
BOD_L = BOD specific surface loading rate, g/m^2·d
$\text{NH}_4\text{-N}_\text{L}$ = ammonia-N specific surface loading rate, g/m^2·d
Iv = specific hydraulic surface loading rate L/m^2·d
T = filter effluent temperature, °C

The model fitted experimental data for various hydraulic and organic loading conditions ($R^2 = 0.78$). The temperature effect is not as pronounced as for suspended growth systems due the combined effects of the high biomass inventory, microbial kinetics, and mass transfer in the trickling filter.

EXAMPLE 9–4 **Combined BOD Removal and Nitrification in a Trickling Filter with Plastic Packing** Determine the volume and area of plastic packing required for 90 percent TKN removal in trickling filter with a depth of 6.1 m for the wastewater characteristics given. Assume low-density cross-flow packing with a BOD volumetric loading of 0.20 kg BOD/m^3·d. How does the computed volume compare to the volume predicted based on a volumetric oxidation rate of 0.40 kg/m^3·d? How does the specific nitrification rate compare to the relationship shown in Eq. 9–22? What percent nitrification is estimated from the nitrification model in Eq. 9–23? Assume the specific surface area of the plastic packing material is 90 m^2/m^3 from Table 9–2 and the trickling filter effluent temperature is 20°C.

Also, determine the hydraulic loading rate.

Wastewater characteristics:

Parameter	Unit	Value
Flowrate	m^3/d	8000
BOD	g/m^3	160
TKN	g/m^3	25
TSS	g/m^3	70

Solution

1. Determine the packing volume based on a loading of 0.20 kg BOD/m^3·d.

$$\text{Volumetric BOD loading} = 0.20\ \text{kg/m}^3\cdot\text{d} = \frac{(8000\ \text{m}^3/\text{d})(160\ \text{g/m}^3)(1\ \text{kg}/10^3\ \text{g})}{\text{Packing volume, m}^3}$$

$$\text{Packing Volume} = \frac{(8000\ \text{m}^3/\text{d})(160\ \text{g/m}^3)(1\ \text{kg}/10^3\ \text{g})}{(0.20\ \text{kg/m}^3\cdot\text{d})} = 6400\ \text{m}^3$$

2. Determine the volume based on the volumetric oxidation rate using Eq. (9–21).

$$\text{VOR} = \frac{[S_o + 4.6(\text{NO}_x)]Q}{(V)(10^3\ \text{g/1 kg})} = 0.40\ \text{kg/m}^3\cdot\text{d}$$

$$V = \frac{[S_o + 4.6(\text{NO}_x)]Q}{(0.40\ \text{kg/m}^3\cdot\text{d})(10^3\ \text{g/1 kg})}$$

$$V = \frac{[160\ \text{g/m}^3 + 4.6(25\ \text{g/m}^3)](8000\ \text{m}^3/\text{d})}{(0.40\ \text{kg/m}^3\cdot\text{d})(10^3\ \text{g/1 kg})} = 5500\ \text{m}^3$$

3. Determine the specific nitrification rate at 90% removal.

Packing surface area = 6400 m^3 (90 m^2/m^3) = 576,000 m^2

$$R_n = \frac{(Q)(\text{NO}_x)}{\text{Surface Area}} = \frac{(0.90)(8000\ \text{m}^3/\text{d})(25\ \text{g/m}^3)}{576{,}000\ \text{m}^2} = 0.32\ \text{g/m}^2\cdot\text{d}$$

4. Determine the specific nitrification rate from Eq. (9–22).

BOD/TKN = 160/25 = 6.4

$$R_n = 0.82\left(\frac{\text{BOD}}{\text{TKN}}\right)^{-0.44}$$
$$= 0.82\,(6.4)^{-0.44}$$
$$= 0.36\ \text{g/m}^2\cdot\text{d}$$

5. Determine the hydraulic loading rate.

$$\text{Filter area} = \frac{\text{volume}}{\text{depth}} = \frac{6400\ \text{m}^3}{6.1\ \text{m}} = 1049\ \text{m}^2$$

Hydraulic loading rate, q

$$q = \frac{Q}{A} = \frac{(8000\ \text{m}^3/\text{d})(10^3\ \text{L}/1\ \text{m}^3)(\text{d}/1440\ \text{min})(\text{min}/60\ \text{s})}{1049\ \text{m}^2} = 0.09\ \text{L/m}^2\cdot\text{s}$$

To meet the minimum hydraulic loading rate given previously as 0.5 L/m^2·s, recirculation will be required.

6. Estimate the effluent NH_4-N concentration using Eq. (9–23).

$$\text{NH}_4\text{-N}_e = 20.81(\text{BOD}_L)^{1.03}(\text{NH}_4\text{-N}_L)^{1.52}(\text{Iv})^{-0.36}(T)^{-0.12}$$

$$\text{BOD}_L = \frac{(8000\ \text{m}^3/\text{d})(160\ \text{g/m}^3)}{576{,}000\ \text{m}^2} = 2.22\ \text{g/m}^2\cdot\text{d}$$

$$\text{NH}_4\text{-N}_L = (0.32\ \text{g/m}^2\cdot\text{d})/0.9 = 0.36\ \text{g/m}^2\cdot\text{d (from step 3)}$$

$$\text{Iv} = \frac{(8000\ \text{m}^3/\text{d})(10^3\ \text{L}/1\ \text{m}^3)}{576{,}000\ \text{m}^2} = 13.9\ \text{L/m}^2\cdot\text{d}$$

$$\text{NH}_4\text{-N}_e = 20.81(2.22)^{1.03}(0.36)^{1.52}(13.9)^{-0.36}(20)^{-0.12} = 1.2\ \text{mg/L}$$

$$\text{Percent nitrification} = \frac{(100)[(25 - 1.2)\ \text{mg/L}]}{(25\ \text{mg/L})} = 95.2\%$$

Comments The computed value for the volume required based on the BOD volumetric loading rate is higher than that predicted by the volumetric oxidation rate (Daigger et al. (1994). For the wastewater BOD/N ratio, the specific nitrification rate is close to that predicted based on the BOD/TKN ratio using Eq. (9–22) and the percent nitrification is close to that predicted by Eq. (9–23).

Tertiary Nitrification. A number of facilities exist where trickling filters with plastic packing are used for nitrification after secondary treatment. Advantages for tertiary nitrification include (1) low energy consumption, (2) simplicity of operation, and (3) stable performance.

For tertiary nitrification applications, very little BOD is applied to the trickling filter and a thin biofilm develops on the packing that consists of a high proportion of nitrifying bacteria. Effluent NH_4-N concentrations will vary with summer and winter operation and can range from <1.0 mg/L at warm temperatures and from <1 to 4 mg/L at cold temperatures. Hydraulic loading rates may range from 0.40 to 1.0 L/m^2·s and recycle is commonly used to maintain packing surface wetting. Some tertiary nitrification systems have been constructed without downstream liquid-solids separation because of the low net biomass yield by the nitrifying bacteria. This depends on site specific wastewater characteristics and treated effluent goals.

Design and Operation. In the design and operation of tertiary nitrifying trickling filters it is important to consider (1) the media type and surface area density, (2) mechanical ventilation, (3) hydraulic loading rates and recycle, (4) minimizing slug ammonia loads, and (5) control of predatory micro fauna. It is generally well accepted that in the upper portion of the trickling filter the nitrification rate is limited by oxygen availability and diffusion into the biofilm. To mitigate the oxygen limitation, forced draft air is generally used to assure maximum oxygen availability. Higher hydraulic rates including recirculation that provide better wetting efficiency and agitation of the biofilm surface generally produce better performance. Distributor speed control to provide a dosing rate in the range 25 to 75 mm/pass and flushing intensity ≥300 mm/pass is recommended (WEF, 2011). Because plugging is less of an issue, a medium density packing material is preferred (i.e., specific surface area of 138 m^2/m^3) to provide more area as a function of the percent of the reactor volume. Equalization of high ammonia concentration flows from solids processing is recommended to minimize slug loads and diurnal load fluctuations to obtain a low and consistent effluent ammonia concentration. Snail growth [see Figs. 9–10(a) and (b)] in nitrifying trickling filters has occurred and can result in a serious loss of the nitrifying bacteria population and treatment efficiency. Predation control methods are discussed after the process design methodology.

Nitrification Rate. The rate of nitrification in a trickling filter varies with packing media depth and is related to bulk liquid oxygen and ammonia-N concentrations and hydraulic application rate. In the upper portion of a nitrification tower, the ammonia-N concentration may be high enough so that the nitrification rate is oxygen limited, and thus zero order with respect to the ammonia-N concentration. Further down in the packing, as the ammonia-N concentration decreases, the nitrification rate is limited by the ammonia-N concentration and thus decreases. The decline in nitrification rate is further affected by less growth of nitrifying bacteria due to the low amount of ammonia-N available. The use of nitrification trickling filters in series with operational modifications has been shown to compensate for this limitation (Boller and Gujer, 1986). The order of operation of the towers is reversed every few days so that a higher nitrifying bacteria population can be developed and be available where the ammonia-N concentration is low. Anderson et al. (1994) showed a 20 percent improvement in nitrification efficiency with this method.

The nitrification removal efficiency has been related to the packing surface area and correlated with the nitrogen removal rate per unit of surface area (g $N/m^2 \cdot d$) (Okey and Albertson, 1989; Parker et al., 1990; WEF, 2011). Boller and Gujer (1986) developed an empirical equation that relates the ammonia-N removal flux from the bulk liquid as a function of the bulk liquid ammonia-N concentration. The ammonia-N removal flux is equal to the nitrification rate per unit area in the biofilm.

$$J_N(z) = J_{N,\max}\left(\frac{N}{K_N + N}\right) \tag{9–24}$$

where $J_N(z)$ = NH_4-N removal flux, $g/m^2 \cdot d$

$J_{N,\max}$ = maximum ammonia-N removal flux at temperature T, $g/m^2 \cdot d$

N = bulk liquid ammonia-N concentration, g/m^3

K_N = half-velocity ammonia-N coefficient, g/m^3

The value of $J_{N,\max}$ has been determined by observations on zero-order nitrification rates in tertiary trickling filter operations where the ammonia-N concentration is significantly greater than K_N. As noted above, approximate zero-order nitrification rates may occur in the upper portion of the trickling filter tower until the ammonia-N concentration decreases to below 6.0 mg/L. After zero order removal, the packing media surface biofilm growth declines due to the lower ammonia-N concentration and lower ammonia-N removal rate. The value of

Table 9–7

Reported maximum ammonia-N removal flux for tertiary nitrification trickling filters

Location	Packing[a]	Range of $J_{N,\max}$ values, g N/m²·d	Reference
Central Valley, UT	XF 138	2.1–2.9	Parker (1990)
Malmö, Sweden	XF 138	1.6–2.8	Parker (1990)
Littleton/Englewood, CO	XF 136	1.2–2.3	Parker (1997)
Midland, MI	VF 89	1.1–1.8	WEF (2011)
Lima, OH	VF 89	1.2–1.8	WEF (2011)
Zurich, Switzerland	VF 92	1.6	WEF (2011)
Zurich, Switzerland	XF 223	1.2	WEF (2011)

[a] XF = cross-flow, VF = vertical flow. Numbers correspond to specific surface area in m²/m³.

the maximum ammonia-N removal flux is decreased with depth to account for the decline in the surface biofilm growth. A reduction of 0.1 g/m²·d per meter of increasing depth has been proposed for a correction to the maximum ammonia-N removal flux (Daigger and Boltz, 2011).

Maximum surface nitrification fluxes ($J_{N,\max}$) vary widely as reported in Table 9–7. Cross-flow plastic packing appears to produce higher nitrification flux. The higher nitrification flux may be due to better flow distribution and greater wetting of the packing to develop a higher biofilm surface area. However, the flux was worst with the XF 223, higher density, cross-flow packing.

No temperature correction is used with Eq. (9–24) between 10 and 25°C. Other investigators have also observed minimal temperature effects for tertiary nitrification, and have attributed the minimal observed rate change more to the effect of dissolved oxygen concentration and hydraulics (Okey and Albertson, 1989). Below 10°C the following temperature correction coefficient is recommended (WEF, 2011).

$$J_{N,\max(T)} = J_{N,\max(10)}(1.045)^{(T-10)} \tag{9–25}$$

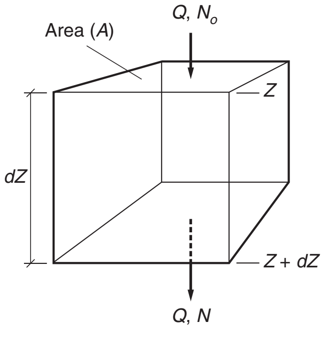

Figure 9–13

Schematic of trickling filter incremental depth section for derivation of Eq. (9–29).

Equation (9–24) is applied in a mass balance across an incremental depth of packing media, as shown on Fig. 9–13, to develop a general equation for the bulk liquid ammonia-N concentration with media depth. The ammonia-N removal rate across the incremental depth is equal to the flux of ammonia-N into the biofilm.

$$V\frac{dN}{dt} = -J_{N,\max}\left(\frac{N}{K_N + N}\right)(aV) \tag{9–26}$$

where V = volume of incremental section, m³
a = specific surface area of media, m²/m³

The volume of the incremental section is equal to Adz and dt equals dz(A)/Q. Substitution for dt in Eq. (9–26) with q equal to the hydraulic load (m³/m²) as defined previously yields:

$$dN = -J_{N,\max}\left(\frac{N}{K_N + N}\right)(a)\left(\frac{dZ}{q}\right) \tag{9–27}$$

Rearranging yields:

$$dN\left(\frac{K_N + N}{N}\right) = -\frac{J_{N,\max}}{q}(a)dZ \tag{9–28}$$

where Z = packing media depth, m
q = hydraulic loading rate, m³/m²·d

Integration of Eq. (9–28) with limits of N equal the influent concentration (N_o) at $Z = 0$ and N equal N at $Z = Z$ results in the following general expression for the ammonia-N concentration with depth.

$$(N_o - N) + K_N Ln\left(\frac{N_o}{N}\right) = \frac{ZaJ_{N,\max}}{q} \tag{9–29}$$

When recirculation is used an iterative solution approach is necessary, in which an assumed effluent ammonia-N concentration is first assumed to calculate N_o.

$$N_o = \frac{N_{\text{sec}} + RN}{1 + R} \tag{9–30}$$

where N_{sec} = NH_4-N concentration in secondary effluent feed to the nitrification tower, g/m^3
R = Recirculation ratio

The total hydraulic load is also used in place of q in Eq. (9–29) and equals $(1 + R)q$.

EXAMPLE 9–5 **Tertiary Nitrification Trickling Filter Design** Determine the total plastic packing media depth for a nitrification filter is to treat a flow of 6000 m^3/d after secondary treatment at a temperature of 15°C. The influent NH_4-N concentration is 25 g/m^3 and an effluent NH_4-N concentration of 1.0 g/m^3 is desired. Assume a $J_{N,\max}$ value of 1.8 $g/m^2{\cdot}d$ from information in Table 9–7 and a K_N value of 1.5 g/m^3. A medium density cross-flow plastic packing material with a specific surface area of 138 m^2/m^3 will be used, as little BOD or TSS exists in the influent wastewater to pose plugging problems. Assume that the $J_{N,\max}$ value is decreased by 0.10/m after the NH_4-N concentration is decreased to 6.0 g/m^3. Compare the plastic tower height and total packing volume needed for two design assumptions in which both provide a total hydraulic loading rate of 1.0 $L/m^2{\cdot}s$ to provide a sufficient media packing wetting efficiency: (a) the recirculation ratio = 0 and (b) the recirculation ratio = 1.0.

Solution with No Recycle

(a) $R = 0$ and $q = 1.0\ L/m^2{\cdot}s$

1. Convert q to units of $m^3/m^2{\cdot}d$ for use in Eq. (9–29).

$$q = (1.0\ L/m^2{\cdot}s)\left(\frac{1\ m^3}{10^3\ L}\right)\left(\frac{60\ s}{min}\right)\left(\frac{1440\ min}{d}\right) = 86.4\ m^3/m^2{\cdot}d$$

2. Solve for depth Z in Eq. (9–29), where N_o is 25.0 g/m^3 and N is 6.0 g/m^3. Because no recirculation is used, the NH_4-N concentration at the top of the tower is 25.0 g/m^3. $J_{N,\max} = 1.8\ g/m^2{\cdot}d$

$$(N_o - N) + K_N \ln\left(\frac{N_o}{N}\right) = \frac{ZaJ_{N,\max}}{q}$$

$$[(25.0 - 6.0)\ g/m^3] + (1.5\ g/m^3)\ln\left(\frac{25.0}{6.0}\right) = \frac{Z(138\ m^2/m^3)(1.8\ g/m^2{\cdot}d)}{(86.4\ m^3/m^2{\cdot}d)}$$

$Z = 7.4$ m

3. For the next 1 m of depth $J_{N,\max} = (1.8 - 0.1) g/m^2{\cdot}d = 1.7\ g/m^2{\cdot}d$

Solve for N using Eq. (9–29).

$$[(6.0 - N)\ g/m^3] + (1.5\ g/m^3)\ln\left(\frac{6.0}{N}\right) = \frac{1.0\ m(138\ m^2/m^3)(1.7\ g/m^2{\cdot}d)}{(86.4\ m^3/m^2{\cdot}d)}$$

$N = 3.9\ g/m^3$

4. Continue this calculation procedure until N is $\leq 1.0\ \mathrm{g/m^3}$.
5. The volume of packing media for each depth increment is the depth times the tower cross-section area.

$$\text{Area} = \frac{\text{flow}}{\text{hydraulic application rate}}$$

$$\text{Area} = \frac{Q}{q}$$

$$\text{Area} = \frac{(6000\ \mathrm{m^3/d})}{(86.4\ \mathrm{m^3/m^2{\cdot}d})} = 69.4\ \mathrm{m^2}$$

Plastic packing volume at 7.4 m depth = (A)(Z) = $(69.4\ \mathrm{m^2})(7.4\ \mathrm{m}) = 513.6\ \mathrm{m^3}$

Plastic packing volume for 1.0 m depth increment = $(69.4\ \mathrm{m^2})(1.0\ \mathrm{m}) = 69.4\ \mathrm{m^3}$

The results are summarized in the following table:

$J_{N,max}$, g/m²·d	NH_4-N, mg/L	Incremental depth, m	Volume, m³
1.8	6.0	7.4	513.6
1.7	3.9	1.0	69.4
1.6	2.2	1.0	69.4
1.5	1.0	1.0	69.4
	Total	10.4	721.8

The plastic tower depth = 10.4 m (or use two in series at 5.2 m each)

6. Determine the tower diameter.

Assume two towers in parallel.

Cross-section area per tower = $69.4\ \mathrm{m^2}/2 = 34.7\ \mathrm{m^2}$

$$\text{Area} = A = \frac{\pi D^2}{4},\ \text{Diameter} = \sqrt{\frac{4A}{\pi}}$$

$$\text{Diameter} = \sqrt{\frac{4(34.7\ \mathrm{m^2})}{3.14}} = 6.64\ \mathrm{m}$$

Solution with Recycle

(b) $R = 1.0,\ q = 0.50\ \mathrm{L/m^2{\cdot}s} = \dfrac{(0.50\ \mathrm{L/m^2{\cdot}s})(86.4\ \mathrm{m^3/m^2{\cdot}d})}{(1.0\ \mathrm{L/m^2{\cdot}s})} = 43.2\ \mathrm{m^3/m^2{\cdot}d}$

The total hydraulic load with the recycle = $86.4\ \mathrm{m^3/m^2{\cdot}d}$ for use in Eq. (9–29)

1. Determine the NH_4-N concentration at the top of the tower due to influent dilution by the recycle using Eq. (9–30).

Assume effluent NH_4-N = $1.0\ \mathrm{g/m^3}$.

$$N_o = \frac{N_{sec} + RN}{1 + R} = \frac{(25.0\ \mathrm{g/m^3}) + (1.0)(1.0\ \mathrm{g/m^3})}{1.0 + 1.0} = 13.0\ \mathrm{g/m^3}$$

2. Solve for depth Z in Eq. (9–29), where N_o is 13.0 g/m^3 and N is 6.0 g/m^3.

$$(N_o - N) + K_N \ln\left(\frac{N_o}{N}\right) = \frac{ZaJ_{N,\max}}{q}$$

$$[(13.0 - 6.0)\ \text{g/m}^3] + (1.5\ \text{g/m}^3)\ln\left(\frac{13}{6}\right) = \frac{Z(138\ \text{m}^2/\text{m}^3)(1.8\ \text{g/m}^2\cdot\text{d})}{(86.4\ \text{m}^3/\text{m}^2\cdot\text{d})}$$

$Z = 2.8$ m

3. For the next 1 m of depth $J_{N,\max} = (1.8 - 0.1)\ \text{g/m}^2\cdot\text{d} = 1.7\ \text{g/m}^2\cdot\text{d}$

Solve for N using Eq. (9–29).

$$[(6.0 - N)\ \text{g/m}^3] + (1.5\ \text{g/m}^3)\ln\left(\frac{6}{N}\right) = \frac{1.0\ \text{m}(138\ \text{m}^2/\text{m}^3)(1.7\ \text{g/m}^2\cdot\text{d})}{(86.4\ \text{m}^3/\text{m}^2\cdot\text{d})}$$

$N = 3.9$, Note: this now yields the same solution at the greater depths as in (a) as the NH_4-N concentrations and total hydraulic load are the same.

4. The volume of packing media for each depth increment is the depth times the tower cross-section area.

$$\text{Area} = \frac{Q}{q}$$

$$\text{Area} = \frac{(6000\ \text{m}^3/\text{d})}{(43.2\ \text{m}^3/\text{m}^2\cdot\text{d})} = 138.8\ \text{m}^2$$

Plastic packing volume at 2.8 m depth = (A)(Z) = (138.8 m^2)(2.8 m) = 388.6 m^3

Plastic packing volume for 1.0 m depth increment = (138.8 m^2)(1.0 m) = 138.8 m^3

The results are summarized in the following table:

$J_{N,max}$, g/m^2·d	NH_4-N, g/m^3	Incremental depth, m	Volume, m^3
1.8	6.0	2.8	388.6
1.7	3.9	1.0	138.8
1.6	2.2	1.0	138.8
1.5	1.0	1.0	138.8
	Total	5.8	805.0

The plastic tower depth = 5.8 m (This is in the range of common tower heights used)

5. Determine the tower diameter.

Assume two towers in parallel.

Cross-section area per tower = 138.8 m^2/2 = 69.4 m^2

$$\text{Area} = A = \frac{\pi D^2}{4},\ \text{Diameter} = \sqrt{\frac{4A}{\pi}}$$

$$\text{Diameter} = \sqrt{\frac{4(69.4\ \text{m}^2)}{3.14}} = 9.4\ \text{m}$$

6. Summary and comparison of the plastic tower designs.

Design parameter	(a)	(b)
Recirculation ratio	0.0	1.0
Hydraulic load, $m^3/m^2 \cdot d$	86.4	43.2
Total hydraulic load, $m^3/m^2 \cdot d$	86.4	86.4
Number of towers	2	2
Tower diameter, m	6.64	9.40
Total tower depth, m	10.4	5.8
Plastic packing volume per tower, m^3	360.9	402.5

Comment The effect of using the 100 percent recirculation results in a shorter tower and larger tower diameter and an 11.5 percent increase in the total packing media volume required. Note that the system design with no recirculation would still have an effluent recirculation wet well and pump so that the tower design total hydraulic load can be maintained during periods of low influent flowrates.

9–3 SEQUENTIAL COMBINED TRICKLING FILTER AND SUSPENDED SOLIDS PROCESSES

Several treatment process combinations have been developed that couple trickling filters with suspended solids or activated sludge process. The three principal types of combined processes are the (1) trickling filter/solids contact (TF/SC) process, (2) trickling filter/activated sludge (TF/AS) process, and (3) series trickling filter/activated sludge process (Series TF/AS). The combined biological processes are commonly referred to as dual processes or coupled trickling filter/activated sludge systems. Topics considered in this section include (1) process applications, (2) the trickling filter/solids contact process, (3) the trickling filter/activated sludge process, and (4) the series trickling-filter activated sludge process.

Process Development

In addition to the TF/AS process described in the Sec. 9–1, another sequential combined trickling filter and activated sludge process is the *trickling filter/solids contact process*. The TF/SC process was developed in the late 1970s from research in Corvallis, OR aimed at a higher quality effluent after trickling filter treatment of domestic wastewater (Norris et al., 1982). In this case the trickling filter was designed to remove most of the soluble BOD, and was followed by an aerated solids contact channel also receiving return activated sludge from secondary clarifiers. The primary purpose of the aerated solids contact channel was to flocculate trickling filter effluent suspended solids in the activated sludge.

Process Applications

Sequential combined processes have often been the result of plant upgrading where either a trickling filter or suspended solids process is added, but they have also been provided in new facility designs (Parker et al., 1994). Combined processes are mainly applicable for BOD removal applications as the consumption of influent BOD in the trickling filter is a detriment to biological nutrient removal processes. The advantages of combined fixed film and suspended growth processes include (1) the stability and resistance to shock loads of the attached growth process, (2) the volumetric efficiency and low energy requirement of attached growth process for partial BOD removal, (3) the role of attached growth pretreatment as a biological selector to improve activated sludge settling characteristics, and (4) the high quality effluent possible with the downstream suspended growth or activated sludge treatment.

Trickling Filter/Solids Contact Process

The first full-scale field demonstration of a trickling filter/solids contact (TF/SC) process was at Corvallis, OR., where it was demonstrated that the combined process could provide advanced secondary treatment performance with effluent TSS and BOD concentrations below 10.0 mg/L (Norris et al., 1982).

Process Description. The process consists of a low-loaded trickling filter followed by a short-duration, aerated suspended growth solids contact tank prior to secondary clarification as shown on Figs. 9–14(a) and (b). The majority of the soluble BOD is removed in the trickling filter and the aerated solids contact tank is operated with a sufficient aerobic SRT for the production of biomass exocellular polymer to promote bioflocculation of dispersed colloids and particulates in the trickling filter effluent. Residual

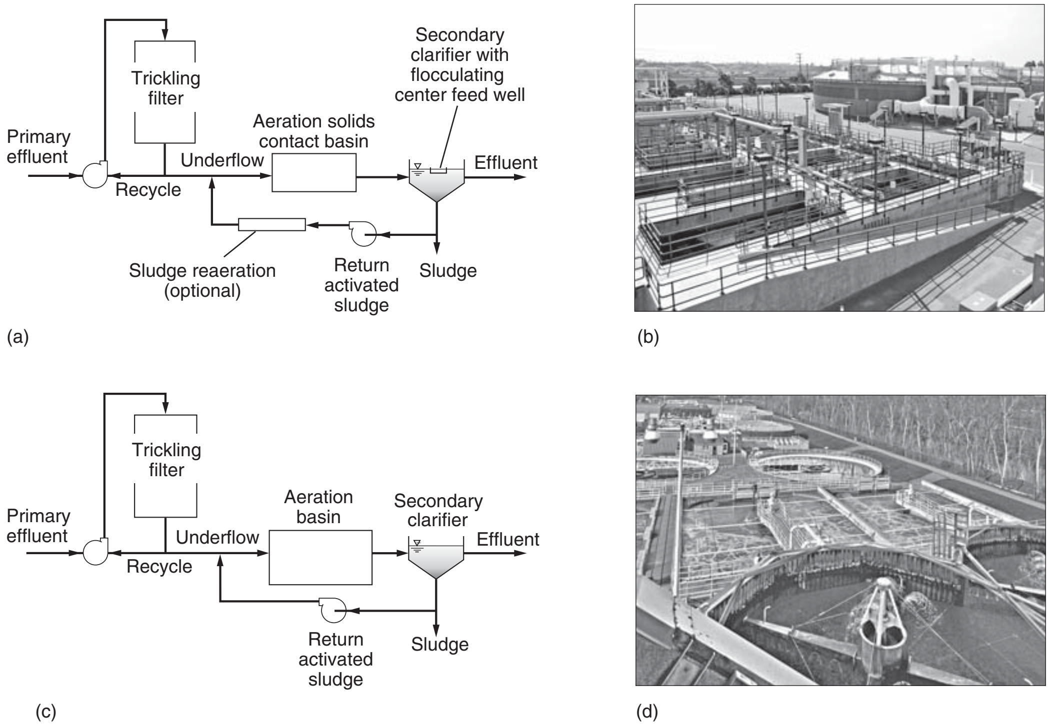

Figure 9–14

Combined trickling filter/activated sludge processes: (a) schematic flow diagram of trickling filter/solids contact (TF/SC) process with option to include return sludge reaeration, (b) view of solids contact channel with tower trickling filters in the background, (c) schematic flow diagram of trickling filter/activated sludge (TF/AS) process, and (d) view of trickling filter/solids contact installation taken from above the tower trickling filter.

sBOD in the trickling filter effluent is also removed in the solids contact tank. Newbry et al. (1988) found that with an SRT of 1.0 d or more for the aeration basin, the effluent sBOD concentration could be minimized.

Secondary Clarifier. The solids contact unit is generally followed by a secondary clarifier with a flocculating feed well to promote additional solids contact under gentle mixing conditions and bioflocculation of dispersed solids. The process is referred to as solids contact and bioflocculation treatment instead of an activated sludge step, because most of the BOD removal and biomass growth occurs in the trickling filter (Parker and Bratby, 2001).

Use of Sludge Recycle. About half of the TF/SC processes installed have used recycle sludge reaeration, as shown as an optional operating mode on Fig. 9–14(a). Sludge recycle is used to increase the sludge inventory and SRT without an increase in the solids contact detention time. A higher solids inventory is preferred for applications with higher trickling filter BOD loadings and to help attenuate the effects of occasions with increased amounts of trickling filter solids sloughing. For low-loaded trickling filter conditions (0.30 to 0.70 kg BOD/m^3·d), nitrifying bacteria may grow in the trickling filter and seed the solids contact unit to result in significant nitrification at a lower than expected aerobic SRT.

Design Considerations. Key design considerations for the TF/SC process are summarized in Table 9–8. Solids contact hydraulic retention times used range from 30 to 120 min, with 60 min close to many designs. The aerobic SRT is based on the solids inventory in the solids contact and sludge aeration tanks. Parker and Bratby (2001) noted that an SRT above 1.0 to 1.2 d is needed to obtain effluent TSS concentrations below 10 mg/L. They also advocated higher trickling filter BOD loadings of up to at least 2.0 kg BOD/m^3·d, while still achieving low effluent TSS concentrations. The secondary clarifier area requirement was found to be limited by solids loading instead of surface overflow rates (SOR), with allowable peak values as high as 12.2 kg/m^2·h due to the good settling sludge resulting from the trickling filter biomass growth. The 90th percentile SVI values for results at four TF/SC WWTPs ranged from 110 to 130 mL/g (Parker and Bratby, 2001).

Process Advantages. The major advantages of the TF/SC process are: (1) it provides an optimal design for the trickling filter and suspended growth process with minimal energy requirements due to most of the BOD oxidation occurring in the trickling filter, and (2) it achieves low effluent BOD and suspended solids with a small suspended growth aeration tank (5 to 20 percent of that needed for activated sludge treatment) (Daigger and Boltz, 2011).

Table 9–8

Process design criteria for trickling filter-solids contact (TF/SC) process[a]

Parameter	Units	Range	Common
Trickling filter BOD loading	kg BOD/m^3·d	0.4–1.8	0.80
Solids contact average detention time	min	45–120	60
Peak flow solids contact detention time	min	15–30	30
Total solids contact/reaeration tank SRT	d	1.0–2.0	1.2
Solids contact DO concentration	mg/L	1.0–2.0	2
Solids contract MLSS concentration	mg/L	1500–3000	2000
Secondary clarifier average SOR[b]	m/h	0.9–1.7	1.3

[a] Adapted from Parker and Bratby (2001) and Daigger and Boltz (2011).

[b] SOR = surface overflow rate, m^3/m^2·h.

Trickling Filter/Activated Sludge Process

The trickling filter/activated sludge process (TF/AS), as shown on Fig. 9–14(c), is similar to the TF/SC described above with the exception that instead of a contact process, a conventional activated sludge process is used.

Process Description. In contrast to the TF/SC process, the trickling filter in a TF/AS process is designed at a much higher BOD loading to serve as a roughing filter (40 to 70 percent BOD removal) and an appreciable amount of soluble BOD removal also occurs in the activated sludge process. The activated sludge SRT is designed to achieve effluent goals for BOD removal and possibly nitrification. Little reduction in the needed aeration basin size occurs as compared to that without the trickling filter because the overall solids production is only slightly less than what would have occurred without the upstream trickling filter.

Design Considerations. Common design conditions used for TF/AS processes are summarized in Table 9–9. The SRT needed is a function of the mixed liquor temperature and effluent BOD or ammonia-N concentration needed. The trickling filter acts as a bioselector for good settling floc in the activated sludge process and sustained SVI values of 100 to 120 mL/g are possible to allow for a higher MLSS concentration in the activated sludge system compared to that without the trickling filters (Biesinger et al., 1980).

Oxygen Required. The amount of oxygen required in the activated sludge aeration tank depends on how much influent BOD remains after the trickling filter treatment, and the amount and endogenous oxygen demand of trickling filter biomass fed to the activated sludge tank. The net amount of biomass produced in the trickling filter is a function of the amount of BOD removed and the trickling filter biomass SRT.

Removal of BOD. The amount of BOD removed and metabolized in the trickling filter is difficult to predict. Both particulate and soluble BOD are removed by biomass in the trickling filter and current empirical design models (Sec. 9–2) are generally based on influent and final settled BOD, and thus do not distinguish between particulate (pBOD) and soluble BOD (sBOD) removal rates. These models may be used to estimate the sBOD removal by subtracting the estimated BOD of the effluent suspended solids. However, pBOD not degraded in the trickling filter will most likely be degraded in the activated sludge process, therefore affecting the oxygen demand. Thus, to determine the oxygen required for the activated sludge process, the amount of pBOD degraded in the trickling filter is critical.

Table 9–9

Process design criteria for trickling filter-activated sludge (TF/AS) process

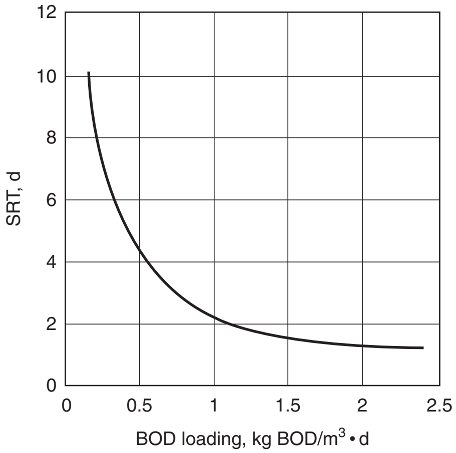
Parameter	Units	Range	Common
Trickling filter BOD loading	kg BOD/m^3·d	1.6–4.0	2.5
Activated sludge SRT	d	3.0–10.0	Varies[a]
Aeration tank DO concentration	mg/L	1.0–2.0	2
Aeration tank MLSS concentration	mg/L	2500–5000	3500
Secondary clarifier average SOR[b]	m/h	0.9–1.7	1.3

[a] Function of temperature, SRT selected to stay below nitrification.

[b] SOR = surface overflow rate, m^3/m^2·h.

Figure 9–15

Equivalent SRT for biomass in a trickling filter as a function of the BOD loading. (Adapted from WEF, 2000.)



Removal of pBOD. The removal of pBOD was studied in a combined trickling filter-activated sludge pilot plant over a wide range of trickling filter BOD loadings. Intensive sampling with COD and BOD solids balances on the trickling filter were used to determine the amount of pBOD degradation (Bogus, 1989). The amount of pBOD degraded increased as the BOD loading to the trickling filter was decreased. An estimate of the percent of influent pBOD degraded as a function of the BOD loading, is provided on Fig. 9–16.

Trickling Filter/Activated Sludge Design Approach. The design procedure to determine the oxygen requirements, sludge production and aeration volume of the activated sludge basin for a TF/AS process is summarized in Table 9–10. With an estimate of the trickling filter SRT and amount of pBOD and sBOD removal in the trickling filter, the amount of biomass produced can be calculated. With that information the amount of oxygen demand satisfied in the trickling filter can be estimated. The trickling filter effluent biomass and non-degraded pBOD and sBOD concentrations can then be used to estimate the activated sludge aeration basin oxygen demand. A solids balance is also done to determine the basin volume as a function of the design SRT and MLSS concentration. The biomass yield and endogenous decay coefficients and basic equations are the same as those

Figure 9–16

Approximate amount of particulate BOD degraded in a trickling filter as a function of organic loading. (From Bogus, 1989).

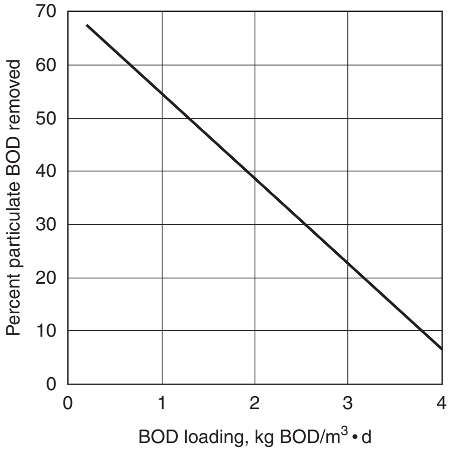


Table 9–10

Computation procedure for the design of a trickling filter/activated sludge process

Item	Description
1.	Select a BOD loading for the trickling filter that is compatible with the combined process selection.
2.	Select the SRT of the activated sludge process. For highly loaded trickling filters longer SRTs will be used in the activated sludge process.
3.	Determine the trickling filter tower size and hydraulic loading rate.
4.	Estimate the soluble BOD removal in the trickling filter.
5.	Based on the BOD loading to the trickling filter use Fig. 9–16 to determine the fraction of particulate BOD removed in the trickling filter.
6.	Use Fig. 9–15 to estimate the biomass SRT in the trickling filter. Use this value to estimate the biomass production.
7.	From the biomass production in the trickling filter and the amount of BOD removed, perform a mass balance on the ultimate BOD, including biomass production, to determine the amount of oxygen demand satisfied in the trickling filter.
8.	Assume that the portion of influent BOD not degraded in the trickling filter is degraded in the activated sludge basin if the SRT is ≥ 4 d. From the BOD removal calculate the biomass production in the activated sludge tank. Adjust the biomass produced from the trickling filter by the loss due to endogenous decay in the activated sludge tank.
9.	Based on the total biomass produced, perform an ultimate BOD mass balance to determine the total oxygen demand for the entire system. Subtract the amount of oxygen demand satisfied in the trickling filter to obtain the oxygen requirements for the activated sludge tank. Add a sufficient peaking factor to account for variable loadings.
10.	Sum the sludge production from biomass, nonbiodegradable VSS (nbVSS) in the influent wastewater and inorganic TSS (TSS–VSS) in the influent wastewater.
11.	Using the net sludge production, SRT, and assumed MLSS concentration calculate the volume of the activated sludge aeration tank.
12.	Evaluate solids and hydraulic loadings for the secondary clarifier design.

presented in Table 8–14 in Chap. 8. A TF/AS process design using the procedure outlined in Table 9–10 is illustrated in Example 9–6.

EXAMPLE 9–6 **Trickling Filter/Activated Sludge (TF/AS) Process Design** Determine the following design elements for a TF/AS process treating a high strength combined domestic and industrial food processing wastewater to meet an effluent BOD and TSS concentration of ≤ 20 mg/L. No nitrification is required:

a. Trickling filter diameter and hydraulic loading rate
b. The amount of oxygen demand satisfied in the trickling filter, kg/d
c. The amount of oxygen required in the activated sludge aeration tank, kg/d
d. The amount of solids wasted per day, kg/d
e. The volume and hydraulic retention time of the aeration tank
f. Compare the energy required for the trickling filter and activated sludge treatment steps in terms of kW/kg O_2 demand satisfied

Wastewater characteristics after primary treatment are given below for the domestic and industrial wastewaters and for their combined flow to the trickling filter.

Item	Unit	Domestic	Industrial	Combined
Flow	m^3/d	6000	1000	7000
BOD	g/m^3	130	600	197
sBOD	g/m^3	90	480	146
TSS	g/m^3	60	120	69
VSS	g/m^3	52	110	60
nbVSS	g/m^3	20	5	18

For TF/AS design assume the following conditions apply:

1. Number of trickling filters = 2
2. Domestic wastewater plastic packing coefficient $(k_{20}A_S) = 0.21\ (\text{L/s})^{0.5}/\text{m}^2$ (see Table 9–6)
3. Industrial wastewater plastic packing coefficient $(k_{20}A_S) = 0.181\ (\text{L/s})^{0.5}/\text{m}^2$ (see Table 9–6)
4. Depth of packing = 6.1 m
5. Biomass yield $Y_H = 0.6$ g VSS/g BOD
6. Endogenous decay $b_H = 0.08$ g/g·d
7. UBOD/BOD = 1.6
8. MLSS = 3500 g/m^3
9. Biomass VSS/TSS ratio = 0.85
10. Temperature = 15°C

Solution

1. Determine the weighted average trickling filter BOD removal coefficient $(k_{20}A_S)$ for the combined wastewater.

$$\text{Net } k_{20}A_S = \frac{(6000\ \text{m}^3/\text{d})(130\ \text{g/m}^3)(0.21(\text{L/s})^{0.5}/\text{m}^2) + (1000\ \text{m}^3/\text{d})(600\ \text{g/m}^3)[0.181(\text{L/s})^{0.5}/\text{m}^2]}{(7000\ \text{m}^3/\text{d})(197.1\ \text{g/m}^3)}$$

$$\text{Net } k_{20}A_S = 0.197(\text{L/s})^{0.5}/\text{m}^2$$

2. Select the organic loading rate for a partial BOD removal filter application from Table 9–1.

$$L_{\text{org}} = 2.5\ \text{kg BOD/m}^3\cdot\text{d}$$

3. Select the SRT of the activated sludge based on avoiding nitrification.

$$\text{SRT} = 5.0\ \text{d}$$

4. Determine the trickling filter tower size and hydraulic loading rate.
   a. Determine the trickling filter volume

   The organic volumetric loading rate, as given by Eq. (7–69), is

$$L_{\text{org}} = \frac{QS_o}{(V)(10^3\ \text{g/1 kg})} = 2.5\ \text{kg BOD/m}^3\cdot\text{d}$$

$$V = \frac{QS_o}{(2.5\ \text{kg BOD/m}^3\cdot\text{d})(10^3\ \text{g/1 kg})}$$

$$= \frac{(7000\ \text{m}^3/\text{d})(197.1\ \text{g/m}^3)}{(2.5\ \text{kg BOD/m}^3\cdot\text{d})(10^3\ \text{g/1 kg})} = 551.9\ \text{m}^3$$

b. Determine the hydraulic loading rate.

$$V = AD$$

$$A = \frac{V}{D} = \frac{551.9\ \text{m}^3}{6.1\ \text{m}} = 90.48\ \text{m}^2$$

$$q = \frac{Q}{A} = \left[\frac{(7000\ \text{m}^3/\text{d})}{(90.48\ \text{m}^2)}\right]\left(\frac{10^3\ \text{L}}{1\ \text{m}^3}\right)\left(\frac{\text{d}}{1440\ \text{min}}\right)\left(\frac{\text{min}}{60\ \text{s}}\right) = 0.90\ \text{L/m}^2\cdot\text{s}$$

c. Determine the trickling filter diameter.

$$\text{Area per tower} = \frac{(90.48\ \text{m}^2)}{2\ \text{towers}} = 45.24\ \text{m}^2/\text{tower}$$

Diameter/tower = 7.6 m

5. Determine the amount of soluble and particulate BOD removed in the trickling filter using Eq. (9–19). Note Eq. (9–19) is based on an effluent settled BOD. Assume a settled effluent TSS concentration of 30 mg/L.

a. Determine the effluent BOD concentration from Eq. (9–19) where $R = 0$, the effluent sBOD from Eq. (8–26) and the amount of sBOD removed in the trickling filter.

$$S_e = \frac{S_o}{(R+1)\exp\left\{\dfrac{k_{20}A_sD\theta^{T-20}}{[q(R+1)]^n}\right\} - R}$$

where S_o = influent BOD based on primary effluent flow, g/m^3
S_e = effluent BOD, g/m^3
k_{20} = filter treatability constant at 20°C, (L/s)$^{0.5}$/m
A_s = clean packing specific surface area, m^2/m^3
D = depth of packing, m
θ = temperature correction coefficient, 1.035
q = hydraulic loading rate based on primary effluent flow, L/m^2·s
R = ratio of recirculation flowrate to primary effluent flowrate, 0
n = constant characteristic of packing used = 0.50

$$S_e = \frac{(197.1\ \text{g BOD/m}^3)}{\exp\left\{\dfrac{(0.197(\text{L/s})^{0.5}/\text{m}^2)(6.1\ \text{m})1.035^{15-20}}{[(0.90\ \text{L/m}^2)\cdot\text{s}]^{0.5}}\right\}} = 67.8\ \text{g BOD/m}^3$$

Determine the soluble BOD from Eq. (8–26)

$$\text{BODe} = \text{sBODe} + \left(\frac{0.60\ \text{g BOD}}{\text{g UBOD}}\right)\left(\frac{1.42\ \text{g UBOD}}{\text{g VSS}}\right)\left(\frac{0.85\ \text{g VSS}}{\text{g TSS}}\right)\left(\frac{30\ \text{g TSS}}{\text{m}^3}\right)$$

$$67.8\ \text{g/m}^3 = \text{sBODe} + 21.7\ \text{g/m}^3,\ \text{sBODe} = 46.1\ \text{g/m}^3$$

$$\text{sBOD removal} = (145.7 - 46.1) = 99.6\ \text{g/m}^3$$

b. Determine the particulate BOD removed.

Particulate BOD in influent = BOD – sBOD

$$\text{pBOD} = (197.1 - 145.7) = 51.4\ \text{g/m}^3$$

From Fig. 9–16, amount of pBOD removed at 2.5 kg BOD/m^3·d = 30%

pBOD in trickling filter effluent = (1 – 0.30) (51.4 g/m^3) = 36.0 g/m^3

The pBOD removed in the trickling filter effluent is:

pBOD removed = 51.4 g/m^3 – 36.0 g/m^3= 14.4 g/m^3

c. Determine the undegraded influent BOD in the trickling filter effluent.

Trickling filter effluent BOD = sBOD + pBOD = (46.1 + 36.0) g/m^3

= 82.1 g/m^3

6. Determine oxygen demand satisfied in the trickling filter.

From Fig. 9–15, the trickling filter SRT = 1.2 d at an organic rate of 2.5 kg BOD/m^3·d

Determine biomass produced using Eq. (7–42) in Table 8–10. (Note: SRT = τ),:

$$X = \frac{Y_H(S_o - S)}{1 + b_H(\text{SRT})}$$

Substrate removal (S_o – S) in trickling filter

= (197.1 – 82.1) = 115.0 g BOD/m^3

$$X_{TF} = \frac{(0.6 \text{ g VSS/g BODr})(115 \text{ g BOD/m}^3)}{[1 + (0.08 \text{ g/g·d})(1.2 \text{ d})]} = 63.0 \text{ g VSS/m}^3$$

For short SRT values, cell debris is very small and is not included here.

Determine the oxygen satisfied in trickling filter with a COD balance.

$$\text{O}_2 \text{ used} = \text{bCOD}_{\text{IN}} - \text{bCOD}_{\text{OUT}} - 1.42X_{TF}$$

$$= 1.6(197.1 \text{ g/m}^3 - 82.1 \text{ g/m}^3) - 1.42(63.0 \text{ g/m}^3)$$

Oxygen used in trickling filter = 94.5 g/m^3

7. Determine biomass produced in the activated sludge aeration tank.

Approximate BOD removed = 82.1 g/m^3, SRT = 5.0 d

Biomass due to oxidation of organic matter

$$X_{AS} = \frac{(0.6 \text{ g VSS/g BODr})(82.1 \text{g BOD/m}^3)}{[1 + (0.08 \text{ g/g·d})(5.0 \text{ d})]} = 35.2 \text{ g VSS/m}^3$$

Trickling filter biomass remaining in the activated sludge aeration tank after endogenous decay:

$$X_{TF,AS} = \frac{(63.0 \text{ g VSS/m}^3)}{[1 + (0.08 \text{ g/g·d})(5.0 \text{ d})]} = 45.0 \text{ g VSS/m}^3$$

Net biomass produced or fed to the aeration tank = 35.2 g/m^3 + 45.0 g/m^3 = 80.2 g VSS/m^3

8. Determine oxygen demand in the aeration tank in mg/L and kg O_2/d.

Total oxygen consumed = 1.6(197.1 g/m^3) – 1.42(80.2 g/m^3)

= 201.5 g O_2/m^3

Activated-sludge oxygen demand = total demand − *TF* demand

$$= 201.5 \text{ g O}_2/\text{m}^3 - 94.5 \text{ g O}_2/\text{m}^3 = 107.0 \text{ g O}_2/\text{m}^3$$

$$\text{kg O}_2/\text{d} = (107.0 \text{ g O}_2/\text{m}^3)(7000 \text{ m}^3/\text{d})(1 \text{ kg}/10^3 \text{ g}) = 749 \text{ kg O}_2/\text{d}$$

9. Determine the sludge production rate in the activated sludge.

Amount of solids wasted per day (TSS) using Eq. (8–21) in Table 8–10.
(Cell debris term ignored)

$$P_{X,\text{TSS}} = \frac{P_{X,\text{Bio}}}{0.85} + Q(\text{nbVSS}) + Q(\text{TSS}_o - \text{VSS}_o)$$

$$P_{X,\text{TSS}} = \frac{(7000 \text{ m}^3/\text{d})(80.2 \text{ g VSS/m}^3)}{(0.85 \text{ g VSS/g TSS})} + (7000 \text{ m}^3/\text{d})(18.0 \text{ g VSS/m}^3)$$
$$+ (7000 \text{ m}^3/\text{d})[(69.0 - 60.0) \text{ g TSS/m}^3] = 849{,}470 \text{ g TSS/d}$$

The total solids wasted per day expressed in kg/d = 849.5 kg TSS/d

10. Determine the aeration tank volume and the corresponding hydraulic detention time
    a. Determine the aeration tank volume using Eq. (7–57) in Table 8–10.

$$(X_{\text{TSS}})(V) = P_{X,\text{TSS}}(\text{SRT})$$

$$V = \frac{P_{X,\text{TSS}}(\text{SRT})}{X_{\text{TSS}}} = \frac{(849.5 \text{ kg/d})(5.0 \text{ d})(10^3 \text{ g/1 kg})}{(3500 \text{ g/m}^3)} = 1213.6 \text{ m}^3$$

    b. Determine the hydraulic detention time in the solids contact aeration tank

$$\tau = \frac{(1213.6 \text{ m}^3)(24 \text{ h/d})}{(7000 \text{ m}^3/\text{d})} = 4.2 \text{ h}$$

11. Compare the energy needed per kg O_2 satisfied in the trickling filter versus in the activated sludge step.
    a. The energy required for the trickling filter is to pump the feed flow to above the 6.1 m tower height, which is approximately 1.38 kW/1000 m^3.

The energy needed equals (1.38 kW/km^3)(7000 m^3/d) = 9.66 kW

$$\text{Oxygen demand satisfied} = (94.5 \text{ g/m}^3)\left[\frac{(7000 \text{ m}^3/\text{d})}{(10^3 \text{ g/1 kg})}\right] = 661.5 \text{ kg/d} = 27.6 \text{ kg/h}$$

$$\text{O}_2 \text{ supply efficiency} = \frac{(27.6 \text{ kg/h})}{9.66 \text{ kW}} = 2.85 \text{ kg O}_2/\text{h}\cdot\text{kW}$$

O_2 supply efficiency in activated sludge aeration equals 0.7–1.5 kg O_2/h·kW (Table 5–31, Chap. 5)

Determine the net oxygen supply efficiency for the TF/AS process assuming the high-end efficiency of 1.5 kg O_2/h·kW for the AS process.

$$(0.47)(2.85 \text{ kg O}_2/\text{h}\cdot\text{kW}) + (0.53)(1.5 \text{ kg O}_2/\text{h}\cdot\text{kW}) = 2.13 \text{ kg O}_2/\text{h}\cdot\text{kW}$$

The net energy saving is

$$\left(1 - \frac{1.5}{2.13}\right)100 = 30\%$$

Comments Almost half of the total oxygen demand is satisfied in the trickling filter (94.5 g O_2/m^3 versus a total of 201.5 g O_2/m^3, or about 47 percent. The oxygen demand is provided with a higher oxygen transfer efficiency in the trickling filter than in the activated sludge step. Use of the TF/AS process for this higher strength wastewater reduces the aeration energy required by at least 30 percent compared to treatment with only activated sludge. In addition the activated sludge settling properties are better for the combined TF/AS process so that a higher MLSS concentration and smaller aeration tank volume can be used in the activated sludge process.

Process Advantages. The TF/AS process is attractive for treating higher strength industrial wastewater because of the relatively low energy use per quantity of BOD removed on the trickling filter. The use of the trickling filter also results in good SVI values for the activated sludge mixed liquor, as it acts as a biological selector in removing soluble BOD.

Series Trickling Filter and Activated Sludge Process

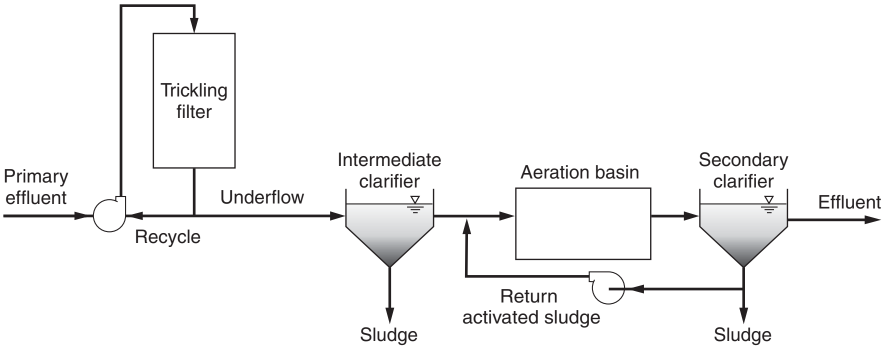
In the third approach employing combined processes, a trickling filter and activated sludge process are operated in series, with an intermediate clarifier between the trickling filter and activated sludge process (see Fig. 9–17). The combination of a trickling filter process followed by an activated sludge process is often used (1) to upgrade an existing activated-sludge system, (2) to reduce the strength of wastewater where industrial and domestic wastewater is treated in common treatment facilities, and (3) to protect a nitrification activated sludge process from toxic and inhibitory substances. In systems treating high-strength wastes, intermediate clarifiers are used between the trickling filters and the activated-sludge units to reduce the solids load to the activated sludge system and to minimize the aeration volume required.

9–4 INTEGRATED FIXED FILM ACTIVATED SLUDGE PROCESS

An *integrated fixed film activated sludge* (IFAS) process, or *hybrid* process, consists of an activated sludge system in which a material to support attached biomass growth has been added in addition to the suspended biomass growth in an activated sludge reactor. A variety of synthetic media for attached growth have been developed for applications in activated sludge processes. These materials may be suspended in the activated sludge or fixed in the aeration tank as shown on Fig. 9–18. The addition of attached growth to the activated

Figure 9–17

Schematic flow diagram of a series trickling filter and activated sludge process with intermediate clarifier.



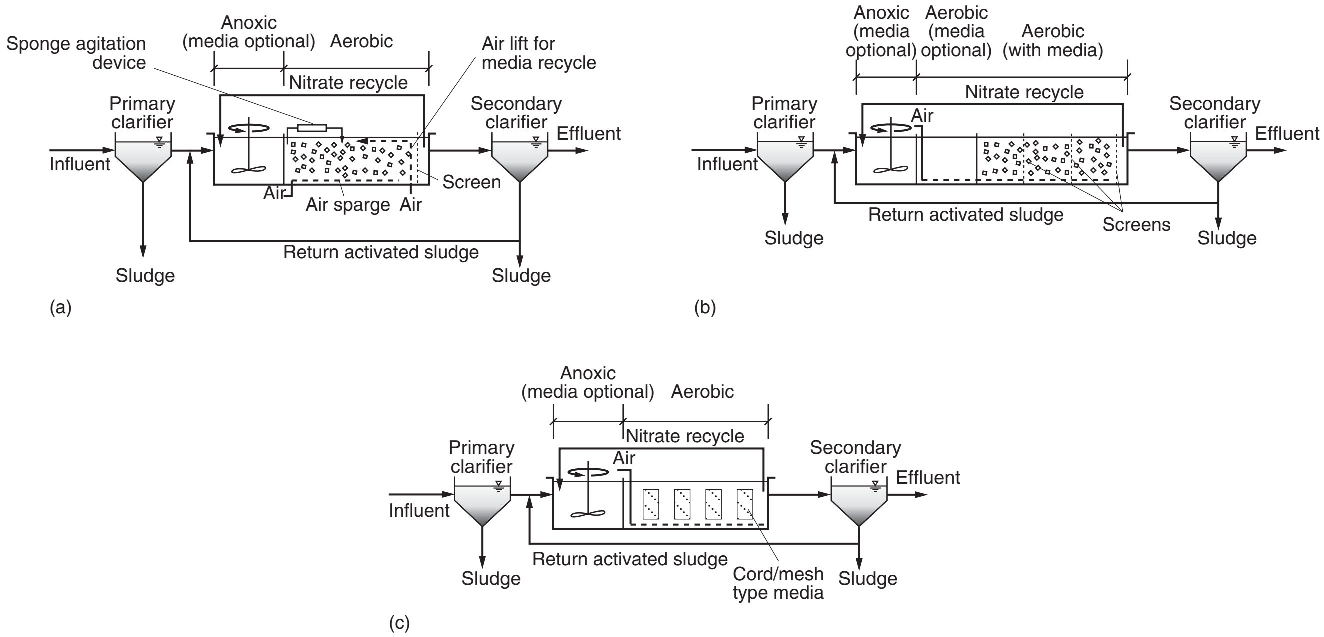


Figure 9–18

Schematic flow diagrams of examples of integrated fixed-film activated sludge (IFAS) systems: (a) suspended sponge biofilm carriers, (b) suspended plastic biofilm carriers, and (c) fixed media. (Adapted from WEF, 2011; and Phillips et al., 2010.)

sludge reactor results in a total equivalent MLSS concentration that may be 1.5 to 2.0 times the activated sludge MLSS concentration alone. The higher biomass inventory in the aeration tank can result in an increase in the effective SRT to provide nitrification or an increase in the system's treatment capacity. Because the additional solids are from attached growth, the higher MLSS inventory occurs without an increase in solids loading on the secondary clarifier. The following topics are considered in this section: (1) process development, (2) process applications, (3) process advantages and disadvantages, (4) design of physical facilities, (5) process analysis, and (6) BOD removal and nitrification design.

Process Development

The attached growth media in an IFAS process may be stationary or moving due to air sparging or mixing. Though most any type of media can provide an effective surface area for biofilm growth in an activated sludge process, the main applications of the IFAS process involve designs using polymeric, petroleum-based proprietary media. The suspended or *floating* media are called biofilm carriers and are typically either a sponge-type polyurethane or polyethylene foam or specially designed polypropylene plastic. The properties of representative types of biofilm carriers used in integrated fixed film activated sludge (IFAS) and moving bed bioreactor (MBBR) processes are summarized in Table 9–11.

Sponge-Type Biofilm Carriers. Linpor™ and Captor™ are IFAS processes using proprietary sponge-type media. The sponge-type biofilm carriers are foam cuboids with a specific gravity of about 0.95 g/cm^3 (see Fig. 9–19). The sponge biofilm carriers are placed in the activated sludge aeration tank with a filling fraction of 15 to 30 percent of the reactor volume. At a 20 percent fill volume with sponges having a bulk specific surface area of about 800 m^2/m^3, the biofilm surface area per unit reactor volume is about 160 m^2/m^3.

Table 9–11

Typical biofilm carriers used for IFAS and MBBR processes

Type of biofilm carrier[a]	Specific gravity	Example of nominal dimensions, mm	Example bulk specific surface area, m^2/m^3
Sponge[a]	0.95	15 × 15 × 12 depth	850
Plastic wheel (K1)[b]	0.96–0.98	7 × 10 dia.	500
Plastic wheel (K3)[b]	0.96–0.98	4 × 25 dia.	800
Plastic wheel (K5)[b]	0.96–0.98	9 × 25 dia.	500
BioChip (P)[b]	0.96–1.02	3 × 45 dia.	900
BioChip (M)[b]	0.96–1.02	2 × 48 dia.	1200
Plastic square	0.96	15 × 15 × 10 depth	680
Rope[c]		45 dia. rope	2.85 m^2/m

[a] From Linpor. See Fig. 9–19 for views of biofilm carriers.

[b] From Kaldness. See Fig. 9–20 for views of biofilm carriers.

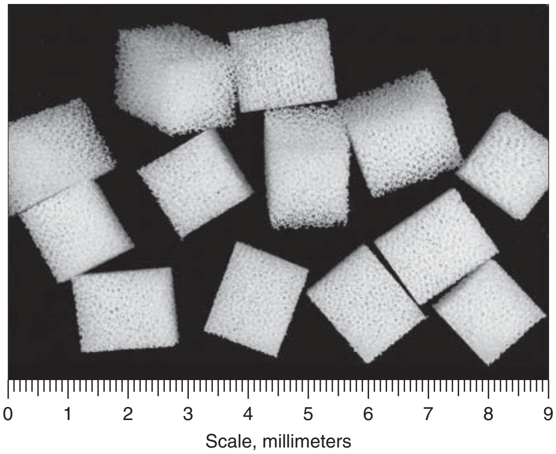
[c] From Ecologix.

As shown on Figs. 9–18(a) and (b), screens are required upstream and downstream of the IFAS reactor to retain the carriers. Coarse or fine bubble air sparging diffusers are used to provide oxygen and promote mixing of the sponges. The diffusers are arranged to promote a rolling mixing pattern. The effluent flow tends to pack the sponges up against the screens at the effluent, where they tend to float on the surface if not removed (WEF, 2011). An air-lift pump has been used to return sponges upstream and an air knife has been installed to clean the effluent screens continuously. A submersible pump is often installed to periodically pump the sponges to agitate and remove the accumulated excess biomass. An impingement plate at the end of the air lift media recirculation line has also been used to remove excess growth from the sponge surface (Warakomski, 2005).

Plastic-Type Biofilm Carriers. Plastic biofilm carriers with a specific gravity of 0.96 to 0.98 g/cm^3 were originally developed by a Norwegian company, Kaldnes Miljøteknolog, for use in the moving bed bioreactor process, but have since been used in IFAS systems with the first U.S. installation at Broomfield, CO. (Phillips et al., 2008). The original designs were a wagon-wheel configuration of about 10-mm diameter and

Figure 9–19

Sponge biofilm carriers used for integrated fixed film activated sludge and moving bed bioreactor processes. (Media samples provided courtesy of Mixing & Mass Transfer Technologies).



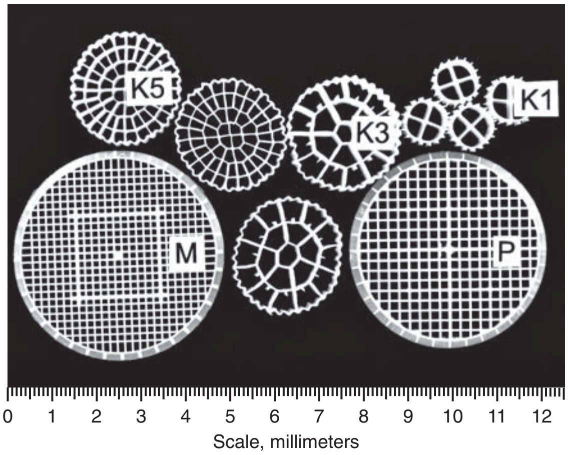


Figure 9–20

Examples of various plastic suspended biofilm carriers used in integrated fixed film activated sludge and moving bed bioreactor processes. The characteristics of the biofilm carriers are presented in Table 9–11. (AnoxKaldness™ Biofilm carriers provided courtesy of Veolia, Inc.)

7 mm height, but the 25 mm diameter design indicated in Table 9–11 is now more common (see Fig. 9–20). A number of companies provide plastic biofilm carrier media, and other shapes including chips and square configurations may be used. Plastic biofilm carriers used in aerobic zones have a bulk specific surface area of 500 to 700 m^2/m^3. With the plastic type carriers, the media fill volume can be higher than that used for sponge media, as they have less of a tendency to bind the downstream screens, with fill fractions ranging from 30 to 60 percent of the tank volume. Coarse or intermediate bubble size diffusers provide mixing in aeration zones and the plastic biofilm carriers are maintained in the reactor by the use of a perforated plate (5 x 25 mm slots) at the tank outlet.

Fixed Material. Some of the early IFAS processes used plastic sheets or asbestos sheets in activated sludge tanks. A Submerged RBC (SRBC) IFAS system has been created by placing standard RBC units in activated sludge with approximately 85 percent submergence instead of the typical operation at 40 percent submergence. The rotation is driven by aeration and may be mechanically assisted. The submerged operation reduces the load on the packing shaft. The more common IFAS process design with fixed material use a rope- or mesh-type media.

Examples of proprietary rope-like material used in IFAS processes are the Ringlace® and BioMatrix® and the mesh-type include the AccuWeb® and BioWeb® designs. The Ringlace and Biomatrix products consist of approximately 5 mm diameter strands of polyvinyl chloride material that are looped around aluminum or stainless-steel frames. The web media, which resembles netting woven in a hexagonal pattern, is also installed as sheets of media with the top and bottom of the media supported by the bars in the frames. An example of a web-mesh fixed material installation is shown on Fig. 9–21. The use of dedicated coarse-bubble sparging underneath the media is often used to ensure good mixing and oxygen transfer and media agitation to control the biofilm thickness and minimize the potential for red worm predators.

Process Applications

A common IFAS process application has been in the conversion of conventional aerobic activated sludge treatment processes to biological nitrification-denitrification processes for nitrogen removal, and especially where space is limited for adding additional tank volume. As an example, the addition of biofilm carriers to the activated sludge aeration tank at the Bloomfield, CO installation allowed a reduction of aerobic volume needed for nitrification,

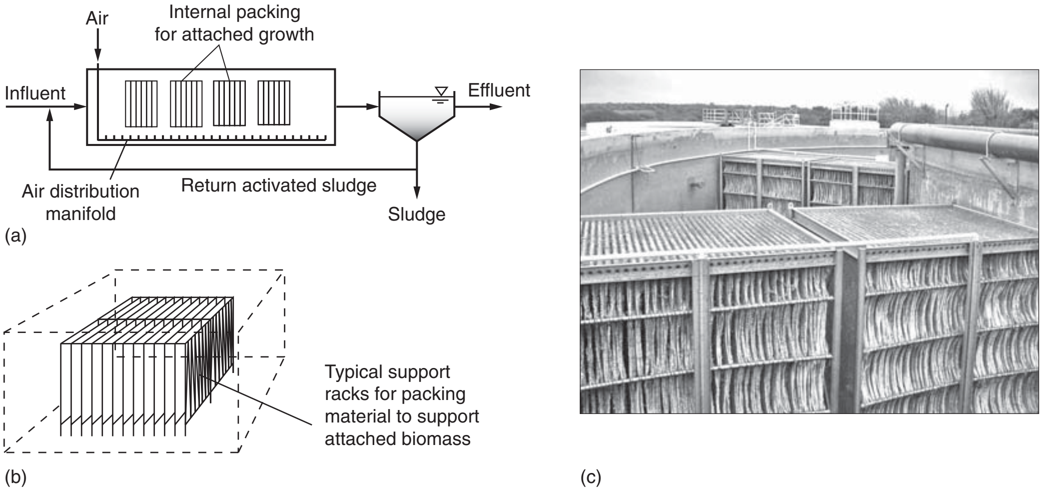

Figure 9–21

Example of a fixed attached growth media: (a) schematic showing the placement in activated sludge reactor (b) isometric view, and (c) view of installation in a circular configuration activated sludge tank (courtesy of J. Barnard).

so that a portion of the existing aeration tank could then be used for a preanoxic tank to convert the system to an MLE nitrogen removal process (Phillips et al., 2008).

Fixed or floating media can be applied in a number of activated sludge configurations to increase the effective volumetric biomass concentration and to reduce the suspended growth SRT needed for nitrification. When conventional activated sludge processes must be upgraded to a higher level of treatment for nitrification, nitrogen removal or phosphorus removal, an IFAS process may be considered as an alternative to provide the higher level of treatment without additional tank construction. Treatment capacity is added without the need to add new tankage or increase the secondary clarifier area. IFAS also offers flexibility in design in terms of the location and amount of biofilm media to be added to an existing or new system.

Nitrification and Biological Nitrogen Removal. The use of IFAS processes for nitrification and biological nitrogen removal is of primary interest due to the potential for upgrading BOD removal only facilities without construction of additional treatment tanks to accommodate longer SRTs and hydraulic retention times. IFAS configurations may include single or multiple-staged aerobic zones, and require higher DO concentrations in the aerobic zones, in the range of 4 to 6 mg/L, to overcome the biofilm substrate diffusion limitations so that the biomass on the media surface area can be utilized more fully for nitrification.

Flow schematics of possible IFAS configurations for nitrogen removal with single or multiple-stage aerobic zones are shown on Fig. 9–22. If a sufficient DO concentration is available, a two-stage aerobic zone provides higher nitrification efficiency due to a higher ammonia-N concentration and removal in the first stage. There are two advantages for using the attached growth process only in the intermediate stage of a three-stage aerobic zone as shown on Fig. 9–22(c). The first is more efficient use of the biofilm carrier surface area for nitrifying bacteria growth by having most of the heterotrophic growth for BOD removal in the first stage by the suspended biomass. The second advantage is that a lower DO concentration can be used in the smaller third aeration zone so that less dissolved oxygen is added to the preanoxic zone in the nitrate recycle flow.

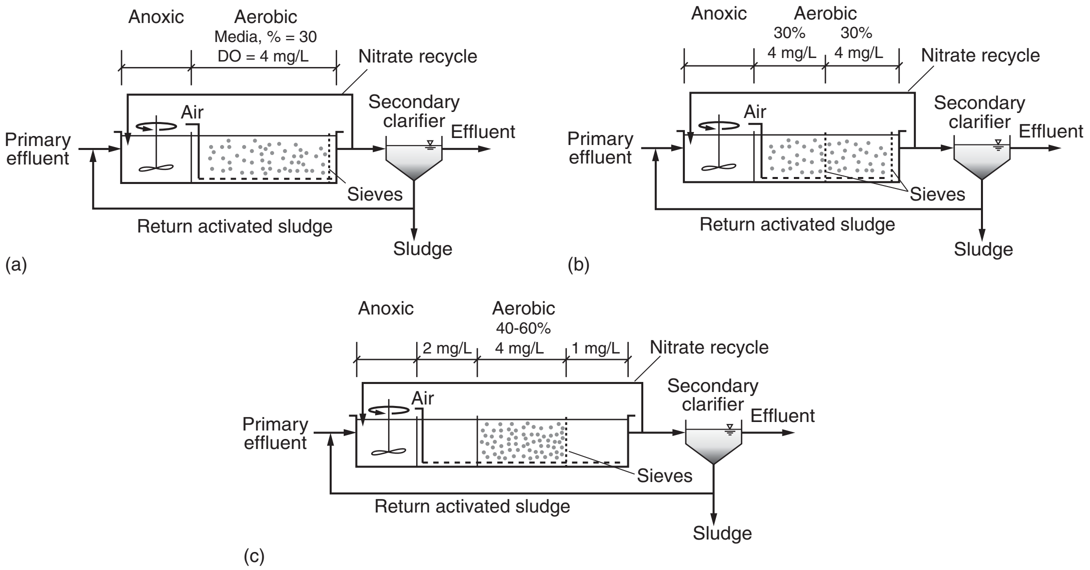

Figure 9–22

Examples of biofilm carrier media locations in the MLE biological nitrogen removal process: (a) single aeration reactor with carrier media, (b) two aeration reactors in series with carrier media, and (c) three aeration reactors in series with carrier media in larger, middle reactor. Typical media percentages and DO values are also shown each of the figures. (Adapted from Phillips et al., 2010.)

Enhanced Biological Phosphorus Removal. Enhanced biological phosphorus removal (EBPR) is possible in IFAS systems using EBPR process schemes (as described in Sec. 8–8) that have anaerobic contact zones with no media and only suspended growth (Christensson and Welander, 2004; Rogalla et al., 2006; and Pastorelli et al., 1999). In a pilot plant comparison of EBPR performance between an activated sludge system, an IFAS system with fixed BioWeb® media in the aerobic zone, and an IFAS system with fixed BioWeb® media in the anoxic and aerobic zones, similar performance was found for the activated sludge and IFAS system with media in the aerobic zone. The IFAS system with media in the anoxic and aerobic zone had slightly less EBPR efficiency, presumably due to anaerobic conditions within the biofilm in the anoxic zone causing phosphorus release (Sriwiriyarat and Randall, 2005). From an investigation of an IFAS system with suspended and attached growth autotrophic nitrifiers, heterotrophic PAOs, and denitrifier populations with plastic biofilm carriers in the aerobic zone, it was found that the slower-growing nitrifiers were mainly attached to the carrier media and the faster-growing heterotrophs were mainly in the suspended mixed liquor (Onnis-Hayden et al., 2011). The need for the PAOs to be exposed to anaerobic and aerobic conditions likely favored their growth in the shorter SRT suspended growth mixed liquor. Because of this decoupling ability, the advantage of operating at shorter SRTs based on suspended growth mixed liquor in an IFAS system, but having a longer SRT for nitrification is of importance.

IFAS Process Advantages and Disadvantages

Several advantages can be gained from an IFAS process compared to an activated sludge process including (1) an increased treatment capacity in a smaller space, (2) an increase in the effective mixed liquor concentration to as much as 4000 to 8000 mg/L without a significant increase in solids loading to the secondary clarifier, (3) the ability to phase in treatment capacity or improve performance by adding media, (4) a more stable nitrification community due to a high attached growth inventory, and (5) the potential for simultaneous nitrification and denitrification by controlling loading and DO conditions.

Process disadvantages compared to an activated sludge treatment process include (1) a higher energy demand due to the need to operate at elevated DO concentrations, (2) the need to use proprietary media, (3) issues of media removal for diffuser maintenance, (4) the need for improved influent wastewater screening, and (5) additional hydraulic profile headlosses due to flow through the media screening devices.

Design of Physical Facilities

Physical facility design considerations for an IFAS process include (1) pretreatment, (2) media retention, (3) aeration and mixing, (4) foam control, (5) biofilm control, and (6) liquid-solids separation.

Pretreatment. Appropriate pretreatment, including screening, grit removal, and primary sedimentation, is necessary to prevent the accumulation of inert material, such as rags, plastics, and sand on the media and in the tank. These materials would be difficult to remove once in the tank because of the presence of the fixed or suspended media. The maximum preferred bar screen spacing or perforation diameter is 6 mm with primary sedimentation and 3 mm without primary treatment (WEF, 2011).

Media Retention. Critical design elements that must be considered for the sponge or plastic biofilm carriers are effluent screens or sieves and the tank forward flow velocity (Phillips et al., 2010; McQuarrie and Boltz, 2011; and WEF, 2011) [see Figs. 9–18(a) and (b)]. Stainless steel effluent sieves are located at the end of the tank to collect the tank effluent flow and retain the media. The effluent sieve can be either a flat plate with orifices or horizontal cylinders, with the top of the cylinder at 35 to 65 percent of the liquid depth. Typical cylinder diameters are 0.30 to 0.40 m with lengths of 1.5 m, 3.0 m, and 3.65 m. The hydraulic application rate across the screen area is limited to 50 to 60 m/h at peak flow conditions including the recycle and secondary treatment influent flows. The sieve orifice size is selected to keep the headloss below 50–150 mm. An orifice flow velocity of less than 0.50 m/s is typically used to control headloss. Coarse bubble air diffusers located on the floor along the length of the flat plate screen provide air agitation to prevent the accumulation of debris and media and has been referred to as an *air knife*.

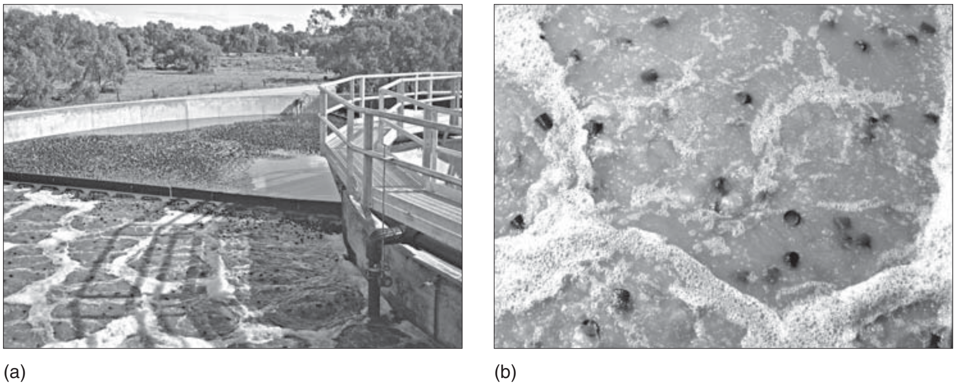
The tank forward flow velocity is the total flowrate out of the tank, including recycle flows, divided by the tank cross-section area. High forward flow velocities push more media to the effluent end of the tank, where it can bunch up and build up on the liquid surface. A forward flow velocity of less than 30 to 35 m/h is recommended (McQuarrie and Boltz, 2011; and WEF, 2011).

The fixed media is installed on frames that are placed at fixed locations in the IFAS aeration tank. The frames may be supported off the floor or supported by attaching structural members to the aeration tank walls. The frames must be sufficiently anchored to withstand the forward liquid flow velocity and the fluid agitation caused by aeration.

Aeration and Mixing. For floating media applications, sparged aeration is used to provide oxygen and to also mix the media. The sparging design is also used to provide agitation and fouling control of the effluent sieves (see Fig. 9–23). Coarse bubble aeration is most common for floating media applications but fine bubble aeration has also been used. The use of coarse bubble aeration avoids the need to move the media out of the basin

Figure 9–23

View of bioreactor with suspended biofilm carriers: (a) view of a bioreactor with a screen to retain the biofilm carriers and (b) suspend biofilm carriers in the air sparging zone.



for diffuser cleaning and maintenance as would be the case for fine bubble aeration, while fine bubble aeration is more energy efficient. In either case the diffuser aeration layout should be done to encourage a rolling action of the media across the basin width. Full floor coverage with fine bubble diffusers is discouraged. The IFAS media does not appear to have a significant impact on the sparged aeration oxygen transfer efficiency. In side-by-side testing of activated sludge and IFAS for a coarse bubble application (Rosso et al., 2011) and for a fine bubble application (Phillips et al., 2010), similar oxygen transfer efficiency was found at standard conditions.

In some fixed media designs, coarse bubble aeration facilities are placed below the fixed racks of media to provide mixing and agitation of the biofilm. In other designs, the objective is to create a flow pattern so that mixed liquor moves up and through the fixed media.

Mixing of floating media in anoxic zones is provided by slow speed mechanical mixers, which are generally placed near the top (but submerged) of the tank with a slight inclination to create a directional flow across the tank and rolling action. Typical mixing energy may range from 15 to 25 W/m^3 tank volume (McQuarrie and Boltz, 2011).

Scum and Foam Control. The use of effluent sieves for IFAS systems with suspended media results in trapping foam in the aeration basin. Trapping of foam in activated sludge basins normally encourages the growth of foam-causing bacteria to enhance the foaming problem. Serious foaming problems have not been reported in the early IFAS installations except for during start up operations. Provisions for chlorinated sprays or defoaming chemicals may be considered (Phillips et al., 2008).

Biofilm Control. Agitation and mixing caused by the sparged aeration system have been shown to be capable of controlling excessive biofilm growth in fixed media and plastic biofilm carriers. The lighter sponge media often needs additional agitation to dislodge excessive biofilm growth, which is done when media is circulated to the front of the aeration tank by an airlift or submersible pump. An impingement plate at the recirculation pipe discharge helps to dislodge the attached solids.

Predators. Blooms of a type of red-worm population have been observed with fixed media in IFAS systems. The occurrence of predators is less of a problem with the floating media, presumably due to the higher level of agitation. The worm growth results in a lower net sludge production, but can reduce the effective biomass and treatment performance. The worms are obligate aerobes and operating changes, such as a decrease in the influent load, that result in an increase in DO concentration may favor their growth. Turning the air off for several hours and chlorinating the return activated sludge is recommended for worm control. This method of control must be repeated to coincide with the worm egg cycle of approximately two weeks (WEF, 2011).

Liquid Solids Separation. In spite of the higher equivalent biomass concentration in the aeration tank, the solids loading to the secondary clarifier can remain within normal values used for activated sludge treatment. Based on limited studies it appears that the mixed liquor from an IFAS process may have a slightly higher SVI than from activated sludge treatment alone (Kim et al., 2009; Parker et al., 2011). The difference in SVI was attributed to more floc disruption from the flow through the effluent sieves and the high air agitation rates in the aeration basin (Parker et al., 2011).

IFAS Process Design Analysis

An IFAS process is typically used where fixed or biofilm carrier media is added to an activated sludge system to enable nitrification without the construction of additional aeration tanks. In such systems the suspended growth SRT is too short to support an adequate ammonia oxidizing bacteria (AOB) population for nitrification. Nitrifying bacteria can grow on the IFAS media to provide nitrification in spite of the limited SRT in the suspended growth process.

Examples of situations in which the benefits of an IFAS retrofit for nitrification have been realized are (1) the effluent treatment requirements have been changed from only BOD removal to include a low effluent ammonia-N concentration, (2) the system must be converted to nitrogen removal such that a portion of the existing aerobic tanks must be used for a preanoxic zone to thus lower the SRT to below that needed for nitrification, and (3) the flowrate and loading to the activated sludge process are increased and the increased sludge production and aeration tank MLSS concentration limits result in an SRT that is too low for nitrification.

Examples of IFAS retrofit applications to accomplish nitrification in activated sludge systems with limited SRT have been described for sponge or plastic biofilm carriers used at Westerly, RI (Masterson et al., 2004), Broomfield, CO (Phillips et al., 2008), the Region of Peel in Ontario, Canada (Stricker et al., 2009), and Conselve, Italy (Falletti and Conte, 2007), and for fixed media at Annapolis, MD (Randall and Sen, 1996) and Blacklick, OH (Sen et al., 2006). In most cases the media is added in the last two-thirds or half of the aeration basin after most of the soluble BOD has been removed by the suspended growth bacteria, so that the media surface area is available for growth by nitrifying bacteria and not overwhelmed by growth of heterotrophic bacteria.

Substrate Removal. The removal of substrate in an IFAS system is a complex process involving both substrate uptake by the suspended biomass and diffusion and consumption of substrate in the biofilm. The sloughing of nitrifying bacteria from the attached growth biofilm results in nitrification in the suspended mixed liquor at low SRTs for which nitrification would not normally be maintained. As was shown in Sec. 9–2 for attached growth nitrification in trickling filters, substrate removal across the biofilm surface area is defined in terms of the removal flux as g substrate/m^2·d. The actual effective surface area is less than the clean surface area of the media due to the biofilm thickness. Excess biofilm thickness growth is controlled in an IFAS system by the aeration designs, which causes hydraulic shearing and turbulent motion of the biofilm floating carriers or agitation of the biofilm in the fixed media designs. Reported biofilm surface concentration for attached growth on plastic carriers ranges from 13 to 39 g TSS/m^2 media surface for BOD removal zones and 7 to 13 g TSS/m^2 for nitrification only zones.

Table 9–12

Representative design conditions for IFAS systems with nitrification[a]

Type of media	Media fill fraction, %	Applied specific surface area, m^2/m^3 tank volume	MLSS concentration, mg/L	Aerobic hydraulic retention time, h
Fixed rope or web	70–80	50–100	3000	5.0
Sponge carrier	20–30	100–150	2500	4.0
Plastic carrier	30–60	150–300	2500	4.0

[a] Adapted from WEF (2011).

Substrate Removal Flux. The substrate removal flux is affected by the diffusion rate of substrate into the biofilm, the biofilm thickness, the external fluid mixing intensity and thickness of the biofilm stagnant layer, biokinetics and biomass density within the biofilm, and the availability of the electron acceptor. At a bulk DO concentration of 2.0 mg/L, the BOD removal flux is not normally impeded by the diffusion rate of the electron acceptor. However, for nitrification a DO concentration above 2 mg/L is normally needed to realize the benefit of an IFAS system for nitrification. Data on substrate removal flux has been gained from pilot- and full-scale plant evaluations.

IFAS Process Design Parameters. Typical process design conditions for different types of IFAS media are summarized in Table 9–12. Key process design parameters are (1) the substrate removal flux, (2) the media specific surface area (m^2/m^3), (3) the amount of media added to the activated sludge tank, which is also expressed in terms of the tank media bulk volume fill fraction or percent fill volume, (4) the aerobic tank DO concentration, and (5) the suspended growth MLSS or biomass concentration. The activated sludge tank is normally divided into stages to prevent influent short circuiting and to take advantage of the biokinetic benefits of staging by having higher soluble substrate concentrations in the upstream stages versus that needed in the final effluent.

For a given removal rate required and possible removal flux by the attached growth in an IFAS treatment zone, the required media surface area can be determined as shown by the following for ammonia-N nitrification.

$$A_{BF} = \frac{Q(N_o - N_e)}{J_N} \tag{9–31}$$

where A_{BF} = biofilm surface area, m^2
N_o = influent NH_4-N concentration to treatment zone, g/m^3
N_e = effluent NH_4-N concentration from treatment zone, g/m^3
J_N = NH_4-N removal flux, $g/m^2 \cdot d$

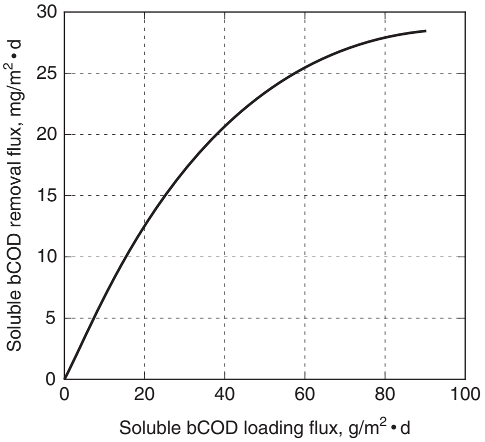
The media fill fraction can then be determined based on the specific surface area of the media and treatment zone reactor volume.

$$\text{Fill fraction (\%)} = \frac{(100)A_{BF}}{V(SS_A)} \tag{9–32}$$

where SS_A = media specific available surface area, m^2/m^3
V = reactor liquid volume, m^3

Figure 9–24

Soluble bCOD removal flux versus loading flux for plastic biofilm carriers. (Adapted from Ødgaard, 2006.)

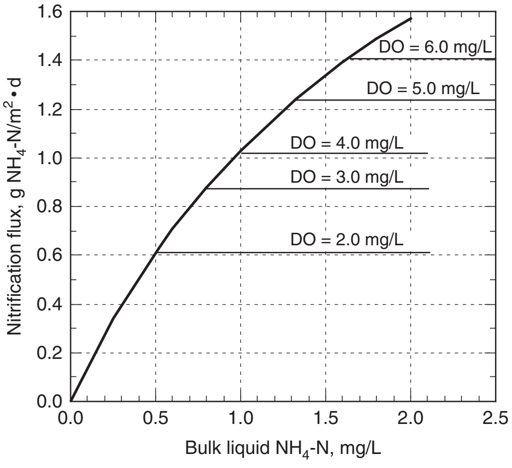


Biofilm Removal Flux. The soluble bCOD loading flux should not exceed 20 to 25 g/m^2·d with biofilm carrier media to achieve a secondary effluent BOD concentration (Ødegaard, 2006). A relationship between soluble bCOD removal flux and loading flux reported by Ødegaard (2006) is shown on Fig. 9–24. At a soluble bCOD loading flux of 10 g/m^2·d, the total BOD loading flux would be approximately 10.4 g/m^2·d, assuming 60 percent of the BOD after primary treatment is soluble. Assuming a media fill fraction of 50 percent and specific surface area of 500 m^2/m^3·d, the volumetric BOD loading would be 2.6 kg BOD/m^3·d. These loading values can be compared to a loading value of 0.30 to 0.70 kg BOD/m^3·d for secondary treatment with conventional activated sludge (see Table 8–19 in Chap. 8).

The nitrification ammonia-N removal flux is much slower than that for soluble bCOD and depends on the bulk liquid DO, ammonia-N, and soluble BOD concentrations. The nitrification ammonia-N removal flux is not affected by the soluble BOD concentration if it is less than or equal to 10 mg/L. A soluble BOD concentration of less than 10 mg/L can normally be achieved in an IFAS process with upstream separate stage BOD removal or with operation in a single tank at a low enough BOD loading. Observed ammonia-N removal flux as a function of bulk liquid DO and ammonia-N concentrations can be approximated by the process relationships presented by Ødegaard (2006) and summarized on Fig. 9–25. For a given DO concentration, the removal flux increases with increased ammonia-N concentration

Figure 9–25

Nitrification flux in biofilm as function of bulk liquid ammonia-N and DO concentration at low soluble BOD. (Adapted from Ødegaard, 2006.)



at an approximate first order relationship, until at some ammonia-N concentration the reaction is DO limited and the removal flux is then fixed by that DO concentration. Based on diffusion limitations and stoichiometric oxygen requirements for nitrification in Sec. 7–7 the theoretical transition point occurs at a ratio of 2.8 g O_2/g NH_4-N. However, the value for the relationship of flux versus NH_4-N on Fig. 9–25 is approximately 3.7. A value of 3.2 has been reported by Rusten et al. (2006). The higher value is related to biofilm substrate diffusivity and oxygen demand by carbonaceous substrates.

BOD and Nitrification Design Approach

The design of IFAS systems has generally been based on empirical approaches that incorporate performance data from pilot plant or full-scale facilities. The empirical models have used an equivalent MLSS concentration for the IFAS process based on media area and removal flux. Semi-empirical process kinetic-based models have also been used to analyze IFAS designs and to evaluate process performance under dynamic conditions. A third approach is the use of simulation software that models substrate diffusion and removal within the biofilm as well as the activated sludge suspended growth reactions.

Equivalent MLSS Approach. An example of the equivalent mixed liquor approach is that advanced by M^2T Technologies for sponge media (WEF, 2011). In this approach an equivalent MLSS is determined as follows:

$$\text{Equivalent MLSS} = (V_M)X_M + (V_{\text{AS}})(AS_{\text{MLSS}}) \tag{9–33}$$

$$V_T = V_M + V_{\text{AS}} \tag{9–34}$$

$$\text{Media fill fraction} = (V_M)/(V_T) \tag{9–35}$$

where V_M = media volume, m^3
X_M = solids concentration within the media volume, g TSS/m^3
V_{AS} = activated sludge volume, m^3
AS_{MLSS} = activated sludge MLSS concentration, g TSS/m^3
V_T = total tank volume, m^3

The activated sludge MLSS concentration can be determined from the design SRT, influent wastewater characteristics, and aeration tank volume using the procedures presented in Sec. 8–6. Assuming the IFAS supplier suggested value of 18,000 g/m^3 for the media solids, a suspended MLSS concentration of 3000 g/m^3, and a 25 percent fill volume, the aeration tank equivalent MLSS concentration is (18,000 g/m^3)(0.25) + (3000 g/m^3)(0.75) = 6750 g/m^3. Empirical relationships for specific removal rates of BOD and ammonia (i.e. g NH_4-N/g MLSS·d) are then used to calculate the amount of BOD and ammonia removal for the given aeration volume and media fill volume.

Empirical Design Approach Based on Media Flux and SRT. A range of removal flux values based on pilot plant or full-scale testing results are used with an empirical approach to estimate the media volume needed as a function of the activated sludge SRT (WEF, 2011). Flux removal values of 0.50 to 5.0 g COD/m^2·d and 0.05 to 0.50 g NH_4-N/m^2·d may be used at a temperature of 15°C and bulk liquid DO concentration of 3.0 mg/L. The fraction of COD and ammonia-N removed on the installed media is a function of the temperature and activated sludge SRT. The percent of total ammonia-N nitrified in the media biofilm is 80, 50, and 20 at suspended growth SRTs of 2, 4, and 8 d. For every °C increase the SRT is decreased by 3.0 percent. The corresponding percent COD removals on the media are 50 and 25 at the 2- and 4-d SRTs and no significant removal on the media at an 8.0-d SRT.

Semi-Empirical Process Kinetic-Based Approach. A semi-empirical process design approach for IFAS and submerged attached growth processes have been presented by Sen and Randall (2008a, 2008b, and 2008c) in a series of papers that describe the model developments, and application and verification. A similar simplified version is presented here for nitrification in the IFAS process. This kinetic approach includes the effect of nitrifying bacteria sloughing from the attached growth to seed or enhance nitrification in the suspended growth. The model provides a means to analyze the tradeoff between the amount of media installed in the activated sludge aeration tank and the operating SRT.

The process modeling approach involves mass balances on (1) ammonia oxidizing bacteria (AOB) on the biofilm media, (2) AOB in the bulk liquid, and (3) the ammonia-N concentration in the bulk liquid. The rate of growth from the nitrification flux, the rate of cell loss due to endogenous decay, and sloughing of the AOB from the biofilm to the bulk liquid are considered in the mass balance for AOB in the biofilm. An average biofilm SRT is used to account for the AOB residence time in the biofilm and sloughing rate. The mass balance is as follows:

$$(SS_A)V_m\frac{dX_{BF}}{dt} = Y_nJ_N(SS_A)V_m - b_nX_{BF}(SS_A)V_m - \frac{(SS_A)V_mX_{BF}}{\mathrm{SRT}_{BF}} \tag{9–36}$$

where, SS_A = bulk specific surface area of the media, $\mathrm{m^2/m^3}$
X_{BF} = AOB concentration in the biofilm, $\mathrm{g\ VSS/m^2}$
Y_n = AOB growth yield, g AOB VSS/g NH_4-N
J_N = nitrification flux to biofilm, g NH_4-N/$\mathrm{m^2 \cdot d}$
V_m = bulk volume of media added to the aeration tank, $\mathrm{m^3}$
b_n = AOB specific endogenous decay rate, g/g·d
SRT_{BF} = solids retention time of the AOB in the biofilm, d

At steady state conditions, X_{BF} is given by

$$X_{BF} = \frac{Y_nJ_N}{b_n + \left(\dfrac{1}{\mathrm{SRT}_{BF}}\right)} \tag{9–37}$$

As shown on Fig. 9–25, the nitrification flux is a function of the bulk liquid ammonia-N and DO concentrations and is described as follows:

$$J_N = \left(\frac{N}{k_{n,BF} + N}\right)J_{N,\max} \tag{9–38}$$

where, N = bulk liquid NH_4-N concentration, $\mathrm{g/m^3}$
$K_{n,BF}$ = biofilm half-velocity constant for nitrification, $\mathrm{g/m^3}$

Thus X_{BF} is determined as follows:

$$X_{BF} = \frac{Y_n\left(\dfrac{N}{k_{n,BF} + N}\right)J_{N,\max}}{b_n + \left(\dfrac{1}{\mathrm{SRT}_{BF}}\right)} \ or \ \frac{Y_nJ_{N,\mathrm{DOmax}}}{b_n + \left(\dfrac{1}{\mathrm{SRT}_{BF}}\right)} \tag{9–39}$$

For a given bulk liquid DO concentration, there is a bulk liquid ammonia-N concentration where the nitrification flux becomes DO limited and at that ammonia-N concentration, J_N equals $J_{N,\mathrm{DOmax}}$. The value for $J_{N,\mathrm{DOmax}}$ is indicated by the horizontal line on Fig. 9–25 for each bulk liquid DO concentration. If the bulk liquid ammonia-N concentration is below the inflection point for the respective DO concentrations shown on Fig. 9–25, the nitrification flux is ammonia limited and the J_N value is determined from Eq. (9–38). The $K_{n,\mathrm{BF}}$ value and $J_{N,\,\max}$ values for Fig. 9–25 are 2.2 mg/L and 3.3 g/m^2·d.

The suspended growth AOB concentration is the net result of the AOB sloughing rate from the biofilm, the growth rate from ammonia-N uptake from the bulk liquid, the rate of loss due to endogenous decay, and rate of solids wasting for SRT control. The mass balance assumes that suspended growth AOB activity does not occur in the bulk volume occupied by the IFAS media.

$$(V - V_m)\frac{dX_n}{dt} = \frac{(SS_A)V_m X_{BF}}{\mathrm{SRT}_{BF}} + Y_n r_N(V - V_m) - b_n X_n(V - V_m) - \frac{X_n(V - V_m)}{\mathrm{SRT}_{AS}} \tag{9–40}$$

$$(V - V_m) = \left(1 - \frac{V_m}{V}\right)V \tag{9–41}$$

where, V = total tank volume, m^3
X_n = suspended growth AOB concentration, g VSS/m^3
V_m/V = media fill fraction, m^3 media volume/m^3 tank volume
r_N = bulk liquid nitrification rate, g/m^3·d
SRT_{AS} = activated sludge SRT, d

Assuming steady state, substituting the relationship for r_N as given by Eq. (7–101) in Table 8–10, dividing by V, and rearranging yields

$$X_n = \frac{SS_A\left(\frac{V_m}{V}\right)\left(\frac{X_{BF}}{\mathrm{SRT}_{BF}}\right)}{b_n\left(1 - \frac{V_m}{V}\right) + \frac{1}{\mathrm{SRT}_{AS}}\left(1 - \frac{V_m}{V}\right) - \left(\frac{\mu_{\max}N}{K_n + N}\right)\left(\frac{\mathrm{DO}}{K_o + \mathrm{DO}}\right)\left(1 - \frac{V_m}{V}\right)} \tag{9–42}$$

The mass balance for the bulk liquid ammonia-N concentration accounts for the rate of ammonia-N added in the tank influent, rate of ammonia-N leaving in the tank effluent, the rate of ammonia-N consumption by the suspended growth AOB, the rate of ammonia-N removed from the bulk liquid by the biofilm nitrification flux, and the rate of ammonia-N released due to endogenous decay of the heterotrophic bacteria (due to the relatively small concentration of AOB, the ammonia-N released from AOB is ignored to simplify the solution).

$$(V - V_m)\frac{dN}{dt} = Q(N_o) - Q(N) - r_N(V - V_m) - J_N(SS_A)V_m + 0.12b_{\mathrm{H}}X_{\mathrm{H}}(V - V_m) \tag{9–43}$$

where N_o = influent available NH$_4$-N concentration, g/m^3
Q = influent flowrate, m^3/d
b_{H} = heterotrophic bacteria specific endogenous decay rate, g/g·d
X_{H} = heterotrophic bacteria concentration, g VSS/m^3
0.12 = g N released/g bacteria VSS loss by endogenous decay

Assuming steady state, substituting for J_N and r_N, and rearranging results in the following:

$$\begin{aligned} N_o = N &+ \left[\frac{(\mu_{\max}/Y_n)N}{K_n + N}\right]\left(\frac{\mathrm{DO}}{K_o + \mathrm{DO}}\right)X_n(\tau) + \left(\frac{N}{K_{n,BF} + N}\right)J_{N,\max}\left(\frac{V_m}{V}\right)(SS_A)(\tau) \\ &- 0.12b_{\mathrm{H}}X_{\mathrm{H}}\left(1 - \frac{V_m}{V}\right)(\tau) \end{aligned} \tag{9–44}$$

Again, if the value for N is above the ammonia-N concentration at the inflection point for a given bulk liquid DO concentration on Fig. (9–25) the value for $J_{N,\text{DOmax}}$ is substituted for the J_N relationship in Eqs. (9–43) and (9–44) reduces to:

$$N_o = N + \left[\frac{(\mu_{\max}/Y_n)N}{K_n + N}\right]\left(\frac{\text{DO}}{K_o + \text{DO}}\right)X_n(\tau) + J_{N,\,\text{DOmax}}\left(\frac{V_m}{V}\right)(SS_A)(\tau) - 0.12b_{\text{H}}X_{\text{H}}\left(1 - \frac{V_m}{V}\right)(\tau) \tag{9–45}$$

The heterotrophic biomass concentration is determined from Eq. (7–42) in Table 8–10, where $S_o - S \simeq S_o$.

$$X_{\text{H}} = \frac{Y_{\text{H}}(S_o)(\text{SRT}_{AS})}{[1 + b_{\text{H}}(\text{SRT}_{AS})]\left(1 - \frac{V_m}{V}\right)\tau} \tag{9–46}$$

The ammonia-N concentration available in the influent to the reactor is equal to the rate of bioavailable TKN added to the reactor minus the amount of nitrogen removed via the waste sludge production.

$$N_o = \text{TKN} - 0.12\left[\frac{X_{\text{H}}(\tau)\left(1 - \frac{V_m}{V}\right)}{\text{SRT}_{AS}}\right] \tag{9–47}$$

The solution for an IFAS design using the above relationships is illustrated in Example 9–7.

EXAMPLE 9–7 **Effect of Media Fill Volume Fraction in IFAS Process** Determine the aeration tank media fill volume fraction needed to provide nitrification to an effluent NH_4-N concentration below 0.70 g/m^3 for an existing activated sludge process following an increase in the average primary effluent flowrate from 20,000 to 30,000 m^3/d. The MLSS must be maintained at 3000 g/m^3 due to clarifier constraints. Provide a graph of effluent NH_4-N concentration and fraction of the IFAS nitrification occurring in the attached growth biofilm versus the media fill volume percent.

The aeration tank volume of the activated sludge system is 6940 m^3 and the primary effluent characteristics are given in the table below. The SRT at the 20,000 m^3/d flowrate with a MLSS concentration of 3000 g/m^3 is determined to be 9.5 d using the activated sludge design procedure shown in Example Problem 8–3 in Sec. 8–6. At the higher influent flowrate and assuming a MLSS concentration of 3000 g/m^3, the SRT is 4.1 d, which is not sufficient to meet the nitrification goals.

Design parameter	Unit	Design condition for activated sludge nitrification	Design condition for IFAS process analysis
Average flowrate	m^3/d	20,000	30,000
BOD concentration	g/m^3	140	140
TKN concentration	g/m^3	35	35
Nonbiodegradable VSS	g/m^3	25	25

(*continued*)

(*Continued*)

Design parameter	Unit	Design condition for activated sludge nitrification	Design condition for IFAS process analysis
TSS	g/m^3	70	70
VSS	g/m^3	60	60
Minimum design temperature	°C	12.0	12.0
Suspended growth aerobic SRT	d	9.5	6.0^a
Aeration tank volume	m^3	6940	6940
Hydraulic detention time, τ	d	0.35	0.233
MLSS	g/m^3	3000	3000
Heterotrophic biomass VSS	g/m^3	1740	1860
X_H, VSS/MLSS	g/g	0.58	0.62
BOD loading	kg BOD/m^3·d	0.40	0.60
Effluent NH$_4$-N	g/m^3	≤ 0.7	

[a] Suspended growth SRT is for without any media addition.

Other assumptions are as follows:

1. Plastic biofilm carrier media is used with a specific surface are of 500 m^2/m^3
2. Aeration tank DO concentration = 4.0 mg/L
3. Critical NH$_4$-N concentration for zero order flux = 1.07 mg/L (Fig. 9–25)
4. Maximum biofilm nitrification flux at DO = 4.0 mg/L is 1.08 g/m^2·d (Fig. 9–25)
5. bCOD/BOD = 1.6
6. Heterotrophic bacteria and AOB kinetic coefficients are from Table 8–14

   $Y_H = 0.45$ g VSS/g bCOD, $b_{H,20} = 0.12$ g/g·d, $\theta = 1.04$ for temperature correction for b_H.

7. AOB kinetic coefficients are from Table 8–14

   $\mu_{max,20} = 0.90$ g/g·d, $b_{n,20} = 0.17$ g/g·d, $\theta = 1.72$ and 1.029 for temperature correction for μ_{max} and b_n, respectively.

   $K_n = 0.50$ mg/L, $K_o = 0.50$ mg/L, $Y_n = 0.15$ g VSS/g NH$_4$-N oxidized

8. $K_{n,BF} = 2.2$ mg/L and $J_{N,\,max} = 3.3$ g/m^2·d
9. Biofilm AOB SRT$_{BF}$ = 6.0 d
10. The first 1/3rd of the aeration tank has no media addition and the soluble BOD leaving that zone is less than 10.0 mg/L, and thus does not interfere with AOB growth on the biofilm carriers.
11. The maximum media fill volume percent allowed for the plastic biofilm carriers in an IFAS process is 60 percent.

Solution

1. Assume a media fill volume percent in 2/3 of tank = maximum at 60 percent. Average fill volume percent = 2/3(60) = 40 percent. $V_M/V = 0.40$
2. Determine the kinetic coefficients at 12°C.

   $b_{H,12} = (0.12)(1.04^{(12-20)}) = 0.088$ g/g·d

   $\mu_{max,12} = (0.90)(1.072^{(12-20)}) = 0.516$ g/g·d

   $b_{n,12} = (0.17)(1.029^{(12-20)}) = 0.135$ g/g·d

3. Determine the influent bCOD concentration.

$$\text{bCOD} = 1.6(140 \text{ g BOD/m}^3) = 224.0 \text{ g/m}^3$$

4. Determine the suspended growth SRT using Eq. (9–46) and $X_H = 1860 \text{ g/m}^3$ from the above table.

$$X_{\text{H}} = \frac{Y_{\text{H}}(S_o)(\text{SRT}_{AS})}{[1 + b_{\text{H}}(\text{SRT}_{AS})]\left(1 - \dfrac{V_m}{V}\right)\tau}$$

$$1860 \text{ gVSS/m}^3 = \frac{(0.45 \text{ g VSS/g bCOD})(224 \text{ g bCOD/m}^3)(\text{SRT}_{AS})}{[1 + (0.088 \text{ g/g·d})(\text{SRT}_{AS})](1 - 0.4)(0.233 \text{ d})}$$

$$\text{SRT}_{AS} = 3.34 \text{ d}$$

5. Determine N_o from Eq. (9–47).

$$N_o = \text{TKN} - 0.12\left[\frac{X_{\text{H}}(\tau)\left(1 - \dfrac{V_m}{V}\right)}{\text{SRT}_{AS}}\right]$$

$$= 35.0 \text{ g/m}^3 - 0.12\left[\frac{(1860 \text{ g/m}^3)(0.233 \text{ d})(1 - 0.40)}{3.34 \text{ d}}\right]$$

$$= 25.7 \text{ g/m}^3$$

6. Assume the bulk liquid N concentration is below the critical value and use the left side of Eq. (9–39) to calculate X_{BF}.

$$X_{BF} = \frac{Y_n\left(\dfrac{N}{k_{n,BF} + N}\right)J_{N,\max}}{b_n + \left(\dfrac{1}{\text{SRT}_{BF}}\right)}$$

$$= \frac{(0.15 \text{ g VSS/g } N_{\text{oxidized}})\left[\dfrac{N}{(2.2 \text{ g/m}^3) + N}\right](3.3 \text{ g N/m}^2\text{·d})}{(0.135 \text{ g/g·d}) + \left(\dfrac{1}{6.0 \text{ d}}\right)}$$

7. Calculate the bulk liquid AOB concentration from Eq. (9–42).

$$X_n = \frac{SS_A\left(\dfrac{V_m}{V}\right)\left(\dfrac{X_{BF}}{\text{SRT}_{BF}}\right)}{b_n\left(1 - \dfrac{V_m}{V}\right) + \dfrac{1}{\text{SRT}_{AS}}\left(1 - \dfrac{V_m}{V}\right) - \left(\dfrac{\mu_{\max} N}{K_n + N}\right)\left(\dfrac{\text{DO}}{K_o + \text{DO}}\right)\left(1 - \dfrac{V_m}{V}\right)}$$

$$= \frac{(500 \text{ m}^2/\text{m}^3)(0.40)(X_{BF}/6 \text{ d})}{(0.135 \text{ g/g·d})(1 - 0.40) + \left(\dfrac{1}{3.34 \text{ d}}\right)(1 - 0.40) - \left[\dfrac{(0.516 \text{ g/g·d})N(4.0 \text{ g/m}^3)(1 - 0.40)}{(0.50 \text{ g/m}^3 + N)(0.50 \text{ g/m}^3 + 4.0 \text{ g/m}^3)}\right]}$$

8. Put in known values for Eq. (9–44).

$$N_o = N + \left[\frac{(\mu_{\max}/Y_n)N}{K_n + N}\right]\left(\frac{\mathrm{DO}}{K_o + \mathrm{DO}}\right)X_n(\tau) + \left(\frac{N}{K_{n,BF} + N}\right)J_{N,\max}\left(\frac{V_m}{V}\right)(SS_A)(\tau)$$
$$- 0.12 b_{\mathrm{H}} X_{\mathrm{H}}\left(1 - \frac{V_m}{V}\right)(\tau)$$

$$25.7\ \mathrm{g/m^3} = N + \frac{[(0.516\ \mathrm{g/g\cdot d})/(0.15\ \mathrm{g\ VSS/g}\ N)](N)(4.0\ \mathrm{g/m^3})X_n(0.233\ \mathrm{d})}{(0.50\ \mathrm{g/m^3} + N)(0.50\ \mathrm{g/m^3} + 4.0\ \mathrm{g/m^3})}$$
$$+ \frac{(N)(3.3\ \mathrm{g\ N/m^2\cdot d})(0.40)(500\ \mathrm{m^2/m^3})(0.233\ \mathrm{d})}{(2.2\ \mathrm{g/m^3} + N)}$$
$$- 0.12(0.088\ \mathrm{g/g\cdot d})(1860\ \mathrm{g/m^3})(0.60)(0.233\ \mathrm{d})$$

9. For steps 6, 7, and 8, there are three unknowns (X_{BF}, X_n, and N) and three equations. These equations can be solved on an excel spreadsheet using a solver function. The result is

$$X_n = 18.0\ \mathrm{g/m^3}$$
$$X_{BF} = 0.20\ \mathrm{g/m^2}$$
$$N = 0.30\ \mathrm{g/m^3}$$

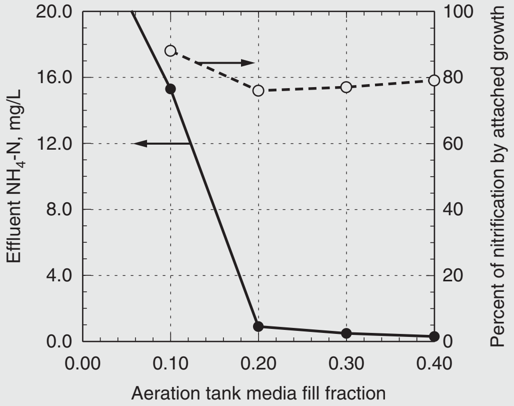
The fraction of the amount of NH_4-N nitrified that occurred in the biofilm = 0.79.

The bulk liquid N concentration is below the critical value of 1.07 g/m^3 so the appropriate equations were selected.

10. Similar calculations were done for V_M/V = 0.30, 0.20, and 0.10 and the results are summarized in the following table, followed by the graph required in the problem statement.

		V_m/V			
Parameter	Unit	0.10	0.20	0.30	0.40
SRT_{AS}	d	5.9	4.9	4.1	3.3
X_{BF}	g/m^2	0.54	0.47	0.29	0.20
X_n	g/m^3	6.6	15.5	17.4	18.0
N	g/m^3	15.3	0.89	0.48	0.30
Fraction of N oxidized in biofilm	—	0.88	0.76	0.77	0.79

Note: for V_m/V = 0.10, the critical NH_4-N value was exceeded and the biofilm nitrification flux was equal to $J_{N,\ DOmax}$.



Comment A fill volume fraction for the plastic biofilm carriers needs to be greater than 0.20 to meet the effluent NH_4-N concentration goal of $\leq 0.70\ g/m^3$. At a fill volume fraction of 0.30, the effluent NH_4-N is within the treatment goal. Because the media is added to only the last 2/3 of the aeration tank the fill volume fraction in the aeration tank with media is 0.45, which is acceptable as it is within the maximum value of 0.60 for plastic biofilm carriers in IFAS. The sloughing of nitrifying bacteria from the biofilm provided bioaugmentation of the suspended growth nitrification with 12 to 21 percent of the nitrification occurring in the suspended growth.

Mechanistic Modeling and Simulation Software. Simulation software is available for dynamic process modeling and analysis of attached growth systems, such as trickling filters, moving bed bioreactors, biological aerated filters and also for the combined attached growth/activated sludge IFAS systems. These are provided by most of the companies that provide activated sludge simulation software and also by others. A description of biofilm model development and types and complexity of current models is provided by Wanner et al. (2006).

In these models the biofilm is defined by several layers in which calculations are carried out for mass transport by diffusion and substrate utilization using the same biokinetic relationships as those used for suspended growth. The models provide calculations for substrate removal flux values for bCOD, ammonia-N, and oxidized-N for anoxic biofilms. The biofilm model is set up with a selected number of reactors in series. Key factors which must be selected by the model user and affect the prediction substrate removal rates within the biofilm are the biofilm thickness and biomass concentration. Assumptions of a thicker film can lead to predicting simultaneous nitrification-denitrification within the film due to the prediction of anoxic conditions in the deeper biofilm layers. Pilot plant or full-scale plant data, including bulk liquid DO concentrations and biofilm growth, can be used to calibrate the models to then analyze the effect of process configuration, media fill volumes, staging, DO concentration, temperature, and SRT for IFAS processes on system performance.

9–5 MOVING BED BIOFILM REACTOR (MBBR)

The MBBR process is similar to the IFAS process with mixed, suspended media contained within the reactor by effluent sieves, as described in Sec. 9–4, with the exception that there is no return activated sludge. The media fill volume fraction is generally higher (up to 70 percent), and the suspended solids concentration in the flow to the secondary clarifier may be in the range of from 100 to 250 mg/L versus 2500 to 3500 mg/L. Process designs for MBBR also include the suspended media in anoxic zones for fixed film biological denitrification. With MBBR reactor effluent, filtration processes, including granular media and membrane filtration, and dissolved air flotation can be used in lieu of gravity settling. Much of the information presented on the IFAS process with suspended media in Sec. 9–4 is applicable to the MBBR process, including the characteristics of the biofilm carrier media, media retention, aeration and mixing, and substrate flux into the biofilm. The topics considered in this section are (1) background, (2) process applications, (3) process advantages, (4) physical facilities, (5) process design analysis, and (5) nitrogen removal for MBBR systems.

Background

A variety of biofilm carrier media are possible for use in MBBR processes but much of the original research and most of the present installations involved the use of plastic biofilm carriers as described in Sec. 9–4 for IFAS applications and also indicated in Table 9–11. Much of the development work on MBBR processes with plastic biofilm carriers was done at the Norwegian University of Science and Technology (NTNU) in Trondheim, Norway with the aim to provide a compact biological nitrogen removal process to reduce point-source discharges of nitrogen to the North Sea. The first patents and commercialization of the MBBR technology was in 1989, through the Norwegian company, Kaldnes Miljøteknolog. Since then, a number of companies provide MBBR processes with proprietary floating plastic biofilm carrier designs, but most out of the hundreds of world-wide MBBR installations have used the Kaldnes media (WEF, 2011).

MBBR Process Applications

Flow schematics of examples of MMBR process configurations that can be used for BOD removal, biological nitrification and biological nitrogen removal are given in Table 9–13. All of the treatment schemes, with the exception of tertiary nitrification [see Table 9–13(d)] and tertiary biological denitrification after secondary treatment [see Table 9–13(h)] require raw wastewater pretreatment with influent screening, grit removal and primary treatment or fine mesh influent screening and grit removal. Chemical addition to the primary clarification step is an option for employing chemically enhanced primary treatment to reduce the BOD load to the MBBR process or as a first step for phosphorus removal. Metal salts and possibly polymer may be added before the MBBR process secondary clarifier for phosphorus removal and/or to improve the effluent suspended solids removal. A highly loaded, high rate BOD removal MBBR process [see Table 9–13(b)] can produce a more dispersed turbid effluent and would likely require chemicals to improve flocculation and effluent suspended solids removal.

Removal of BOD and Nitrification. For BOD removal and nitrification process designs, staged reactors may be used with the first stage primarily for removing most of the soluble BOD to minimize the heterotrophic bacteria growth competing with nitrifying bacteria for surface area on the biofilm carriers in the downstream nitrification reactors. The use of staged reactors [see Table 9–13(c)] for the nitrification zones improves the volumetric efficiency of the MBBR process due to having a higher ammonia-N concentration which can results in a greater nitrification flux in the stages before the final nitrification stage, provided that the nitrification reaction is not DO limited due to an insufficient bulk liquid DO concentration. Another potential MBBR process application for nitrification is tertiary nitrification after an activated sludge process for BOD removal.

Removal of Nitrogen with Activated Sludge. The MBBR process can be designed with similar process configurations used with activated sludge for biological nitrogen removal. An MLE process configuration is shown in Table 9–13(e); it has a preanoxic zone at the front of the system for biological denitrification by biomass growth from influent BOD and consumption of nitrates in the nitrate recycle flow from the last aerobic reactor. A preanoxic and postanoxic configuration shown in Table 9–13(g) is similar to the Bardenpho process, which is used over the MLE process to minimize the effluent total nitrogen concentration by minimizing the effluent nitrate- and nitrite-N concentrations. An external carbon must be added to the postanoxic zones to promote bacteria growth and biological denitrification. An MBBR process can also be used for tertiary denitrification after BOD removal and nitrification in an activated sludge process as shown in Table 9–13(h).

MBBR Process Advantages and Disadvantages

MBBR processes are able to provide similar BOD removal and nitrogen removal treatment performance as activated sludge processes.

Table 9–13

MBBR systems configurations for different biological treatment goals

Process	Description
BOD removal	
(a) 	MBBR system for BOD removal and phosphorus removal by chemical precipitation. The aerobic tank may be a single or two-stage design.
(b) 	MBBR system for high rate BOD removal. Chemicals are added to provide sufficient suspended solids removal and also for phosphorus removal if needed.
BOD removal and nitrification	
(c) 	MBBR system for BOD removal and nitrification. Most of the BOD removal occurs in the first stage before subsequent single or multiple stage reactors for nitrification.
(d) 	MBBR system used as a tertiary nitrification process after secondary treatment for BOD removal.

(*continued*)

Table 9–13 (*Continued*)

Process	Description
Nitrogen removal	
(e) 	MBBR system used for MLE process with preanoxic zone and nitrate recirculation. Chemical addition before the secondary clarifier may be used for phosphorus removal (total nitrogen <10 mg/L).
(f) 	MBBR system used for postanoxic biological denitrification following BOD removal and nitrification. External carbon must be added to the postanoxic reactor (total nitrogen <3 mg/L).
(g) 	MBBR Bardenpho system for biological nitrogen removal with preanoxic and postanoxic reactors. External carbon must be added to the postanoxic reactor. Chemical addition may be used for effluent phosphorus removal and improved suspended solids removal (total nitrogen <3 mg/L).
(h) 	MBBR system for biological denitrification after activated sludge for BOD removal and nitrification and possibly EBPR. External carbon must be added (total nitrogen <3 mg/L).

Advantages. The major advantages of an MBBR process compared to activated sludge are (1) the small space needed, (2) the simplicity of operation with no need for manual sludge wasting and SRT control and sludge recycle, (3) the elimination of concerns of sludge bulking in the secondary clarifiers and its effects on operation and effluent quality, and (4) its ability to withstand peak wet weather flow variations. An MBBR process is well

Table 9–14

Example of hydraulic retention times used for full-scale MBBR process installations

Facility in Norway	Design flow, m^3/d	Process application	MBBR hydraulic retention time, h	Effluent total N, mg/L	Reference
Lillehammer	28,800	Bardenpho	3.2	4.5	Ødegaard (2006)
Nordre Folio	18,000	Bardenpho	4.9	8.0	Ødegaard (2006)
Gardermoen	22,100	Bardenpho	6.3	10.0	Ødegaard (2006)
Sjolunda	126,000	Post Anoxic	1.2	6.8	McQuarrie and Boltz (2011)
Klagshamm	23,800	Post Anoxic	1.1	5.8	McQuarrie and Boltz (2011)

suited for retrofit applications for activated sludge processes with reduced time and little if any tank construction. Because the MBBR process is basically an attached growth treatment process it deserves comparison to other attached growth processes such as trickling filters, rotating biological contactors, and biological aerated filters that are discussed in the following section. Compared to these processes, the MBBR process is much more versatile and adaptable for biological nitrogen removal and is a continuous operation that does not require special operational attention or interruption of treatment for biofilm thickness control or flushing out excess solids. Examples of MBBR full-scale plants in Table 9–14 show the relatively low hydraulic retention times used in MBBR processes.

Disadvantages. Process disadvantages compared to activated sludge treatment include (1) a higher energy demand due to the need to operate at elevated DO concentrations, (2) the need to use proprietary media, (3) issues of media removal for diffuser maintenance, (4) the need for improved influent wastewater screening, (5) additional hydraulic profile headlosses due to flow through the media screening devices, and (6) the limitation of phosphorus removal only by chemical addition.

Design of Physical Facilities

The physical facility design considerations discussed in Sec. 9–4 for an IFAS process with suspended biofilm carriers with regard to (1) pretreatment, (2) media retention and effluent sieves, (3) aeration and mixing, and (4) foam control, apply to the MBBR process. Coarse bubble or intermediate bubble aeration is generally used in MBBR aerobic tanks. Based on off gas testing of a system with plastic biofilm carriers, the SOTE values ranged from 11 to 15 percent, where SOTE is the oxygen transfer efficiency at standard conditions.

The amount of plastic biofilm carriers added is defined in terms of its bulk volume filling fraction or percent of the tank volume. The plastic media carrier is normally added to an empty reactor for the specified volumetric filling percentage. The coarse aeration pipes are designed to withstand the weight of carrier media after the tank is drained for maintenance. During maintenance, plastic carrier can be transferred to a carrier storage with a recessed impeller pump. Media replacement has not been a significant issue in MBBR processes, though the design of mixers must be done to prevent media abrasion. After 10 years of operation of the first MBBR plant installed in Norway in 1996, no observed biofilm carrier wear has been reported (Rusten et al., 2006).

Because of the relatively low suspended solids concentration in the effluent from the MBBR process (typically in the range of 100 to 250 mg/L), solids recycle is not required as it is for activated sludge and IFAS processes, and liquid-solids separation methods other than secondary clarification may be used. Flocculation and flotation, dual media sand filters, cloth disc filters, and ballasted flocculation have been used at full-scale facilities (McQuarrie and Boltz, 2011).

MBBR Process Design Analysis

The mechanisms and important factors for substrate removal by suspended biofilm carriers are discussed in Sec. 9–4 for the IFAS process. The major differences between the IFAS and MBBR processes are that the MBBR normally has a higher biofilm carrier density, with up to a 70 percent media fill volume, and it does not have return activated sludge and a significant suspended mixed liquor or biomass concentration. In the MBBR process, the substrate removal is primarily by the attached growth and does not have the benefit of activated sludge to enhance the flocculation and settling of solids that slough from the attached growth. As described in Sec. 9–4, the amount of substrate removal by biofilm carriers is a function of the available biofilm surface area and substrate flux. The biofilm surface area is the product of the reactor volume, media fill volume fraction, and the media bulk specific surface area. The substrate flux is a key process design parameter and is a function of the bulk liquid substrate and DO concentrations, the reactor mixing conditions, and the biofilm characteristics. Substrate flux relationships determined for BOD removal, nitrification, and nitrate reduction from the analysis of pilot plant and full-scale plant MBBR processes can be used to develop MBBR process designs. As described by Eq. (9–31) the required total surface area of biofilm carriers in an MBBR reactor is the rate of substrate removal (g/d) needed divided by the removal flux ($g/m^2{\cdot}d$).

Typical substrate removal flux values for BOD removal, nitrification, and denitrification are shown in Table 9–15. Note that the surface area loading rate (SALR) is higher than the substrate removal flux and can be estimated by dividing the removal flux by the estimated treatment efficiency. The equivalent volumetric removal rates are also shown for a 60 percent media fill volume. The secondary treatment volumetric BOD load for the MBBR secondary treatment SALR is about 1.7 to 5.0 times greater than a typical conventional activated sludge loading of 1.0 kg $BOD/m^3{\cdot}d$.

The ability of the MBBR process to handle much higher volumetric BOD loadings than a conventional activated sludge process can only be partially explained by differences in reactor biomass concentrations. The biofilm areal solids concentration may range from 12 g TSS/m^2 for a combined carbon and nitrification operation to as high as 28 g TSS/m^2 for a high rate BOD removal operation (McQuarrie and Boltz, 2011). Assuming a media specific

Table 9–15

Typical removal flux for BOD, nitrification and denitrification in MBBR processes[a]

Application	Substrate	Removal flux, $g/m^2{\cdot}d$	Volumetric removal rate,[b] $kg/m^3{\cdot}d$
BOD removal, partial	BOD	15–20	4.5–6.0
Secondary treatment	BOD	5–15	1.7–5.0
Prenitrification	BOD	4–5	1.2–1.5
Nitrification	NH_4-N	0.4–1.4	0.1–0.4
Predenitrification	NO_3-N	0.20–1.0	0.1–0.3
Postdenitification	NO_3-N	1.0–2.0	0.3–0.6

[a] Adapted from McQuarrie and Boltz (2011) and WEF (2011).

[b] Based on 60 percent media fill fraction.

surface area of 500 m^2/m^3 and a 60 percent fill volume, the corresponding volumetric TSS concentrations can vary from 3870 to 8400 mg/L. As the higher volumetric BOD removal rates in the MBBR cannot be related entirely to differences in reactor suspended solids, it has also been suggested that it is due to the use of highly compartmentalized designs and the presence of a higher viable biomass on the media (Ødegaard, 2006).

BOD Removal and Nitrification Design

Designs for BOD removal can be based on appropriate SALRs based on observed substrate removal flux information. The design for nitrification is more complex and requires special consideration to the amount of soluble BOD entering the MBBR nitrification reactor and the DO concentration in the MBBR reactor. To assure effective nitrification and to minimize the volume of biofilm carrier needed, operation at elevated DO concentrations, in the range of 4.0 to 6.0 mg/L, must be considered. In addition, the use of MBBR reactors in series for removal of soluble BOD in upstream reactors prior to nitrification is normally done. Substrate removal flux information for BOD removal and nitrification, operating conditions, and design considerations for MBBR systems for BOD removal only, BOD removal and nitrification, and tertiary nitrification are discussed below. Denitrification in MBBR reactors is discussed in Sec. 9–7. As discussed in Sec. 9–4, computer simulation software is also available for analysis of MBBR designs and can be calibrated to existing plant performance data.

BOD Removal. Three levels of BOD removal design loadings are considered: (1) partial or high rate SALR, (2) secondary treatment or normal SALR, and (3) prenitrification or low SALR. An MBBR process may be added before activated sludge treatment for partial BOD removal to increase the treatment capacity of an industrial or combined domestic/industrial wastewater. It may also be used in initial reactors for BOD removal prior to downstream nitrification reactors. Assuming 70 percent BOD removal, the BOD roughing SALR may be up to 28 g $BOD/m^2 \cdot d$. At this loading, depending on the wastewater BOD concentration, the hydraulic retention time, τ, could be less than 30 min. However, a τ of at least 45 to 60 min is used, as oxygen transfer issues can limit the maximum loading and minimal τ needed for partial BOD removal. A DO concentration of 2 to 3 mg/L has been considered adequate for BOD removal in MBBR designs (Ødegaard, 2006). At the high BOD SALRs the sloughed solids from the MBBR media are more dispersed and poor setting occurs. Thus, if the MBBR is designed as only a roughing BOD treatment, it is necessary to provide chemicals and flocculation before the secondary clarifier.

The BOD SALR for secondary treatment to produce an effluent BOD and TSS concentration of less than 25 mg/L is in the range of 6 to 16 $g/m^2 \cdot d$, based on the assumption of 90 percent BOD removal. Prenitrification designs use much lower BOD SALRs to minimize the MBBR reactor effluent soluble bCOD to downstream nitrification reactors, so that there is less competition by heterotrophic bacteria over nitrifying bacteria for growth on the media surface area. A higher nitrification ammonia-N flux and greater nitrification efficiency is then possible. At a soluble BOD concentration of less than 10 mg/L maximum use of the biofilm carrier surface area by ammonia-oxidizing bacteria is possible. If the soluble COD concentration of the wastewater is known, the relationship shown on Fig. 9–24 can be used to determine the amount of media and the reactor volume needed to reduce the soluble COD to a low level before nitrification (Ødegaard, 2006). The use of designs with multiple MBBR reactors in series is recommended to provide high rate BOD uptake, a low soluble BOD prior to nitrification, and more efficient ammonia removal to thus provide more process stability and to minimize reactor volume and media requirements. Another advantage of using reactors in series is to minimize the possibility of short circuiting of the influent flow.

Nitrification. The MBBR process has been used for nitrification in various process schemes (Table 9–13), including combined with BOD removal, in the later stages of an MBBR process with reactors in series after depletion of most of the soluble BOD, and for tertiary nitrification. Nitrification substrate flux design values that can be used to estimate the reactor volume and the volume of biofilm carriers needed for nitrification in different process modes are considered below. The factors that govern the nitrification substrate flux include the bulk liquid ammonia-N and DO concentrations, temperature, soluble BOD concentration which is related to the reactor BOD loads, and pH. As described in Sec. 8–6, an alkalinity balance should be done for each application to assure that a minimum alkalinity of 70 mg/L as $CaCO_3$ is present in the nitrification reactor so that a pH of at least 6.8 is present to allow uninhibited nitrification due to pH limitations. Higher nitrification flux occurs for nitrification reactor designs with a (1) lower organic loading rate, (2) minimal soluble BOD concentration, (3) higher bulk liquid DO concentration, (4) higher temperature, and (5) higher bulk liquid ammonia-N concentration. The bulk liquid ammonia-N concentration may be the rate-limiting factor at low concentrations (<1–3 mg/L), and thus the use of nitrification reactors in series is recommended to provide a more optimal reactor volume and media addition to achieve a low effluent ammonia concentration of less than 1.0 mg/L.

Tertiary Nitrification. Tertiary nitrification in an MBBR process involves growth of primarily AOB on the plastic carrier biofilm. The growth of AOB can occur when the MBBR nitrification reactor receives clarifier effluent following secondary treatment [see Table 9–13(d)] or after extensive BOD removal and a low organic loading in an upstream reactor before nitrification in a MBBR process with a number of reactors in series. The relationship shown previously on Fig. 9–25 can be used to estimate the nitrification flux as a function of the bulk liquid DO and ammonia-N concentration. The nitrification flux on Fig. 9–25 at ammonia-N concentrations for which the rate is not DO limited can be determined from the Eq. (9–48).

$$J_N = \left[\frac{N}{(2.2 \text{ g N/L}) + N}\right](3.3 \text{ g N/m}^2\cdot\text{d}) \tag{9–48}$$

The data on Fig. 9–25 was developed at 15°C. A temperature adjustment factor, according to Eq. 2–25 of 1.098 was found by Salvetti et al. (2006) for ammonia concentration limited nitrification flux and 1.058 for oxygen limited nitrification flux.

In MBBR reactors with combined BOD removal and nitrification, the heterotrophic bacteria compete with the AOB for dissolved oxygen and space on the biofilm which can hinder the nitrification flux. The effect of BOD SALR and DO concentration is shown on Fig. 9–26. As the BOD SALR increases to above 2.0 g/m²·d, a bulk liquid DO concentration of 4.0 to 6.0 mg/L is needed to provide an appreciable nitrification flux. An empirical equation, developed by Rusten et al. (1995), can be used to estimate the nitrification flux under ammonia rate limiting conditions in a combined BOD removal and nitrification process at 10°C.

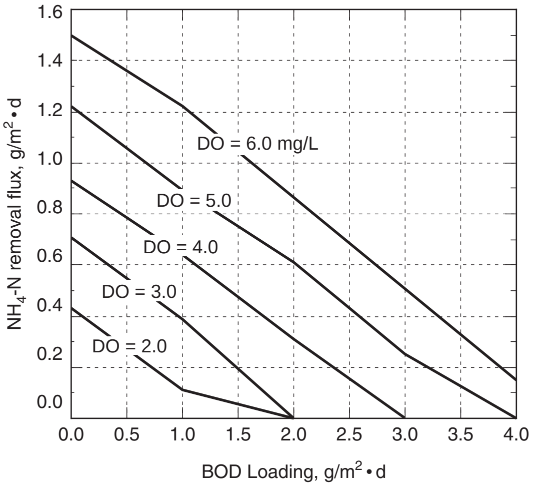
$$J_N = k_{nf}(N)^{n'} \tag{9–49}$$

where k_{nf} = rate coefficient dependent on pretreatment
n' = reaction rate coefficient, 0.70

Values for k_{nf} were given as 0.40, 0.47, 0.50, and 0.53, for (1) screening but no primary clarifier, (2) primary clarification or predenitrification, (3) primary clarification and predenitrification and (4) chemically enhanced primary treatment, respectively. The temperature correction value is 1.09. Determination of the MBBR media and reactor volumes for BOD removal and nitrification is illustrated in Example 9–8.

Figure 9–26

Effect of DO concentration and BOD surface area loading rate on nitrification flux. (Adapted from Ødegaard, 2006.)



EXAMPLE 9–8 **MBBR Process Media and Reactor Volumes for BOD Removal and Nitrification** Using the same primary effluent wastewater characteristics as for Example Problem 8–3, determine the plastic carrier media volume required and the aeration tank volume for an MBBR process to produce an effluent NH_4-N concentration of 0.70 mg/L. Use four reactors in series with the first two of equal size for BOD removal and the last two of equal size for nitrification. Assume a 50 percent media fill volume for the BOD removal reactors and 60 percent for the nitrification reactors. Assume a DO concentration of 4.0 mg/L for the nitrification reactors.

Design parameter	Unit	Design condition
Average flow	m^3/d	30,000
BOD concentration	g/m^3	140
TKN concentration	g/m^3	35
Nonbiodegradable VSS	g/m^3	25
TSS	g/m^3	70
VSS	g/m^3	60
Minimum design temperature	°C	12.0
Effluent NH_4-N	g/m^3	≤0.7

Note: g/m^3 = mg/L

Other assumptions are as follows:

1. Plastic biofilm carrier media specific surface area = 500 m^2/m^3.
2. First reactor roughing BOD removal flux (Table 9–15) = 12 $g/m^2 \cdot d$ at 12°C for 75% BOD removal.
3. Second reactor for prenitrification BOD removal flux (Table 9–15) = 4.0 $g/m^2 \cdot d$ at 12°C for 90 percent BOD removal.
4. Use Fig. 9–25 for nitrification flux as function of bulk liquid DO concentration and NH_4-N concentration. Assume ammonia removal in first nitrification reactor is DO limited. Thus the biofilm nitrification flux at 15°C = 1.07 $gN/m^2 \cdot d$.

5. Nitrification flux temperature (θ) correction for DO limited condition = 1.058 (Salvetti et al., 2006).
6. Nitrification flux temperature (θ) correction for ammonia limited condition = 1.098 (Salvetti et al., 2006).
7. bCOD/BOD = 1.6.
8. Heterotrophic bacteria synthesis yield and specific endogenous decay coefficients from Table 8–14.

   $Y_H = 0.45$ g VSS/g bCOD, $b_{H,20} = 0.12$ g/g·d, $\theta = 1.04$ for temperature correction for b_H.
9. BOD removal biofilm SRT = 6.0 d.

Solution

1. Determine plastic media volume needed and tank volume for 1st reactor.

   a. Applied BOD flux $= \dfrac{\text{BOD removal flux}}{(\%\text{ BOD removal}/100)} = \dfrac{(12\ \text{g/m}^2\cdot\text{d})}{0.75} = 16.0\ \text{g BOD/m}^2\cdot\text{d}$

   b. Media area:

   $$= \frac{\text{BOD application rate}}{\text{Applied BOD flux}} = \frac{(30{,}000\ \text{m}^3/\text{d})(140.0\ \text{g BOD/m}^3)}{(16.0\ \text{g BOD/m}^2\cdot\text{d})} = 262{,}500\ \text{m}^2$$

   c. Media volume $= \dfrac{262{,}500\ \text{m}^2}{(500\ \text{m}^2/\text{m}^3)} = 525\ \text{m}^3$

   d. First reactor tank volume $= \dfrac{525\ \text{m}^3}{(0.50\ \text{m}^3/\text{m}^3)} = 1050\ \text{m}^3$

   e. Hydraulic retention time, $\tau = V/Q = \dfrac{1050\ \text{m}^3}{30{,}000\ \text{m}^3}\left(\dfrac{24\ \text{h}}{\text{d}}\right) = 0.84\ \text{h}$

2. Determine plastic media volume needed and tank volume for 2nd reactor.

   a. Applied BOD flux $= \dfrac{(4.0\ \text{g/m}^2\cdot\text{d})}{0.90} = 4.44\ \text{g BOD/m}^2\cdot\text{d}$

   b. Media area: BOD remaining to 2nd reactor

   $$= 0.25(30{,}000\ \text{m}^3/\text{d})(140\ \text{g/m}^3) = 1{,}050{,}000\ \text{g BOD/d}$$

   $$= \frac{(1{,}050{,}000\ \text{g BOD/d})}{(4.44\ \text{g BOD/m}^2\cdot\text{d})} = 236{,}486\ \text{m}^2$$

   c. Media volume $= \dfrac{236{,}486\ \text{m}^2}{(500\ \text{m}^2/\text{m}^3)} = 473\ \text{m}^3$

   d. Second reactor tank volume $= \dfrac{473\ \text{m}^3}{(0.50\ \text{m}^3/\text{m}^3)} = 946\ \text{m}^3$

   use same volume as first reactor = 1050 m^3

   e. Hydraulic retention time, $\tau = V/Q = \dfrac{1050\ \text{m}^3}{30{,}000\ \text{m}^3}\left(\dfrac{24\ \text{h}}{\text{d}}\right) = 0.84\ \text{h}$

3. Determine available NH_4-N for nitrification after nitrogen consumption for heterotrophic bacteria synthesis from BOD removal using Eq. (8–20), Table 8–10.

   $$P_{x,\text{bio}} = \frac{Q(Y_H)(\text{BOD})}{[1 + b_H(\text{SRT})]} + \frac{f_d(b_H)Q(Y_H)(\text{BOD})\text{SRT}}{[1 + b_H(\text{SRT})]}$$

   $$\frac{P_{x,\text{bio}}}{Q} = \frac{(Y_H)(\text{BOD})[1 + f_d(b_H)(\text{SRT})]}{[1 + b_H(\text{SRT})]}$$

$$b_{H,12} = b_{H,20}(1.04)^{(12-20)} = (0.12\text{ g/g·d})(1.04)^{(12-20)} = 0.087\text{ g/g·d}$$

$$Y_H = 0.45\frac{\text{g VSS}}{\text{g bCOD}}\left(\frac{1.6\text{ g bCOD}}{\text{g BOD}}\right) = 0.72\text{ g VSS/g BOD}$$

$$\frac{P_{x,\text{bio}}}{Q} = \frac{(0.72\text{ g VSS/g BOD})(140\text{ g/m}^3)[1 + 0.15(0.087\text{ g/g·d})(6\text{ d})]}{[1 + (0.087\text{ g/g·d})(6\text{ d})]} = 71.4\text{ g VSS/m}^3$$

Ammonia available for nitrification (Eq. 8–24, Table 8–10):

$$\text{NH}_o = \text{TKN} - (0.12\text{ g N/g biomass})\frac{P_{x,\text{bio}}}{Q}$$

$$\text{NH}_o = 35.0\text{ gN/m}^3 - 0.12(71.4\text{ g VSS/m}^3) = 26.4\text{ g N/m}^3$$

4. Determine media volume and tank volume for nitrification reactors.
   a. Adjust DO limited flux for temperature

$$J_{N,12} = 1.07\text{ g N/m}^2\text{·d}(1.058)^{(12-15)} = 0.90\text{ g N/m}^2\text{·d}$$

   b. Determine nitrification flux in 2nd nitrification reactor under ammonia limited conditions from Eq. (9–48).

$$J_{N,15} = \left[\frac{N}{(2.2\text{ g/m}^3) + \text{N}}\right]3.3\text{ g N/m}^2\text{·d}$$

$$= \left[\frac{(0.70\text{ g/m}^3)}{(2.2\text{ g/m}^3 + 0.70\text{ g/m}^3)}\right](3.3\text{ g N/m}^2\text{·d}) = 0.797\text{ g N/m}^2\text{·d}$$

$$J_{N,12} = 0.797\text{ g N/m}^2\text{·d}(1.098)^{(12-15)} = 0.60\text{ g N/m}^2\text{·d}$$

   c. Design the two tanks with equal media area; they will have same volume as they have the same fill volume fraction.

$$\text{Media area} = \frac{(\text{g N removed/d})}{(\text{flux, g N/m}^2\text{·d})}$$

Reactor 3

$$\text{Media area} = A_3 = \frac{[(26.4 - X)\text{g N/m}^3](30{,}000\text{ m}^3\text{/d})}{(0.90\text{ g N/m}^2\text{·d})},$$

where $X = \text{NH}_4\text{-N}$ concentration in reactor

Reactor 4

$$\text{Media area} = A_4 = \frac{[(X - 0.70)\text{ g N/m}^3](30{,}000\text{ m}^3\text{/d})}{(0.60\text{ g N/m}^2\text{·d})},$$

$$A_3 = A_4$$

$$\frac{[(26.4 - X)\text{ g N/m}^3](30{,}000\text{ m}^3\text{/d})}{(0.90\text{ g N/m}^2\text{·d})} = \frac{[(X - 0.70)\text{g N/m}^3](30{,}000\text{ m}^3\text{/d})}{(0.60\text{ g N/m}^2\text{·d})}$$

solve for X; $X = 10.98\text{ g N/m}^3$

$$\text{Media area for each tank} = \frac{[(10.98 - 0.70)\text{g N/m}^3](30{,}000\text{ m}^3\text{/d})}{(0.60\text{ g N/m}^2\text{·d})} = 514{,}000\text{ m}^2$$

   d. Media volume $= \dfrac{514{,}000\text{ m}^2}{(500\text{ m}^2\text{/m}^3)} = 1028\text{ m}^3$

e. Nitrification reactors tank volume $= \dfrac{1028\ \text{m}^3}{(0.60\ \text{m}^3/\text{m}^3)} = 1713\ \text{m}^3$

f. Hydraulic retention time, $\tau = V/Q = \dfrac{1713\ \text{m}^3}{30{,}000\ \text{m}^3}\left(\dfrac{24\ \text{h}}{\text{d}}\right) = 1.37\ \text{h}$

5. Summary of media and tank volumes.

Reactor	Function	DO, mg/L	Media volume, m^3	Tank volume, m^3	τ, h
1	BOD removal	2.0	525	1050	0.8
2	BOD removal	3.0	473	1050	0.8
3	Nitrification	4.0	1030	1720	1.4
4	Nitrification	4.0	1030	1720	1.4
Total			3058	5540	4.4

9–6 SUBMERGED AEROBIC ATTACHED GROWTH PROCESSES

A number of other aerobic attached growth process designs have been used in addition to the moving bed bioreactor process presented in Sec. 9–5. These are compact biological treatment processes with a major difference from the MBBR process being that they do not have secondary clarification. Suspended solids are removed by filtration within the process media or by side stream solids harvesting in the case of the fluidized bed reactor. The purpose of this section is to (1) describe the more common designs used, (2) identify advantages and disadvantages, (3) address the design physical facilities, and (4) provide a process analysis of removal mechanisms and basic design considerations. The more commonly used aerobic attached growth processes are presented in this section and include the downflow *biological aerated filter* (BAF), the upflow BAF, and a fluidized bed biological reactor (FBBR).

Process Development

The term biological aerated filter refers to the fact that the attached growth process is aerated to provide oxygen for BOD removal and nitrification. The biological aerated filter falls within a broader term for these types of systems, which is a *biological active filter*. The term biological active filter includes the biological aerated filter and similar designs that have been employed under anoxic conditions for biological denitrification for nitrogen removal. Attached growth processes for biological denitrification are discussed in Sec. 9–7.

The development of submerged aerobic attached growth processes began in the late 1970s. Examples of such systems reported in the literature are the FBBR with preoxygenation of the influent (Jeris et al., 1977), an upflow granular media reactor with air sparging from the bottom of the media (Young and Steward (1979), a downflow granular media reactor with air sparging near the bottom of the bed above the effluent collection nozzles (Leglise et al., 1980), and an upflow plastic media reactor with air sparging from the bottom (Rusten, 1984). The downflow granular media design by Leglise et al. (1980) was termed the Biocarbone® process because of the early use of granular activated carbon for the media. Later, the media was changed to a fired clay material and the process name was changed to *biological aerated filter* (BAF). The predecessor to wide commercial applications of submerged attached growth processes was the start up of the first commercial

Biocarbone® process near Paris, France, in 1982 (Stephenson et al., 2004). The term *sunken media* has been applied to this application in reference to the immobile high specific density of the fired clay material used.

A similar design using an expanded shale media was developed with its first installations in England (Smith and Edwards, 1994). The trapping of rising air in the downflow operation mode could result in undesirable increased headloss in the downflow BAF, and led to upflow BAF designs, in France and in the United Kingdom, with both sunken and a lighter plastic media (Rogalla and Bourbigot, 1990; Meaney and Strickland, 1994; and WEF 2011). Since the mid-1980s, hundreds of BAFs have been installed, most of which are in Europe.

Process Applications

The aerobic attached growth BAF processes presented in this section have been used primarily for municipal wastewater treatment for the following applications: (1) secondary treatment for BOD removal, (2) secondary treatment for BOD removal and nitrification, and (3) tertiary treatment for nitrification. In addition they have found some use for BOD removal from dilute industrial wastewaters. Phosphorus removal can be accomplished by chemical addition to the influent of the aerobic attached growth processes. While FBBR systems have been used for biological denitrification in tertiary treatment applications, their more common use has been for nitrification and to treat groundwater contaminated with hazardous substances. In some of these applications activated carbon media has been used to provide both carbon adsorption and biological degradation (Sutton and Mishra, 1994).

Most of the aerobic attached growth processes are proprietary designs from various suppliers. Factors that distinguish the different designs and products are (1) the flow direction; upflow or downflow, (2) media density, (3) media size, (4) media material, (5) media depth, (6) fluid velocity, and (7) the method used for excess solids removal. No clarification is used with aerobic submerged attached growth processes and excess solids from biomass growth and influent suspended solids trapped in the system must be removed periodically. Most designs require a backwashing system much like that used in a water filtration plant to flush out accumulated solids, usually on a daily basis.

Process design features for typical aerobic attached growth processes are summarized in Table 9–16. The BAF processes are capable of producing effluent BOD and TSS concentrations of less than 10 mg/L for secondary treatment. Lower loaded single BAF units can provide combined BOD and nitrification or tertiary BAF and FBBR units can provide nitrification to produce effluent ammonia-N concentrations less than 1.0 mg/L or between 1.0 to 4.0 mg/L, depending on the ammonia-N loading and dissolved oxygen concentration.

The high hydraulic application rates possible in BAF and FBBR processes result in empty bed contact times from 0.50 to 1.5 h or even less for FBBR applications. The upflow BAFs are more popular due to their lower and more reliable headloss but they may require a higher amount of product water for backwashing. During demonstration testing in San Diego, California, of upflow BAFs for BOD removal, the floating media BAF backwash water needs were between 10.3 and 13.9 percent of the product water compared to 7.4 to 7.9 percent for an upflow sunken media BAF (Newman et al., 2005).

Process Advantages and Disadvantages

The advantages and disadvantages of BAF and FBBR processes compared to activated sludge treatment are as follows:

Advantages for BAF Processes. The major advantages of BAF processes include (1) their relatively small space requirement, (2) the ability to effectively treat dilute

Table 9–16

Summary of design and operating features of commonly used aerobic submerged attached growth processes[a]

Process	Description
Downflow BAF	
(a)Downflow, sunken media  	Primary effluent wastewater is applied above a bed of heavy media at a depth of 1.6 to 2.0 m. Typical media is a 3.0 to 5.0 mm expanded clay or shale with a specific gravity of about 1.6. Air distribution piping is located about 30 cm above underdrain and uniformly distributed across bottom area. Downflow velocity ranges 2.4 to 4.8 m/h. Backwashing with air scour at about 90 $m^3/m^2 \cdot h$ followed by water at about 15 $m^3/m^2 \cdot h$. Backwash once per d or headloss at about 1.8 m. Commercial products include the Biocarbone®, and Biodrof® systems.
Upflow BAF	
(b) Upflow, sunken media  	Primary effluent wastewater is applied through nozzles embedded in a plenum floor below the biofilter bed. Commonly used media are an expanded clay or shale material of 3.5 or 4.5 mm spherical grains, or 2.7 mm angular grains with a specific gravity of 1.6. Typical bed depth is 3 m but range from 2 to 4 m. Upflow velocity ranges from 4 to 6 m/h. Backwashing is typically done once per d with a water flush rate of 10 to 30 $m^3/m^2 \cdot h$ to expand the bed. The backwash usually consists of a drain down, then air scour to breakup the media, followed by concurrent scour air and backwash water, and a final water rinse. Commercial products include the Biofor® system.
(c) Upflow, floating media  	This type uses a floating bed of spherical media that are lighter than water. Two of the major suppliers with similar process designs are: (1) Biostyr® uses a 3.0 to 6.0 mm polystyrene bead with a specific gravity of about 0.5 and (2) Biobead® uses a 2.3 to 2.7 mm polyethylene bead with a specific gravity of about 0.95. The beads form a floating bed in the upper portion of the reactor; typical height of 3 to 4 m. The top of the bed is restrained by a plenum fitted with filtration nozzles to collect the treated wastewater. The media is compressed with the upflow of water during treatment and provides filtration. Plate covered holes in a bottom support plate distribute influent flow and also collect the downflow spent backwash water. Process air is distributed through diffusers located along the bottom of the reactor. Upflow velocity ranges from 4 to 6 m/h. Other commercial products include the Biopure®, and Biolest® systems.
(d) Upflow, floating media with anoxic zone  	A variation of the upflow floating media design for Biostyr systems has been done in full-scale facilities to accomplish nitrification and denitrification in the same attached growth reactor. The process air header is located at about 2 m below the top of the media and a bottom portion of media is a nonaerated, preanoxic zone for biological denitrification. Nitrified effluent is recycled to the influent feed and BOD in the primary effluent provides the electron donor for nitrate reduction.

(*continued*)

Table 9–16 (*Continued*)

Process	Description
Fluidized bed bioreactor	
(e) Upflow fluidized bed bioreactor 	The wastewater is fed upward to a fluidized bed of 0.3 to 0.7 mm sand or 0.6 to 1.4 mm activated carbon. Bed depths range from 3.0 to 4.0 m. The upflow velocity used for 0.5 mm silica sand is from 30 to 40 m/h. Recycle flowrate is 2 to 5 times the influent flowrate to maintain media fluidization. Influent hydraulic retention times range from 10 to 20 min. The influent is introduced through a perforated plate or downward facing nozzle.

[a] Borregaard (1997), Freihammer et al. (2007), Holbrook et al. (1998), Lazarova et al. (2000), Mendoza and Stephenson (1999), Pujol et al. (1994), Sutton et al. (1981), and U.S. EPA (1993).

wastewaters, (3) no issues with regard to sludge settling characteristics, (4) simplicity of operation, and (5) ability to house it due to the small space needs. The ability to house it has the advantage of aesthetics and less effect of weather on operating personnel. Also for many processes solids filtration occurs to produce a high quality effluent.

Disadvantages for BAF Processes. Their disadvantages include (1) a more complex system in terms of operation and maintenance of instrumentation and controls, (2) limitations of economies of scale for application to larger facilities, (3) generally a higher capital cost unless land is at a premium or not available, and (4) vulnerable to high headloss from high solids loadings. The design and cost of BAF and FBBR processes are impacted directly by the hydraulic flowrate. Flow equalization should be considered for high hydraulic peak flows from wet weather events.

Advantages for FBBR Process. The main advantages for the FBBR technology for treatment of dilute organic substrates and for biodegradation of xenobiotics are (1) it provides an extraordinary long SRT for microorganisms necessary to degrade the xenobiotic and toxic compounds, (2) shock loads or non-biodegradable toxic compounds can be absorbed onto the activated carbon, (3) a high quality effluent with low TSS and COD concentration is possible, (4) the oxygenation method prevents stripping and emission of toxic organic compounds to the atmosphere, and (5) the system operation is simple and reliable.

Disadvantages for FBBR Process. The main disadvantages recognized for FBBR are (1) high energy requirement for high recycle flow pumping, (2) higher oxygen supply rate required, and (3) operational challenges in biomass and process control.

Design of Physical Facilities

The design components of a BAF system are very similar to those for water treatment filtration facilities, including influent flow distribution, media selection, and backwash water storage, water pumps, air scour compressors, and automated controls and valves.

It is common for a supplier to provide package or modular designs for standard BAF treatment units with necessary piping, valving, pumps, blowers and controllers. For wastewater treatment applications the physical facility designs depend on the characteristics of the influent wastewater, methods to remove accumulated solids, and process air supply. Important physical facility design issues addressed in this section are (1) pretreatment requirements, (2) methods to remove excess solids, and (3) oxygen supply.

Pretreatment Requirements. Pretreatment is required for both the upflow and downflow BAF processes to avoid clogging of the influent or effluent flow distribution nozzles from the collection of fibers or large influent particle size. In addition, primary treatment is normally used to control the amount of solids that must be removed by filtration. Higher influent suspended solids concentrations would result in more frequent backwashing and the use and recycle of a greater portion of the effluent product water. The net effect would be the need for more BAF treatment area and possibly more treatment units.

The need for and type of additional pretreatment required following primary treatment depends on the type of BAF process selected. A downflow BAF with sunken media does not require additional pretreatment as the primary effluent solids are removed in the filter bed before the effluent flow reaches the underdrain collection nozzles. An upflow sunken media design introduces the primary effluent flow through underdrain nozzles and thus fine screening with a screen size of 2.5 mm is typically recommended. The upflow floating media BAF design does not have influent flow distribution nozzles, but prescreening with a screen size of about 10 mm is recommended to prevent the collection of fibers on the effluent nozzles or on the media.

Excess Solids Removal. Periodic backwashing of a BAF is needed to remove accumulated solids from the influent wastewater filtration and produced by biological growth on influent wastewater soluble and particulate substrates. The backwash procedure varies depending on whether sunken or floating media is used, but in both cases air scour and water flushing are employed. The backwash water source is treatment effluent water from a backwash water storage tank or from the effluent flow from a number of BAF modules in larger plants. The backwash frequency may be set for 24 h increments or governed by a preset headloss value.

Backwashing of the sunken media BAF involves taking the unit off line and subjecting it to an air scour and water backwash flushing cycle that is automatically controlled by timers and actuated valves. During backwashing of BAFs with floating media, treated water flows down through the media at a very high rate to cause a downward expansion of the originally compressed material. The solids retained in the lower portion of the reactor and excess biomass produced on the packing is flushed out through the influent underdrain plate. The normal backwash procedure consists of repeated rinse (water flushing) and air agitation steps. The air flowrate in the process air header is increased during backwashing. The downward water flow expands the bed to release solids held in the media pore space and air scouring agitates the bed to dislodge solids from the media. Typically, 4 water phases and 3 air phases are used (WEF, 2011). Similar backwash air and water application rates are used for both types of BAF processes. Air and water flush rates vary from 0.8 to 1.0 m/min and water flush rates vary from 0.6 to 1.0 m/min (Stensel et al., 1988; Mendoza-Espinosa and Stephenson, 1999).

The biofilm thickness on FBBR media increases with time as substrate is removed, which then lowers the particle specific density and the lighter particles migrate to the top of the bed. Wasting of excess biogrowth is then done by transporting the biofilm carrier media from the top of the bed to an external device, such as vibrating screen, hydrocyclone or airlift system, for agitation and stripping off the excess biomass. The media carrier is then recycled back to the fluidized bed reactor.

Processing Backwash Water. Spent backwash water is returned to head of the treatment plant prior to primary settling tanks or is treated in a separate unit. Recycle of BAF backwash water to the primary treatment step is thought to improve BOD removal in primary treatment due to adsorption of BOD by the BAF waste biomass. Treatment in a separate unit is done if the existing primary treatment has limited hydraulic and/or solids loading capacity or may be preferred for larger facilities. The types of technologies used include ballasted flocculation and settling, a solids contact/sludge recirculation system, dissolved air flotation thickening, and gravity settling (WEF, 2011). The treatment of return flows is considered in Chap. 15.

Aeration Equipment. Process air is typically supplied by coarse bubble aeration through a piping grid system located at the bottom of the sunken media or below the floating media. The sparge air pipes may be placed 250 to 300 mm apart with holes for coarse bubble air drilled at equal intervals to provide a uniform air application rate across the bed area. The use of fine bubble diffusers does not provide any improvement in oxygen transfer efficiency because the bubbles coalesce into large bubble size in the media (Harris et al., 1996). Blower design for a downflow sunken media BAF must consider the effect of headloss on the blower air supply rate. As solids accumulate in the bed, the headloss and liquid level above the bed increases, which can decrease the blower air supply rate. The upflow BAF designs with sunken and floating media do not have this problem as the liquid level on top of the bed is set with effluent overflow.

BAF Process Design Analysis

A BAF process is a high rate treatment system that employs dual functions of biological oxidation of BOD and/or ammonia and physical removal of particulate and colloidal solids by absorption and filtration. Important issues that affect the design and performance of BAF processes are discussed in this section and include (1) media characteristics, (2) process loadings, (3) aeration design, and (4) sludge production.

Media Size. The average media size affects (1) the surface area available per unit of reactor volume for biofilm growth and substrate removal rates and (2) the pore size and filtration efficiency. The specific surface area of a sphere is given by Eq. 9–50.

$$SSA_{sp} = \frac{6000}{D_{sp}} \tag{9–50}$$

where: SSA_{sp} = specific surface area of a spherical particle, m^2/m^3
D_{sp} = diameter of particle, mm

As an example of the magnitude of surface area available for biomass growth in submerged attached growth processes, a BAF system with 3-mm sunken media and bed porosity of 40 percent would have a bulk reactor volume specific media surface area of 1800 m^2/m^3. For a FBBR process with a 0.50 mm sand and 100 percent bed expansion, the bulk reactor specific surface area is estimated at 6000 m^2/m^3. The actual area would be less as the media is normally given in terms of the effective size and the biofilm growth increases the effective particle diameter.

The media size selection in a BAF design must be based on a consideration of the effluent TSS concentration needed and filtration efficiency, the organic removal efficiency needed and organic loading, and backwash requirements. A smaller media size allows a greater organic loading due the higher bulk specific surface area and produces a lower effluent TSS concentration. However, the BAF run time before backwashing would be less, a greater fraction of the effluent would be needed for backwashing, and the operating costs would be higher. A media size of about 6 mm for partial BOD removal, an intermediate size of 4 to 5 mm for secondary treatment, and less than or equal to 3 mm for effluent polishing or tertiary nitrification is recommended (Mendoza-Espinosa and Stephenson, 1999).

Process Design Loadings. Substrate removal mechanisms in a BAF process include removal of soluble substrates by diffusion and biodegradation kinetics in the media biofilm area, and adsorption and filtration of colloidal and particulate material. Soluble substrate removal is a diffusion-limited biological treatment process with removal rates affected by the biofilm area, bulk liquid substrate and DO concentrations, upflow or downflow fluid velocity, and temperature. The particulate BOD removal is affected by media size, fluid velocity, operating headloss and backwash frequency. Because of the process complexity with regard to predicting the biofilm growth, biofilm thickness and biomass density, and hydraulic flow patterns process, designs are based on volumetric process loading rates and performance observed in full-scale and pilot-scale facilities. BAF performance for secondary treatment, combined BOD removal and nitrification, and tertiary nitrification is usually measured as a function of kg BOD/m^3·d or kg N/m^3·d. For more dilute wastewaters, hydraulic loading rates may govern the design. Typical hydraulic application rates for each type of BAF process are included with the process descriptions in Table 9–16.

A range of volumetric BOD loading rates reported for BAF processes is given in Table 9–17 for treatment for BOD removal only and for treatment at lower BOD loadings to accomplish BOD removal and nitrification in the same BAF unit. Though the loadings are typically based on total BOD, the soluble BOD loading is of importance in determining the effluent soluble BOD and final total BOD concentration. It has been found that for a downflow sunken media BAF process the soluble BOD volumetric loadings below 1.0, 1.2, and 1.4 kg/m^3·d were needed to achieve a secondary effluent BOD at 10–12, 12–16, and >16°C, respectively (Stensel et al., 1988). Thus, the volumetric BOD loading selected should be at the lower range of the values shown in Table 9–18 for wastewater with a higher soluble BOD fraction.

BAF processes have been operated at low BOD loadings to achieve BOD removal and nitrification. As was discussed in Sec. 9–4 and 9–5 for trickling filters and MBBR processes, nitrification in a BAF process does not occur until most of the soluble BOD is first removed so that surface area is available for nitrifying bacteria. The net effect on the process design is that a much lower overall volumetric BOD loading is used for combined BOD removal and nitrification BAF processes as shown in Table 9–17. The DO concentration for nitrification applications should be at least 3 to 4 mg/L to obtain reasonable nitrification rates as the process is often DO limited. Maintaining elevated DO concentration is difficult

Table 9–17

Process volumetric loadings for biological aerated filters[a]

Process application	Loading units	Range	Removal efficiency, %
BOD removal	kg BOD/m^3·d	3.5–5.5	≥85
BOD removal and nitrification	kg BOD/m^3·d	1.8–2.5	≥85
Tertiary nitrification	kg NH_4-N/m^3·d	1.0–1.5	≥90

[a] Mendoza and Stephenson (1999), WEF (1998), Tchobanoglous et al. (2003), WEF (2011).

Table 9–18

Oxygen transfer efficiencies expressed in percent/m of depth observed for biological aerated filters

BAF Design	Test system depth, m	O_2 transfer efficiency, %/m	Test system	Reference
DF, sunken	1.6	3.4–5.5	Full-scale	Stensel et al. (1988)
DF, sunken	2.0	5.0–8.5	Full-scale	WER (2011)
UF, sunken	3.6	1.6–5.8	Lab-scale	Stenstrom et al. (2008)
UF, sunken	4.0	5.0	Full-scale	Laurence et al. (2003)
UF, floating	3.6	3.6–8.0	Lab-scale	Stenstrom et al. (2008)
UF, floating	3.0	6.7	Full-scale	Laurence et al. (2003)

in combined BOD removal and nitrification processes due to the high volumetric oxygen demand for BOD removal.

An alternative to a combined BOD removal and nitrification process is to use two BAF units in series with the first unit designed at a BOD loading to meet a secondary effluent BOD concentration of less than 15 mg/L and the second stage unit designed for nitrification. With two units, design and operating conditions for nitrification are more optimal, with each unit operating at different DO concentrations, hydraulic application rates, and backwash frequency. Based on nitrification studies, 85 to 90 percent nitrogen oxidation was found at loadings of 1.5 to 1.8 kg N/m^3·d for tertiary nitrification applications (Payraudeau et al., 2000). A range of ammonia-N loadings used for tertiary nitrification is shown in Table 9–17. The volumetric nitrification rate was found to increase by about 3 percent for each degree centigrade temperature increase from 10°C for all types of BAFs (Tschui et al., 1994).

Aeration Design. The volumetric oxygen uptake rates for BAFs are very high compared to activated sludge processes due to their relatively short hydraulic retention times and high organic loading rates. Volumetric oxygen uptake rates as high as 250 mg/L·h have been measured in a 1.7 m deep downflow BAF unit (Stensel et al., 1984). Even though coarse bubble aeration is used, the actual oxygen transfer efficiency is greater than what would be expected for fine bubble diffused aeration at the same depth because of bubble hold up in the BAF media (Stensel et al., 1984; Lee and Stensel, 1986; and Stenstrom et al., 2008). Actual process oxygen transfer efficiencies are higher at lower air application rates per unit area due to greater bubble hold up time. A range of reported oxygen transfer efficiencies are summarized in Table 9–18. When higher air application rates are used to maintain DO concentrations at higher loadings, the lower range of values should be used for design.

The oxygen demand in a BAF process is a function of the wastewater characteristics, BOD loading, and backwash frequency. It has been found that for a downflow sunken media system loaded at 3.5 kg BOD/m^3·d and once per day backwash, only about 20 percent of the influent volatile suspended solids were degraded due to the short solids retention time (Stensel et al., 1984). The following equation can be used to estimate the oxygen demand associated with BOD and volatile suspended solids removal.

$$\mathrm{OR} = 0.82\frac{\mathrm{sBOD}_o}{\mathrm{TBOD}_o} + \frac{1.6(\mathrm{BF}_{\mathrm{VSS}})X_o}{\mathrm{TBOD}_o} \qquad (9\text{–}51)$$

where OR = oxygen required, g O_2/g BOD applied
sBOD_o = influent soluble BOD concentration, g/m^3
TBOD_o = influent total BOD concentration, g/m^3
$\mathrm{BF}_{\mathrm{VSS}}$ = fraction of influent volatile solids degraded, g/g
X_o = influent volatile suspended solids concentration, g/m^3

Sludge Production. As shown above for the oxygen requirements, the sludge production is also related to the influent characteristics and fraction of influent VSS degraded. The following equation can be used to estimate the sludge production (Stensel et al., 1984). The VSS/TSS ratio may be in the range of 0.80 to 0.85 following primary treatment.

$$P_{X,\text{VSS}} = [0.60(\text{sBOD}_o) + (1 - \text{BF}_{\text{VSS}})(X_o)]Q \tag{9–52}$$

where $P_{X,\text{VSS}}$ = volatile solids production rate, g/d
Q = influent flowrate, m^3/d

The solids accumulation capacity before backwashing is needed may be in the range of 2.4 to 3.0 kg TSS/m^3 (Stensel et al., 1984; WEF, 2011). The backwash suspended solids concentration may range from 500 to 1500 mg/L, depending on the influent wastewater characteristics, BOD loading, and backwash frequency.

FBBR Process Design Analysis

Aerobic FBBR applications involve an external oxygen transfer device, bed fluidization, and solids removal for biofilm control. The media biofilm thickness affects the reaction rate, and it can be controlled and optimized by the selection of the bioparticle composite concentration based on support media volume and degree of bed expansion. The bed expansion typically ranges from 50 to 100 percent. A lower degree of expansion allows a lower upflow velocity and requires less energy, but has a higher volumetric oxygen demand due to the increases in biomass concentration.

The application of aerobic treatment with FBBR systems for biodegradation of contaminated groundwaters or dilute industrial wastewater is very site specific and requires an understanding of the degradation characteristics of the compounds of interest. FBBR systems have been used for ammonia removal.

A bed depth of 5 to 6 m has been used for nitrification applications at an ammonia loading in the range of 1.0 kg NH_4-N/m^3·d. The recommended hydraulic loading rate is less than 40 m^3/m^3 bed·d and 25 m^3/m^3 bed·d to achieve effluent ammonia-N concentration of ≤5 mg/L and 0.5 mg/L, respectively (Dempsey et al., 2006).

9–7 ATTACHED GROWTH DENITRIFICATION PROCESSES

Over the years, a number of attached growth denitrification processes have been developed for both postanoxic and preanoxic applications. Topics included in this section include (1) process development, (2) common types of attached growth processes used for biological denitrification, (3) process design analysis, and (4) process operation considerations. The physical facility design considerations are covered elsewhere, either in the previous sections in this chapter or in Chap. 11.

Process Development

The development of attached growth biological denitrification processes began in the early 1970s following an increase in regulations to restrict effluent nitrogen discharges from municipal wastewater treatment plants for control of eutrophication. The aim at that time was to remove nitrate from secondary effluents, and the first two process concepts developed were a downflow denitrification filter patented by Dravo Corp in 1973 (WERF, 2010) and an anoxic fluidized bed reactor (Jeris et al., 1974). The first full-scale anoxic fluidized bed reactor was installed at the Truckee Meadows Water Reclamation Facility near Reno, NV, in the early 1980s following a nitrifying trickling filter (Sedlak, 1991). Since then a number of anoxic attached growth denitrification process designs have been developed and marketed by various suppliers. These include upflow and downflow filters, an anoxic moving bed bioreactor, and an anoxic submerged rotating biological contactor.

Description and Application of Attached Growth Denitrification Processes

Attached growth denitrification processes have been applied most often as a postanoxic treatment step after nitrification. However, in some cases attached growth denitrification has been used in a preanoxic mode prior to nitrification. Both types are discussed in this section.

Attached Growth for Postanoxic Denitrification. The most commonly used attached growth process designs for biological denitrification, shown on Fig. 9–27. can be classified into three types: (1) denitrification filter, (2) suspended media denitrification, and (3) fluidized bed denitrification. All of these systems are provided by different manufacturers, with each specifying their selection of media type and size, media depth, hydraulic application rates, and backwashing methods for denitrification applications.

Denitrification filters have been included under a general category of biological active filters in the Water Environment Federation MOP 35 on biofilm reactors (WEF, 2011). The terminology for biological active filters in the document also includes the biological aerated filters (BAFs) that were discussed in Sec. 9–6. All of the types of BAFs presented in Table 9–16 in Sec. 9–6 are changed to denitrification filters by eliminating the addition of process air, and having nitrate and an exogenous carbon feed in their influent.

As done for the BAFs, these denitrification filters are distinguished by their treatment flow direction and media characteristics and are shown as (1) downflow sunken media [see Fig. 9–27(a)], (2) upflow sunken media [see Fig. 9–27(b)], and (3) upflow floating media [see Fig. 9–27(c)]. In addition, a fourth type of denitrification filter is the continuous

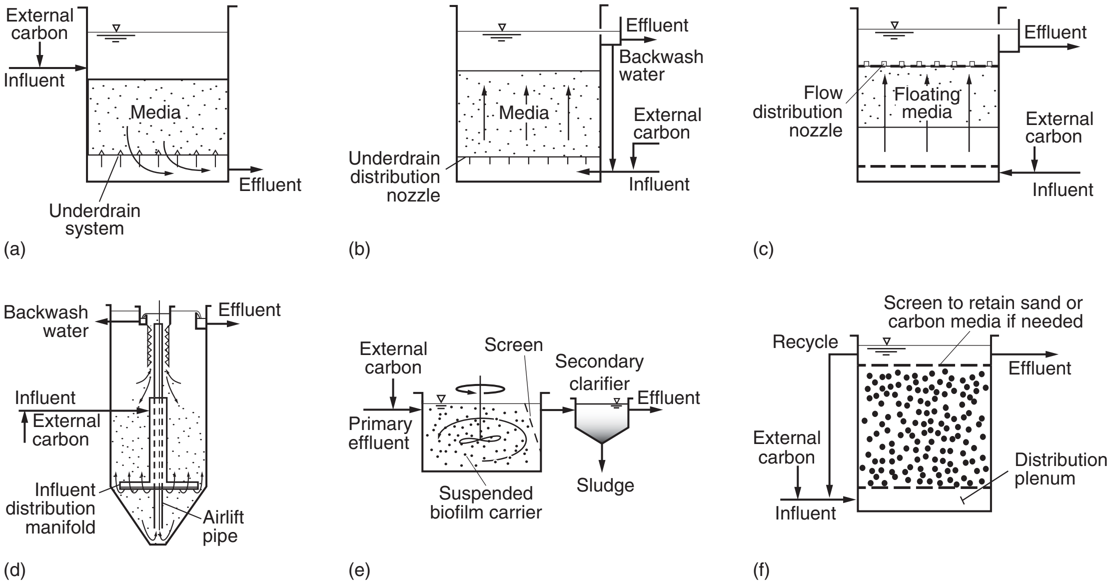


Figure 9–27

Commonly used attached growth processes for biological denitrification. Denitrification filters (DNFs): (a) downflow sunken media, (b) upflow sunken media, (c) upflow floating media, and (d) continuous backwash sand filter. Suspended media denitrification processes: (e) anoxic moving bed bioreactor (AnoxMBBR) and (f) anoxic fluidized bed reactor (AnoxFBBR).

backwash sand filter shown on Fig. 9–27(d). Downflow and continuous backwash sand filters for suspended solids removal are described in Sec. 11–3 in Chap. 11. In the anoxic continuous backwash filter, the wastewater enters the filter at the top and is conveyed to the bottom of the bed where it is distributed through feed radials and then travels upward for treatment through the filter bed. An airlift in a center column in the filter provides a continuous backwash of the media so that the filtration operation is not interrupted and taken off line for backwashing, which is in contrast to the other denitrification filters that must be removed from service for backwashing.

The AnoxMBBR reactor [see Fig. 9–27(e)] has been described in Sec. 9–5 and has been used in both preanoxic and postanoxic zones in an MBBR biological nitrogen removal treatment system and as a postanoxic denitrification process after secondary or tertiary nitrification (see Table 9–13). The AnoxFBBR [see Fig. 9–27(f)] uses a much smaller media size and thus has the highest reactor specific surface area of the attached growth biological denitrification systems.

Need for Carbon Source. A carbon source must be added to the influent of postanoxic attached growth denitrification reactors to support biological growth and create a demand for nitrite/nitrate as an electron acceptor. The use of nitrate and nitrite as an electron acceptor by heterotrophic bacteria for organic substrate consumption with the evolution of nitrogen gas has been discussed in Sec. 7–10 and in Sec. 8–7 for suspended growth anoxic processes. Methanol is the most commonly used exogenous carbon source for postanoxic denitrification because of its low cost per unit of nitrate-N removed and lower solids yield. However other carbon sources, such as ethanol and glycerol, have been considered for postanoxic attached growth denitrification.

Influent Feed Conditions. Typical upstream treatment and influent feed conditions for postanoxic attached growth processes fall into one of two scenarios: Scenario I is treatment of effluent from an activated sludge biological nitrogen removal process (i.e. MLE process) that has a NOx-N (NO_3-N plus NO_2-N) concentration below 10 mg/L, and Scenario II is treatment of an attached growth nitrified process effluent with a NOx-N concentration in the range of 20 to 35 mg/L. Many of the applications with Scenario I also require a low effluent TSS concentration and thus a denitrification filter is often used to remove both NOx-N and TSS to meet low total nitrogen and low TSS effluent concentrations. More stringent effluent TN requirements, such as less than or equal to 3.0 mg/L, cannot be met without effluent filtration. For Scenario II, a greater amount of carbon must be added to the postanoxic denitrification reactor, which results in a higher volumetric denitrification rate and greater amount of biomass production. The AnoxMBBR and AnoxFBBR processes can accommodate the higher nitrate and carbon loadings but normally need an effluent polishing step for suspended solids removal.

Typical Performance. Survey of full-scale facilities with postanoxic attached growth denitrification and with over 3 years of performance was done with data from 4 facilities to provide a statistical treatment performance evaluation. The 50th percentile values for the effluent TN concentrations were less than or equal to 1 mg/L. The 90th percentile effluent TN concentrations ranged from 2.7 to 4.2 mg/L for the different facilities (Bott and Parker, 2010).

Attached Growth for Preanoxic Denitrification. Attached growth denitrification processes that have been used for preanoxic denitrification include applications with (1) trickling filters (Nasr et al., 2000; and Dorias and Baumenn, 1994), (2) denitrification filters (Ninassi et al., 1998), and (3) applications with MBBRs (Lazarova et al., 1998). As shown in Table 9–13(e) and (g) in Sec. 9–5, an AnoxMBBR can be used for preanoxic nitrate removal in an MLE- or Bardenpho-type nitrogen removal process.

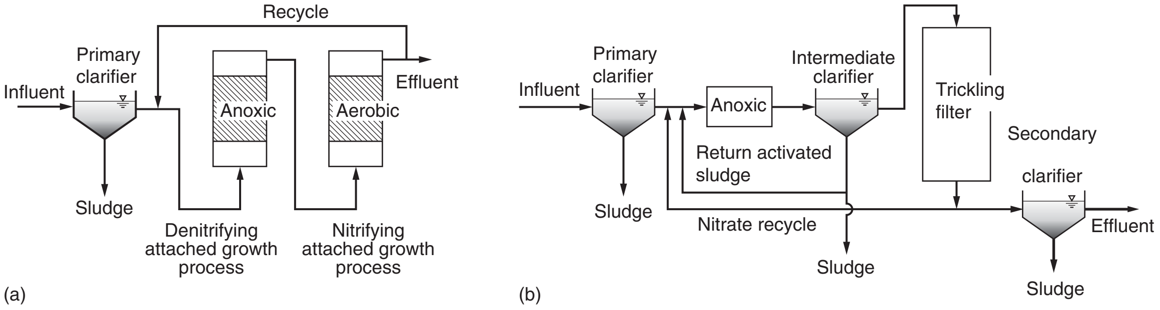

Figure 9–28

Example of preanoxic attached growth processes: (a) sequential upflow denitrification-nitrification biological active filters and (b) recirculation of nitrifying trickling filter effluent to a preanoxic suspended growth process.

Other examples of preanoxic denitrification with attached growth processes are illustrated on Fig. 9–28. In the first case [see Fig. 9–28(a)], an attached growth process is used for denitrification using organic material in the primary effluent wastewater for electron donors to reduce NOx-N that is contained in the recycle from the downstream nitrifying attached growth process. The recirculation rate is about 3 to 4 times the influent flowrate and the nitrogen removal performance is similar to that for the MLE process used in activated sludge nitrogen removal (Sec. 8–7). A nitrate-N loading of 1.0 to 1.5 kg/m^3·d and hydraulic application rate of 20 to 30 m/h has been reported for a preanoxic upflow sunken media process (Ninassi et al., 1998). The high recirculation rate increases the energy needs for pumping flow to the attached growth processes and the hydraulic load.

In the second case [see Fig. 9–28(b)] nitrified trickling filter effluent is recycled to the upstream suspended growth preanoxic system (Melhart, 1994). An intermediate clarifier is used to separate the denitrifying mixed liquor and to provide return activated sludge to the anoxic tank. The recycle flow needed to provide nitrate to the preanoxic zone has a significant effect on the clarifier size and pumping requirements to the trickling filter, and thus the overall system economics.

Examples of converting full-scale trickling filter systems to nitrogen removal have been given by Nasr et al. (2000) and Dorias and Baumenn (1994). Recycle from a second stage nitrifying trickling filter was returned to an upstream first-stage preanoxic submerged or covered gas-tight trickling filter. The recirculation flows greatly increased the trickling filter energy requirements and high DO concentrations in the trickling filter effluent affected the preanoxic nitrate removal efficiency.

An important advantage of using a preanoxic attached growth denitrification process is that influent BOD is used for nitrate reduction, which eliminates the cost of an exogenous carbon source. Major disadvantages are the effects of the nitrate recycle flow on the design and operating cost and the impact of the higher influent solids concentration on attached growth preanoxic designs.

Process Design Analysis of Postanoxic Attached Growth Denitrification

Important design factors for postanoxic attached growth processes discussed here are (1) hydraulic application rate, (2) nitrate loading rate, (3) exogenous carbon supply, (4) excess solids accumulation and backwash needs, and (5) phosphorus limitations.

Table 9–19

Range of reported process loadings for postanoxic attached growth processes

Type of system	Hydraulic application rate, m/h	NO_3-N loading rate, kg/m^3·d	Minimal EBCT[b], min	References
Downflow sunken media DNF	2.4–4.8	0.3–3.2	25	Falk et al. (2011)
Upflow sunken media DNF	4.0–6.0	0.8–5.0	20	WEF (2011)
Upflow floating media DNF	4.0–6.0	1.5–2.0	20	WEF (2011)
Continuous backwash DNF	2.4–8.0	0.3–2.0	15	deBarbadillo et al. (2005)
AnoxFBBR	15.0–25.0	3.0–5.0	6	U.S. EPA (1993)
AnoxMBBR		0.25–0.5	30[a]	Stinson et al. (2009)

[a] Assumes media specific surface area of 500 m^2/m^3 and 50 percent fill volume.

[b] EBCT = empty bed contact time.

Hydraulic Application and Nitrate Loading Rates. Two key design considerations for attached growth postanoxic denitrification processes are the hydraulic application rate and volumetric nitrate loading rate. The nitrate loading rate to achieve a target effluent NO_3-N concentration is the key factor for sizing the AnoxMBBR and AnoxFBBR processes, whereas both the hydraulic loading rate and volumetric nitrate loading rate must be considered for the denitrification filters when the filters must also produce a low effluent TSS concentration. In the case of Scenario I described above, the hydraulic loading rate required to meet a low effluent TSS concentration is the controlling design parameter because after the upstream nitrogen removal system the feed nitrate-N concentration is low enough so that the nitrate loading at the filtration hydraulic applications rates does not stress the nitrate removal performance.

Hydraulic Loading Rates. A range of hydraulic loading rates and volumetric nitrate loading rates reported for attached growth are summarized in Table 9–19. The minimal empty bed contact time (EBCT), which is the tank volume divided by the influent flowrate, is based on assuming a media depth of 2.0 m for the DNFs and using the higher respective hydraulic application rate. The AnoxMBBR EBCT is based on assuming the higher volumetric nitrate-N loading rate shown, a suspended media specific surface area of 500 m^2/m^3, and a 50 percent fill volume.

Nitrate Loading Rates. A wide range of volumetric nitrate loading rates are reported for the denitrification filters; from 0.3 to 5.0 kg NO_3-N/m^3·d. These values are based on pilot plant and full-scale facility observations and represent varying conditions of influent nitrate-N concentration, carbon dose, temperature, hydraulic application rates, and effluent goals. Performance results of a number of postanoxic denitrification filters were evaluated as a function of the EBCT by deBarbadillo et al. (2005). Based on the data from 14 test sites, it was found that greater than 90 percent nitrate-N removal efficiency could be obtained at EBCTs of 10 min or greater. In addition pilot plant performance data for a continuous flow backwash upflow denitrification filter was evaluated with a plug flow, substrate diffusion half-order reaction kinetics model by Harremöes (1976) and applied by Hultman et al. (1994) as follows:

$$NO_e^{(1/2)} = NO_o^{(1/2)} - (1/2)k_{DN}(EBCT) \qquad (9\text{–}53)$$

Where NO_e = effluent NO_3-N concentration, g/m^3
NO_o = influent NO_3-N concentration, g/m^3
k_{DN} = half-order kinetic coefficient, mg/L·min
EBCT = empty bed contact time, min

Note the nitrate-N load is defined as follows:

$$\mathrm{NL} = \frac{Q(\mathrm{NO}_o)}{V} = \frac{1.44(\mathrm{NO}_o)}{\mathrm{EBCT}} \tag{9–54}$$

where NL = volumetric nitrate-N load, kg NO_3-N/m^3·d

By combining Eq. (9–53) and (9–54), the volumetric nitrate-N load can be related to the influent and effluent NO_3-N concentrations and the kinetic coefficient:

$$\mathrm{NL} = \frac{-0.5k_{\mathrm{DN}}\,(1.44\mathrm{NO}_o)}{\mathrm{NO}_e^{(1/2)} - \mathrm{NO}_o^{(1/2)}} \tag{9–55}$$

A value of 0.36 mg/L·min was obtained by deBarbadillo et al. (2005) from the pilot test results when operating at a higher loading of 1.6 kg NO_3-N/m^3·d to stress the system performance.

The required nitrate-N volumetric loading rate as a function of effluent nitrate-N concentration for influent nitrate-N concentrations from 10 to 30 mg/L was calculated using Eq. (9–55) and k_{DN} = 0.36 mg/L·min. The results are shown on Fig. 9–29. An effluent concentration of 1.0 mg/L can be met at volumetric nitrate-N loadings of 1.2 to 1.7 kg NO_3-N/m^3·d, which is within the range of loadings given in Table 9–19. The EBCT calculated for the same conditions are shown on Fig. 9–30. The calculated EBCT of 12 min for an effluent nitrate-N concentration of 1.0 mg/L generally agrees with the observations noted above by deBarbadillo et al. (2005) that 90 percent nitrate removal can be achieved at EBCTs of 10 min or more. For a 2-m denitrification filter bed depth and nominal hydraulic application rate of 4 m/h, the EBCT is 30 min. Based on these results, it was found that the denitrification filter hydraulic loading design needed to meet a low effluent TSS filtration goal will result in sufficient contact time for postanoxic nitrate removal needs. In the above analysis it was assumed that the carbon dose was sufficient to drive the nitrate-N reduction reaction.

Exogenous Carbon Supply. A carbon source must be added to the postanoxic denitrification process in proportion to the rate of nitrate, nitrite, and oxygen addition in the influent feed. Methanol has been the most common carbon source used in postanoxic

Figure 9–29

Predicted denitrification filter nitrate volumetric loading (kg NO_3-N/m^3·d) versus effluent nitrate-N concentration for influent NO_3-N concentrations from 10 to 30 mg/L (based on Harremöes (1976) substrate diffusion half-order kinetics model).

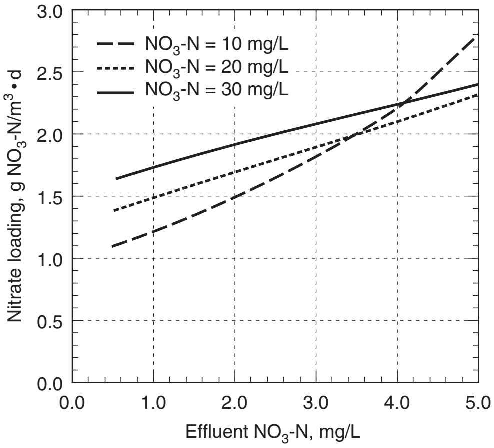

Figure 9–30

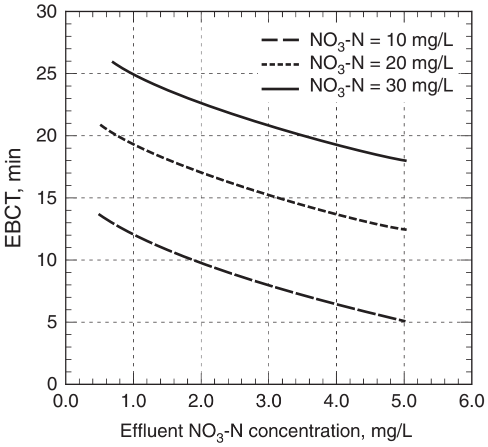
Calculated necessary denitrification filter empty bed contact time (EBCT) versus effluent nitrate-N concentration for influent NO_3-N concentrations from 10 to 30 mg/L (based on Harremöes (1976) substrate diffusion half-order kinetics model).



attached growth denitrification processes, in view of its lower cost per unit of nitrate removed and lower solids production. A typical methanol to NO_3-N dose ratio that accounts for some influent DO is in the range of 3.0 to 3.5 kg methanol/kg NO_3-N removed. However, issues with methanol handling and the possible need for intermittent nitrate removal has spurred interest in other carbon sources, such as ethanol and glycerol or commercial products with glycerol. The impact of other carbon sources on dose requirements and biomass solids production has been addressed in Sec. 8–7. The use of ethanol or glycerol increases the carbon dose ratio and sludge production by approximately 22 and 30 percent, respectively, compared to that for methanol. A higher sludge production rate can increase backwashing needs and backwash energy for the removal of excess solids.

Efforts should be made to optimize the upstream nitrogen removal performance to minimize the carbon dose and cost for a postanoxic denitrification process. Issues to address for an upstream MLE process include the internal recycle ratio, management of recycle flows from digester biosolids dewatering, and DO addition to the preanoxic zone from the internal nitrate recycle flow and influent flow.

Excess Solids Control. During operation of a denitrification filter, headloss gradually increases because of solids accumulation (filtration), biomass growth, and accumulation of nitrogen gas due to denitrification. The nitrogen gas accumulation is more pronounced in downflow filters. The downflow filter is "bumped" periodically by an upflow hydraulic surge. A water-only flush is used at a rate of 12 m/h for about 3 to 5 min for a "bump" to release the accumulated nitrogen gas. The bump frequency may vary from once every 2 to 4 h. No special backwash "bumping" is provided for nitrogen gas release for the upflow and continuous backwash filters.

Upflow and downflow denitrification filters must be taken off line for an air and water backwash about every 24 to 48 h, depending on the solids accumulation and headloss. An advantage of the continuous backwash filter is that it does not have to be taken off line. The solids storage capacity is estimated to be about 4.0 kg TSS/m^3 before an unacceptable headloss occurs. Most of the solids accumulated are from the biomass growth from the external carbon source. For example, at a nitrate-N loading of 1.5 kg NO_3-N/m^3·d, the biomass solids accumulation in 24 h would be about 2.8 kg TSS/m^3; assuming a methanol dose of 3.5 kg/kg NO_3-N, and biomass yield of 0.30 g VSS/g CH_3OH COD. Assuming the influent TSS concentration is the same as the influent NO_3-N concentration at 10 mg/L and the effluent TSS is 5 mg/L, the additional solids accumulation from removal of influent solids is an additional 0.75 kg TSS/m^3 for a total of 3.5 kg TSS/m^3. The backwash typically

Table 9–20

Backwash requirements for postanoxic attached growth denitrification filters[a]

Type of system	Backwash rate, m/h	Air scour rate, m/h	Approx. backwash water duration, min	Approx. backwash water, % of feed flow[b]
Downflow sunken media	18	90	15	4.7
Upflow sunken media	20	97	10	3.5
Upflow floating media	55	12	12	11.4
Continuous backwash	0.4	air lift	continuous	10

[a] Adapted from WERF (2010).

[b] Based on average hydraulic application rate of 4 m/h.

consists of an air scour followed by an air and water backwash. Typical backwash rates and fraction of product water use for backwashing are summarized in Table 9–20.

Phosphorus Limitations. Combined biological denitrification and chemical phosphorus removal has been used by several municipal WWTPs to meet effluent TN and TP concentrations of less than 3.0 and 0.10 mg/L, respectively. In such cases, upstream processes may be used before a postanoxic attached growth denitrification process to meet low effluent TN and TSS concentrations in addition to a low effluent TP concentration. The upstream process may be enhanced biological phosphorus removal, chemical treatment, or a combination of processes. However, it should be noted that the postanoxic denitrification process can become phosphorus-limited if the influent phosphorus concentration is too low to support the biogrowth needed for biological denitrification. During pilot testing of continuous backwash denitrification filters at the Hagerstown, MD, WWTP, the effluent NOx-N concentration remaining in the effluent stream increased when the influent PO_4-P/NOx-N ratio dropped below 0.02 g P/g N (deBarbadillo et al., 2006). Other investigators reported acceptable influent P/NOx-N ratios: 0.005 by (Scherrenberg et al., 2008); 0.01 to 0.02 (Husband and Becker, 2007); and 0.023 and 0.026 (Peric et al., 2009). Using a mechanistic modeling approach and data from various studies, Boltz et al. (2012) determined that biological denitrification performance declines greatly due to phosphorus limitation at an influent ratio of 0.009 g P/g NOx-N. One operating alternative used to overcome phosphorus limitations on postanoxic denitrification has been to dose phosphoric acid to the postanoxic process influent (WERF, 2010).

Operational Considerations for Postanoxic Attached Growth Denitrification

Key operational considerations for optimal performance of a postanoxic attached growth denitrification process are (1) backwash frequency and biofilm control, (2) control of the carbon dose, and (3) preventing phosphorus limitation.

Biofilm Control. Backwashing postanoxic denitrification filters, solids harvesting in an AnoxFBBR and scouring the media by mixing in an AnoxMBBR is a balancing act between minimizing costs associated with backwash/scour and maintaining the appropriate amount of biomass. Too frequent backwashing uses more energy and reduces the available biomass, which could have an effect on treatment performance. On the other hand, infrequent backwash/scour may result in thick biofilms that are diffusion-limited with poor removal performance and/or cause low hydraulic efficiency in the denitrification filters.

Carbon Dose Control. Overdosing of the carbon can lead to odor production from biological sulfate reduction and increase the effluent BOD concentration. Too low of a dose will result in higher effluent NOx-N concentrations and possibly an increase in effluent NO_2-N concentration. The rate of carbon addition can vary diurnally due to changes in the influent TKN concentration with time and to seasonal or wet weather loading variations. Manual operation or flow-paced chemical addition relies on an operator's experience with changes in the facility and finding the appropriate dose ratios. Feed forward control with online or manual measurements of nitrate-N or NOx-N in the upstream tank or feed stream to the postanoxic process provides a more effective approach to optimize performance and to reduce chemical wastage.

Preventing Phosphorus Limitation. As discussed above an insufficient influent phosphorus ratio to the postanoxic attached growth process can result in lowered performance. Modifications in the upstream treatment process and controls or adding phosphorus to the postanoxic process are options for assuring sufficient phosphorus for nitrogen removal. Online monitoring of upstream phosphorus concentrations is also used in such cases. The design of a denitrification filter is illustrated in Example 9–9.

EXAMPLE 9–9 **Denitrification Filter Design** Given the following flow and secondary effluent characteristics for feed to a 2 m deep downflow postanoxic denitrification filter, determine the following design parameters to achieve effluent TSS and NO_3-N concentrations of less than 5.0 and 1.0 mg/L, respectively. Assume a filtration rate of 4 m/h at average flow and a half-order nitrate removal kinetic coefficient of 0.27 mg/L·min at 15°C.

Design parameters to be determined:

1. Filter dimensions
2. Backwash water rate and percent of product water
3. Backwash air rate
4. Backwash water bump rate
5. Methanol requirements, kg/d
6. Daily solids production, kg/d
7. Backwash water TSS concentration, g/m^3

Wastewater characteristics:

Item	Unit	Value
Flowrate	m^3/d	8000
TSS	g/m^3	20
NO_3-N	g/m^3	25
Temperature	°C	15

Note: $g/m^3 = mg/L$.

Operational parameters and assumptions

1. Filter backwash frequency = 1/d
2. Water backwash flowrate/time = 18 $m^3/m^2 \cdot h$ for 15 min (see Table 9–20)
3. Air backwash rate = 90 $m^3/m^2 \cdot h$ (see Table 9–20)
4. Bump water flush rate/frequency = 12 m/h at once/3h
5. One filter required for standby

6. Net yield with methanol = 0.25 g VSS/g CODr
7. VSS/TSS = 0.85

Solution

1. Determine the dimensions of the denitrification filter.
   a. Determine filter size based on nitrogen loading (NL). Apply Eq. (9–55):

$$NL = \frac{-0.5k_{DN}(1.44\ NO_o)}{NO_e^{1/2} - NO_o^{1/2}}$$

$$NL = \frac{-0.5(0.27\ g/m^3{\cdot}min)(1.44)(25.0\ g/m^3)}{(1.0\ g/m^3)^{(1/2)} - (25.0\ g/m^3)^{(1/2)}} = 1.21\ kg/m^3{\cdot}d$$

$$NO_3\text{-N applied} = [(25.0)\ g/m^3](8000\ m^3/d)(1\ kg/10^3\ g)$$
$$= 200\ kg/d$$

$$\text{Volume} = \frac{(200\ kg/d)}{(1.21\ kg/m^3{\cdot}d)} = 165.3\ m^3$$

$$\text{Area} = V/D = 165.3\ m^3/2.0\ m$$
$$= 82.7\ m^2$$

   b. Determine filter size based on filtration hydraulic loading bases.

Hydraulic application rate = 4 m/h

Filtration rate = 8000 m^3/d = 333.33 m^3/h

Filter area = (333.33 m^3/h)/(4 m/h)

= 83.3 m^2

Thus, the filter size is controlled by the hydraulic application rate.

Assume 5 filters installed with 1 filter used as standby. Use of the filters should be rotated so that active biofilm is maintained in all of the filters.

$$\text{Area/filter} = \frac{83.3\ m^2}{4} = 20.8\ m^2$$

Use a square configuration.

Filter bed dimensions = 4.6 × 4.6 × 2.0 m

(check supplier standard modules)

2. Determine air and water backwash flowrates and percent of product water used as backwash water.
   a. Determine backwash air flowrate at an air backwash application rate of 90 $m^3/m^2{\cdot}h$.

Air flowrate = (90 $m^3/m^2{\cdot}h$)(20.8 m^2/filter) = 1870 m^3/h

   b. Determine backwash water flowrate at a water backwash application rate of 18 $m^3/m^2{\cdot}h$.

Water flowrate = (18 $m^3/m^2{\cdot}h$)(20.8 m^2/filter) = 374.4 m^3/h

= 6.24 m^3/min

   c. Determine volume of backwash water at 1 backwash/24 h for each filter with a duration of 15 min

Backwash water volume = (6.24 m^3/min)(15 min/filter)(4 filters)

= 374.4 m^3d

d. Determine percent of product water used as backwash water.

$(374.4\ \text{m}^3/\text{d})(8000\ \text{m}^3/\text{d}) = 0.0468$

$= 4.68\%$

3. Determine volume of water used to flush (bump) filters at 1 bump/3 h with a duration of 4 min/bump and a flowrate of 12 m/h.

Total bump water volume

$= (83.2\ \text{m}^2)(12\ \text{m/h})(3\ \text{min/bump})(1\ \text{bump}/3\ \text{h}\cdot\text{filter})(24\ \text{h/d})(\text{h}/60\ \text{min})$

$= 399.4\ \text{m}^3/\text{d}$

Percent of product water used for nitrogen release bumping:

$= (399.4\ \text{m}^3/\text{d})/(8000\ \text{m}^3/\text{d}) = 0.0499$

$= 5.0\%$

4. Determine the total product water used as percent of influent treated.

Percent backwash plus bump water $= 4.68 + 5.0 = 9.7\%$

Actual filtration rate required including product water used for backwashing and bumping:

$(4\ \text{m/h})(1.097) = 4.39\ \text{m/h} = 105\ \text{m}^3/\text{m}^2\cdot\text{d}$

Note: An iterative calculation can be performed to develop an actual filtration rate approaching 4 m/h by using a lower rate in step 1b.

5. Methanol (CH_3OH) requirements.

Nitrate removal $= (25.0\ \text{g/m}^3 - 1.0\ \text{g/m}^3)(8000\ \text{m}^3/\text{d}) = 192\ \text{kg/d}$

Calculate methanol dose from Eq. (8–69)

$$C_{R,\text{NO}_3} = \frac{2.86}{1 - 1.42(Y_\text{H})} = \frac{2.86}{1 - 1.42(0.25\ \text{g VSS/g COD})}$$

$$= 4.43\ \text{g methanol COD/g NO}_3\text{-N}$$

add 10% for DO and NO_2-N in influent

Methanol dose $= (1.1)(4.43) = 4.88$ g methanol COD/g NO_3-N

$$\text{As methanol} = \frac{(4.88\ \text{g methanol COD/g NO}_3\text{-N})}{(1.5\ \text{g COD/g methanol})} = 3.25\ \text{g methanol/g NO}_3\text{-N}$$

Methanol $= (3.25\ \text{kg/kg})(192\ \text{kg/d}) = 624.0\ \text{kg/d}$

6. Determine the solids production.

Solids = filtered solids + biomass production

Use effluent TSS = 5 mg/L (g/m^3)(given value)

Filter solids $= [(20 - 5)\ \text{g/m}^3](8000\ \text{m}^3/\text{d})(1\ \text{kg}/10^3\ \text{g})$

$= 120\ \text{kg/d}$

Biomass production: based on 0.25 g VSS/g methanol COD (given)

Biomass produced =

$$P_{X,\text{bio}} = \frac{\left(\dfrac{0.25\text{ g VSS}}{\text{g COD}}\right)\left(\dfrac{1.5\text{ g COD}}{\text{g CH}_3\text{OH}}\right)(624\text{ kg CH}_3\text{OH/d})}{(0.85\text{ g VSS/g TSS})} = 275.3\text{ kg TSS/d}$$

Total solids = 120 kg TSS/d + 275.3 kg TSS/d = 395.3 kg TSS/d

Volume per filter = $(20.8\text{ m}^2)(2\text{ m}) = 41.6\text{ m}^3$

$$\text{Solids Storage/24 h} = \left(\frac{395.3\text{ kg}}{\text{d}}\right)\left(\frac{1}{4\text{ filters}}\right)\left[\frac{\text{filter}}{(41.6\text{ m}^3\text{/d})}\right] = 2.4\text{ kg TSS/m}^3$$

Comment Because the solids storage value is well below 4.0 kg TSS/m^3, backwashing may be required only once every 1.5 d. However, to maintain the health of the filter, backwashing once per day is recommended (see Sec. 11–4 in Chap. 11).

9–8 EMERGING BIOFILM PROCESSES

There are several emerging biofilm reactors that are briefly described below, including (1) membrane biofilm reactors, (2) biofilm airlift reactors, and (3) aerobic granule process.

Membrane Biofilm Reactors

Membrane biofilm reactors (MBfR) refers to processes that use membrane to deliver gaseous substrate such as oxygen and hydrogen and as biofilm growth support (Timberlake et al., 1988, Brindle and Stephenson, 1996; Lee and Rittmann, 2000; Syron and Casey, 2008). Microporous, hydrophobic materials and hollow-fiber membranes are typically used in MBfRs because of the high specific surface areas (up to 5000 m^2/m^3). The hollow-fibers are collected into bundles with one end as gas-supplying manifold and the other end sealed. Pressurized gas (i.e. hydrogen or oxygen) diffuses through the dry membrane pores and into the biofilm on the other side of the membrane. This mode of operation leads to counter-diffusion, where one substrate (electron donor or acceptor) diffuses into the biofilm from the dry membrane and the other one diffuses through the bulk liquid into the biofilm.

The advantage of an MBfR is the greater fluxes possible by supplying the gaseous electron donor or electron acceptor directly to the biofilm without traversing a liquid layer. However, this advantage can be lost due to biofilm diffusion from the back to the liquid side where substrate is most consumed if the biofilm is too thick. Therefore, control of biofilm accumulation is important in MBfRs. Hydrogen-based MBfRs have been investigated for water treatment such as denitrification and, for remediation processes that use hydrogen as electron donor for reduction such as for perchlorate, trichloroethane, selenite, arsenate etc. (Ergas and Reuss, 2001; Chung et al., 2006a; Chung et al., 2006b; Nerenberg and Rittmann 2004; Chung and Rittmann, 2007).

Oxygen-based MBfR has been demonstrated for concurrent carbon removal, nitrification and denitrification (Timberlake et al., 1988; Suzuki et al., 1993; Brindle et al., 1998; Schramm et al., 2000). The oxygen concentration gradient, which is higher near the membrane and lower closer to the bulk liquid, leads to nitrification in the inner portion of the biofilm and BOD removal and denitrification activities in the outer portion of the biofilm. A study by Downing and Nerenberg (2007) showed the possibility of using MBfR in a hybrid system that incorporates hollow-fibers into the activated sludge process. MBfR applications have been evaluated in lab and pilot testing and challenges remain for full-scale configurations and process control.

Biofilm Airlift Reactors

Biofilm airlift reactors were developed in the Netherlands in the late 1980s and contain a center column air lift zone and small-sized sand media which supports a very high effective volumetric biomass concentration. The concept can be used for both aerobic and anaerobic processes. For aerobic processes, the airlift in the center column provides oxygen and recirculation of the biofilm and media. It has been used for aerobic wastewater treatment for BOD removal, nitrification and denitrification (Heijnen et al., 1993; Frijters et al., 2000; Nicolella et al., 2000). The commercial CIRCOX process is based on this type of reactor. The CIRCOX process has a high loading capacity (4 to 10 kg COD/m^3·d), short HRTs (0.5 to 4 h), high biomass settling velocities (50 m/h), and high biomass concentrations (15 to 30 g/L) (Frijters et al., 2000; Nicolella et al., 2000).

Aerobic Granules Reactor

Aerobic reactors with dense granular biomass particles can be considered with attached growth processes because the granular biomass behaves as a biofilm with substrate removal being diffusion limited. A number of aerobic granular biomass reactor operations have been reported (Liu and Tay 2002; Morgenroth et al., 1997; Beun et al., 2002; de Kreuk and van Loosdrecht, 2006, Adav et al., 2008). The advantage of aerobic granular biomass reactors is a high treatment capacity with a much smaller footprint than an activated sludge system. Post treatment is normally required to obtain low effluent suspended solids. A combination of an aerobic granular biomass process with membrane separation has been proposed to achieve high effluent quality (Wang et al., 2008). Aerobic granular processes have been investigated for simultaneous removal of organics, nitrogen and phosphorus in wastewater treatment as shown in Table 8–27, and for industrial applications (de Kreuk et al., 2005; Yilmaz et al., 2008; Schwarzenbeck et al., 2005).

PROBLEMS AND DISCUSSION TOPICS

9–1 A 20-m diameter plastic packing trickling filter, containing cross-flow plastic packing at a 6.1-m depth with a specific surface area of 100 m^2/m^3, receives domestic wastewater after primary treatment. The average flowrate is 390, 440, or 490 m^3/h (value to be selected by instructor) and the BOD concentration is 150 mg/L. Determine and compare the effluent BOD concentration and percent BOD removal at 20°C and 15°C. Assume an n value of 0.5 and recirculation ratio equal to zero.

9–2 Two 15-m diameter trickling filters containing conventional cross-flow plastic packing at a 6-m depth are used to treat a pharmaceutical wastewater at an average flowrate of 2120 m^3/d. The influent BOD concentration is 600, 900, or 1200 mg/L (value to be selected by instructor) and the temperature is 20°C. Each tower has a 2-arm distributor. Determine: (a) the operating dose and flushing dose from Table 9–3 and distributor speeds in revolutions/min for each case; and (b) the recirculation ratio and total pumping rate in m^3/h to each filter.

9–3 For Example 9–3, using the same design criteria given for the trickling towers, influent BOD concentration and temperature, and effluent BOD concentration, determine the following using a plastic packing depth of 4.0, 5.0, or 7.0 m (value to be selected by the instructor):

a. Volume of plastic packing, m^3

b. Hydraulic loading rate in L/m^2·s

c. Volumetric BOD loading in kg/m^3·d

Compare the results to the values determined for the same design parameters in the example.

9–4 The following data were obtained for a pilot plant study involving the treatment of a combined domestic-industrial wastewater with a tower trickling filter filled with plastic packing at a depth of 6.1 m. The diameter of the pilot plant tower was 1 m and the specific surface area of the plastic packing was 90 m^2/m^3. The wastewater temperature at the time of the test was 12, 18, or 24°C (value to be determined by the instructor). During the testing the influent BOD concentration was 350 mg/L. The following table summarizes the average BOD removal efficiency at different flowrates. Using these data, determine the value of the wastewater treatability coefficient, *k* (assume the value of *n* is 0.50), at the test temperature and at 20°C.

Pilot-plant test results:

Flowrate, m^3/d	BOD removal efficiency, %
6	88
12	82
18	67
24	63
48	54

9–5 The following design information is given for a domestic wastewater (wastewater 1, 2, or 3 to be selected by instructor):

		Wastewater		
Design information	Unit	1	2	3
Flowrate	m^3/d	10,000	10,000	10,000
BOD	mg/L	270	300	220
TSS	mg/L	240	280	210
Minimum temp.	°C	15	12	15

Using the above information, and assuming 30 percent BOD removal in primary clarification, a packing depth of 6.1 m, a packing specific surface area of 100 m^2/m^3, and a value for *n* of 0.50, determine the following design parameters for a trickling filter treatment system.

a. Primary and secondary clarifier diameters, m

b. Trickling filter tower diameter, m

c. Packing volume, m^3

d. Recirculation ratio, if required

e. Total pumping rate, m^3/h

f. Flushing and normal dose rates, mm/pass

9–6 Determine the diameters and packing volume of two 4.0-m deep plastic-media filters, operated in series, for a domestic wastewater treatment application with the following characteristics and requirements. Assume a plastic media vertical-flow packing from Table 9–2 with a specific surface area of 102 m^2/m^3.

Parameter	Unit	Value
Flowrate	m^3/d	5000
Influent BOD	mg/L	
Wastewater 1		220
Wastewater 2		200
Wastewater 3		180

(*continued*)

(*Continued*)

Parameter	Unit	Value
Temperature	°C	14
Primary clarifier BOD removal efficiency	%	35
Trickling filter average effluent BOD	mg/L	20

Note: Wastewater 1, 2 or 3 to be selected by instructor.

9–7 An 18-m diameter trickling filter tower containing conventional plastic packing at a 6.1-m depth and a packing specific surface area of 100 m^2/m^3 treats a primary effluent flowrate of 7600 m^3/d. The primary effluent BOD is 100, 120, or 150 mg/L (value to be selected by instructor) and the wastewater temperature is 18°C. The air temperature varies from 2 to 23°C. The BOD loading peaking factor is 1.5. Assume a factor of 1.5 with Eq. (9–10) to account for the inlet and outlet pressure losses for the tower. Determine the following:

a. The required oxygen supply rate, kg/h

b. The required air flowrate at the warmest temperature, m^3/min

c. The airflow pressure drop across the packing, Pa

9–8 Two 20-m diameter plastic tower trickling filters containing 6.1 m of conventional plastic media (100 m^2 area/m^3 volume) receive a primary clarifier effluent at an average flowrate of 11,200 m^3/d. The TKN concentration is 24 mg/L and the BOD concentration is 150, 130, or 120 mg/L (value to be selected by the instructor). The temperature is 18°C. Evaluate the trickling filter BOD loading and determine the nitrogen removal efficiency due to nitrification.

9–9 Compare the design of a trickling filter alternative to the activated sludge designs provided in Example 8–3 for (a) BOD removal, (b) combined BOD removal and nitrification, and/or (c) BOD removal followed by tertiary nitrification (to be selected by the instructor). Use the same wastewater characteristics and temperature. Prepare a summary table comparing (1) the total volume of the biological process units, (2) the area used for the biological process units, (3) the secondary clarifier area, and (4) the monthly energy requirement in kW for the secondary treatment processes. Assume the following:

a. Trickling filter packing depth equals 6.1 m

b. Trickling filter packing specific surface area equals 100 m^2/m^3 for BOD removal and combined BOD removal/nitrification and equals 138 m^2/m^3 for tertiary nitrification

c. Trickling filter effluent BOD equals 25 mg/L

d. Trickling filter effluent NH_4-N equals 1.0 mg/L

e. The trickling filter recirculation ratio equals 0.50

f. The amount of the influent TKN used for heterotrophic bacteria growth in the trickling filter is 8.0 mg/L

g. The aeration tank depth is 5 m

h. The blower energy requirement for activated sludge aeration, considering the piping headlosses and diffuser submergence depth is 1.80 kW per m^3/min air flowrate.

i. The tricking filter feed flow pumping energy requirement is 1.58 kW per 1000 m^3/d.

9–10 Prepare a table to compare the advantages and limitations of a tower trickling filter with plastic packing versus activated sludge treatment in terms of space, ease of process operation, sludge settling characteristics, energy requirements, maintenance, treatment flexibility, nitrification reliability, potential odors, and potential for future nitrogen or phosphorus removal.

9–11 A 20-m diameter trickling filter tower containing a 5-m depth of high-density plastic packing (138 m^2 area/m^3 packing volume) is used in a tertiary nitrification application. The influent flowrate is 37,000, 39,000, or 41,000 m^3/d (value to be selected by the instructor) and the NH_4-N concentration is 20 mg/L. Assuming that the nitrification $J_{N,\max}$ value is 1.8 $g/m^2 \cdot d$ from information in Table 9–7 and the K_N value is 1.5 g/m^3, compare the trickling filter effluent NH_4-N concentration (mg/L) with no recycle and with a 100 percent recirculation ratio. Why is no gravity settling tank used for the trickling filter effluent?

9–12 A TF/AS process is used to treat a combined domestic and industrial wastewater after primary clarification, and the primary effluent wastewater characteristics are given below. For the following design parameters, compare the effect of designing the plastic tower trickling filter step for 40 percent versus 80 percent BOD removal:

a. Trickling filter diameter, m, and hydraulic loading rate, $L/m^2 \cdot s$

b. Oxygen required in the activated sludge aeration tank, kg/d

c. The amount of solids wasted per day, kg/d

d. The volume, m^3, and hydraulic retention time, h, of the aeration tank

Use the following assumptions for the trickling filter and activated-sludge designs.

Trickling filter:
Plastic packing treatability coefficient, $k_{20} = 0.18(L/s)^{0.5}/m^2$
Packing depth = 6.1 m
Number of towers = 2

50 percent of theoretical effluent BOD is soluble.
Activated sludge:
SRT = 5.0 d (no nitrification)
MLSS = 3000 mg/L
Biomass yield, Y, = 0.6 g VSS/g BOD removed
Endogenous decay, b = 0.12 g VSS/g VSS·d
UBOD/BOD = 1.6

Wastewater characteristics:

Item	Unit	Value
Flowrate	m^3/d	8000
BOD	mg/L	
Wastewater 1		400
Wastewater 2		500
Wastewater 3		600
sBOD	mg/L	60% of BOD
TSS	mg/L	65
VSS	mg/L	55
nbVSS	mg/L	22
Temperature	°C	12

Note: Wastewater 1, 2 or 3 to be selected by instructor.

Which design is preferred? State your reasons.

9–13 An existing activated-sludge facility with primary treatment is operated at an SRT of 18 d and minimal temperature of 12°C so that complete nitrification is maintained. The system is operated with an MLSS concentration of 2200 mg/L, and the SVI is generally in the range of 180 to 200 mL/g. At these conditions, the treatment flowrate is 8000 m^3/d. The city engineer requests that your firm design a plastic tower pretreatment system for about 60 percent BOD removal before the activated sludge unit. You are to list for the city engineer the potential impacts of converting the existing activated sludge process to a TF/AS process, including flow capacity, solids production, oxygen requirements, energy demand, sludge settling characteristics, and effluent NH_4-N and BOD concentrations. Provide an explanation of the basis of your opinion on the potential impacts.

9–14 An industrial waste is to be treated with a tower trickling filter followed by an activated-sludge process (TF/AS process). The wastewater flowrate is 20,000 m^3/d and is equalized. Primary settling is not used because the wastewater contains mainly soluble organic substances. The tower trickling filter contains conventional plastic packing with a specific surface area of 100 m^2/m^3 and the operational SRT for the activated sludge process is to be 5 d during the critical summer period and a maximum of 15 d during the winter. The lowest average sustained winter temperature (at least two weeks) is 5°C and the highest average sustained summer temperature is 26°C. The characteristics of the industrial waste, data derived from pilot plant studies, and related design data are presented below. Using these data, size the units and determine the following:

a. Concentration of mixed liquor suspended solids to be maintained during summer and winter operation, mg/L

b. Recycle flowrates around the filter and activated-sludge process, m^3/d

c. Quantity of sludge to be disposed daily, kg/d

d. Effluent BOD concentration from the trickling and activated-sludge processes, mg/L

e. Quantity of nutrients that must be added daily, kg/d

Wastewater characteristics:
BOD = 1200, 1500, or 1800 mg/L (value to be selected by instructor)
TSS = 100 mg/L
VSS = 0 mg/L
Total nitrogen as N = 10 mg/L
Total phosphorus as P = 4 mg/L

Trickling filter pilot plant results:
$k_{20^\circ C} = 0.075\ (L/s)0.5/m^2$
Net solids yield = 0.5 g VSS/g BOD removal
Temperature correction value, $\theta = 1.06$

Activated sludge pilot plant results:
Solids synthesis yield, $Y_H = 0.6$ g VSS/g BOD removal
Endogenous decay, $b_H = 0.12$ g VSS/g VSS·d
$k = 6.0$ g BOD/g VSS·d
$K_s = 90$ mg BOD/L
$\theta = 1.035$

Design parameters:
Trickling filter hydraulic application rate = 0.10 m^3/m^2·min

9–15 For the IFAS process analysis in Example 9–7, determine the effect of having a DO concentration of 3.0, 5.0 or 6.0 mg/L (to be selected by the instructor) on the amount of plastic carrier media needed, the V_M/V ratio needed, and the media fill volume fraction needed in the aeration tank with the plastic carrier addition.

9–16 The following biological treatment processes are being considered for a decentralized wastewater treatment plant to treat a domestic wastewater with an average daily flowrate of 1000 m^3/d.

The present requirement is to discharge the treated effluent to a nearby surface water and the effluent BOD, TSS, and NH_4-N concentrations must be less than 25, 25, and 1.0 mg/L, respectively. The plant site available has limited space and it is close to a residential area. Prepare a table that compares the advantages and disadvantages of the following three processes of interest: (a) activated sludge with conventional secondary clarification, (b) membrane bioreactor, and (c) moving bed bioreactor. Include among the criteria considerations for space, operations, and energy requirements. Which process would you recommend and why?

9–17 Use the same wastewater characteristics and effluent goals as used for Example 9–8 and design an MBBR system with only a single stage for BOD removal followed by only a single stage for nitrification. Use a DO concentration of 2.0 mg/L in the BOD removal zone and 4.0 mg/L in the nitrification zone. Compare the design to that for Example 9–8 in terms of media volume and tank volume requirements and determine the sludge production rate and oxygen required. Assume a 50 percent carrier media fill fraction. Assume a biofilm biomass effective SRT of 4.0 d for BOD removal and 8.0 d for nitrifying bacteria.

9–18 Evaluate the effect of the media fill fraction and nitrification zone DO concentration on the amount of carrier media required and tank volumes needed for Example 9–8. Using the given data (a) compare the effect of using a DO of 3.0, 5.0, or 6.0 mg/L (to be determined by instructor) for the nitrification zones with the same carrier media fill fraction used in the example problem and (b) use the same DO concentrations as used in the example problem and compare the effect of using a carrier media fill fraction of 65 percent.

9–19 Perform an MBBR design at 18°C using the same influent wastewater conditions and assumptions as given Example 9–8. Provide a table to compare the designs at 12 and 18°C.

9–20 Design an upflow attached growth BAF process for BOD removal only (assume a floating media process) to achieve an effluent BOD concentration of 20 mg/L or less. Use the wastewater characteristics and average flowrate given for Example 9–8 and a soluble BOD concentration of 80 mg/L. Assume an unexpanded media depth of 2 m, and hydraulic application rate of 6.0 m/h. Design the system with 4 operating units and one standby. Provide a design summary table with (a) the reactor volume in m^3 and equivalent hydraulic retention time in h, (b) the dimensions of each BAF reactor assuming square configuration, (c) the oxygen required in kg/d, (d) the air application rate per treatment unit in m^3/min, (d) the sludge production rate in kg TSS/d, (f) the amount of backwash water used daily per unit in m^3/d, and (g) the backwash water suspended solids concentration in mg/L. Use the following assumptions:

BOD loading equals 3.5 kg BOD/m^3·d from Table 9–17

Actual oxygen transfer efficiency equals 6.0 percent from Table 9–18

Fraction of influent VSS destroyed equals 0.25

A backwash water time of 15 min/d and average flush rate of 40 m/h

9–21 A secondary effluent has the following characteristics:

Parameter	Unit	Value
Flowrate	m^3/d	5000
TSS	mg/L	15
NO_3-N	mg/L	30
Temperature	°C	18

Design a downflow denitrification filter with a sand media depth of 1.6 m to reduce the NO_3-N to an effluent concentration of 3.0, 2.0, or 1.0 mg/L (value to be selected by instructor). Assume a hydraulic application rate of 4.0 m/h and determine the following:

a. Denitrification filter media volume, m^3

b. Number of filters and filter dimensions, assuming square tanks with a maximum dimension of 10 m by 10 m

c. Methanol dose in mg/L and kg/d

d. Amount of solids produced, kg/d

The following assumptions apply:
Methanol biomass synthesis yield equals 0.25 g VSS/g CODr.
The half-order nitrate removal kinetic coefficient equals 0.30 mg/L·min.
Effluent TSS concentration equals 5.0 mg/L

9–22 For Example 9–9 assume that a glycerol type feed is used instead of methanol for the external carbon source for the same denitrification filter design produced in the example. Determine the effect of the different carbon source on (a) the effluent NO_3-N concentration, (b) the carbon dose requirement in kg/d as glycerol and as COD, (c) the solids production rate in kg/d, and (d) the solids storage in kg/m^3 between a once per day backwash event. Is once per day backwashing acceptable?

Use the following assumptions:
The glycerol feed results in higher denitrification rates than methanol and thus the half-order nitrate removal kinetic coefficient is estimate at 0.40 mg/L·min.
The synthesis yield is higher at 0.36 g VSS/g CODr.
The COD to glycerol feed mixture ratio is 1.4 g COD/g glycerol feed.

10 Anaerobic Suspended and Attached Growth Biological Treatment Processes

WORKING TERMINOLOGY

Term	Definition
Ammonia toxicity	Free ammonia (NH_3), at high enough concentrations, is considered toxic to acetoclastic methanogenic organisms.
Anaerobic expanded bed process	An anaerobic upflow process in which the medium, usually silica sand, is expanded but not fluidized by the upward liquid velocity.
Anaerobic fluidized bed process	An anaerobic upflow process which operates in a mode similar to the expanded bed, but the medium is fully fluidized by the upward velocity of the fluid.
Anaerobic granular sludge	Dense 0.50 to 4.0 mm particles in anaerobic upflow reactors containing fermentation, hydrogenotrophic, and methanogenic organisms in close proximity.
Anaerobic sequencing batch reactor	An anaerobic suspended growth process with reaction and solids-liquid separation in the same vessel, much like that for aerobic sequencing batch reactors (SBR).
Anaerobic sludge blanket processes	Influent wastewater is distributed at the bottom of an anaerobic reactor and travels in an upflow mode through a sludge blanket zone that typically contains dense granular biomass particles.
Anaerobic suspended growth processes	A mixed anaerobic reactor containing a suspension of fermentation and methanogenic organisms and feed particulate matter.
Anaerobic treatment processes	Any of a number of biological treatment processes carried out in the absence of oxygen.
Attached growth anaerobic process	Anaerobic treatment processes in which the biomass responsible for treatment is attached to some type of medium. The medium may be fixed, expanded or fluidized. Where fixed medium is used, the flow can either be downflow or upflow.
Covered anaerobic lagoon process	Covered liner earthen lagoon typically used for high-strength industrial wastewaters, such as meat processing wastewaters.
Expanded granular sludge blanket process (EGSB)	An anaerobic sludge blanket process with higher upflow velocities than the UASB process.
Hydrogen sulfide (H_2S)	A malodorous gas toxic gas formed under anaerobic conditions. Sulfur containing compounds in wastewater serve as electron acceptors for sulfate-reducing bacteria, which consume organic compounds and produce hydrogen sulfide (H_2S).
Membrane separation anaerobic treatment process	A suspended growth anaerobic process in which a synthetic membrane is used to separate the treated wastewater from the solids to achieve complete effluent suspended solids removal.
Methane (CH_4)	Methane and carbon dioxide along with cell biomass are the principal carbon end products of anaerobic conversion processes.
Organic loading rate (OLR)	The mass rate of organic substrate (COD) addition per unit volume of an anaerobic reactor.
Solids retention time (SRT)	The average period of time in which solids remain in a biological reactor.
Upflow anaerobic sludge blanket (UASB) reactor	The name of the first and most common of the anaerobic sludge blanket processes (see above).

Anaerobic biological reactions involve specialized bacteria and archaea that use a variety of electron acceptors in the absence of molecular oxygen for energy production. They are used in a number of different anaerobic processes in wastewater treatment. These include processes for nitrate/nitrite reduction to nitrogen gases, fermentation processes to produce volatile fatty acids for use in enhanced biological phosphorus removal, anaerobic contacting for acetate and propionate uptake in enhanced biological phosphorus removal, anaerobic oxidation of organic compounds in municipal and industrial wastewaters, anaerobic digestion of waste sludge, and anaerobic digestion of other organic wastes.

Anaerobic wastewater treatment processes include suspended growth, upflow and downflow attached growth, fluidized bed attached growth, upflow sludge blanket, lagoon, suspended growth with membrane separation, and many other proprietary processes. The purpose of this chapter is to describe and present typical design loadings and treatment process capabilities for the principal anaerobic processes, excluding conventional anaerobic digestion processes which are considered in Chap. 13. Before considering the individual anaerobic treatment processes, it will be helpful to consider the rational for the use of anaerobic treatment processes, the evolution of anaerobic treatment technologies, a brief review of the principal public and commercial processes, and general considerations for the application of anaerobic treatment processes.

10–1 THE RATIONALE FOR ANAEROBIC TREATMENT

The rationale for and interest in the use of anaerobic treatment processes can be explained by considering the advantages and disadvantages of these processes. The principal advantages and disadvantages of anaerobic treatment are listed in Table 10–1 and are discussed below.

Advantages of Anaerobic Treatment Processes

Anaerobic treatment processes have been used as an alternative to aerobic treatment for applications varying from low to extremely high strength wastes. Of the advantages cited in Table 10–1, energy considerations, lower biomass yield, less nutrients required, higher volumetric loadings, and effective pretreatment are examined briefly in the following discussion. The subjects are also considered in Chap. 13, 14, and 17.

Energy Considerations. Anaerobic processes may be net energy producers instead of energy users as is the case for aerobic processes. The potential net energy production that can be achieved with anaerobic treatment depends on the strength of the wastewater, the operating temperature, and whether energy recovery is practiced. An energy balance comparison between anaerobic and aerobic treatment for various wastewater strengths is presented in Sec. 10–4.

Table 10–1

Advantages and disadvantages of anaerobic processes compared to aerobic processes

Advantages	Disadvantages
1. Less energy required	1. Longer startup time to develop necessary biomass inventory
2. Less biological sludge production	2. May require alkalinity addition
3. Less nutrients required	3. May require further treatment with an aerobic treatment process to meet discharge requirements
4. Methane production, a potential energy source	4. Biological nitrogen and phosphorus removal is not possible
5. Smaller reactor volume required	5. Much more sensitive to the negative effect of lower temperatures on reaction rates
6. Elimination of off-gas air pollution	6. May be more susceptible to upsets due to toxic substances or wide feeding changes
7. Able to respond quickly to substrate addition after long periods without feeding	7. Potential for odor production and corrosiveness of gas
8. Effective pretreatment process	
9. Potential for lower carbon footprint	

Lower Biomass Yield. Because the energetics of anaerobic processes result in lower biomass production by a factor of about 6 to 8 times, sludge processing and disposal costs are greatly reduced. Given the major environmental and monetary issues associated with the use or disposal of biomass produced from aerobic processes as discussed in Chap. 14, the fact that less sludge is produced in anaerobic treatment is a significant advantage for anaerobic treatment.

Less Nutrients Required. Because many industrial wastewaters lack sufficient nutrients, the lower cost for nutrient addition due to less biomass production from anaerobic treatment is a clear benefit.

Higher Volumetric Organic Loadings. Anaerobic processes generally have higher volumetric organic loading rates than aerobic processes so that smaller reactor volumes and less space may be required for treatment. Organic loading rates of 3.2 to 32 kg COD/m^3·d may be used for anaerobic processes, compared to 0.5 to 3.2 kg COD/ m^3·d for aerobic processes (Speece, 1996).

Effective Pretreatment Process. Often, anaerobic treatment processes are used in combination with aerobic treatment processes to achieve specific treatment goals. A common application in the wastewater field is the treatment of high strength waste before discharge to a municipal wastewater treatment facility. A typical example is shown on Fig. 10–1. Gas, recovered from the covered anaerobic section of the large anaerobic lagoon is used to produce electricity.

Disadvantages of Anaerobic Treatment Processes

Potential disadvantages also exist for anaerobic processes as reported in Table 10–1. Operational considerations, the need for alkalinity addition, and the need for further treatment are highlighted further in the following discussion.

Operational Considerations. The major concerns with anaerobic processes is their longer start-up time (months for a anaerobic versus days for aerobic processes), their sensitivity to possible toxic compounds, operational stability, the potential for odor production, and corrosiveness of the digester gas. However with proper wastewater characterization and process design these problems can be avoided and/or managed. Operational process knowledge and skill is also needed to maintain anaerobic process stability by

Figure 10–1

Combined anaerobic lagoon/aerobic pond wastewater treatment system: (a) aerial view of large treatment ponds with covered anaerobic pretreatment lagoon, shown in circled area. The white dots are the plumes from large turbine type floating aerators (coordinates 37.9788 S, 144.6417 E). (a) (b)

proper control of the feed, temperature, and pH to maintain a balance between volatile fatty acid production by the acidogens and the capacity of the methanogenic organisms.

Need For Alkalinity Addition. The most significant negative factor that can affect the economics of anaerobic versus aerobic treatment is the possible need to add alkalinity. Alkalinity concentrations of at least 2000 to 3000 mg/L as $CaCO_3$ may be needed in anaerobic processes to maintain an acceptable pH with the characteristic high gas phase CO_2 concentration. If this amount of alkalinity is not in the influent wastewater or cannot be produced by the degradation of proteins and amino acid, a significant cost may be incurred to purchase alkalinity, which can affect the overall economics of the process.

Need For Further Treatment. Anaerobic wastewater treatment processes may have effluent BOD concentrations ranging from 50 to 150 mg/L due to the presence of residual volatile fatty acids and dispersed solids. The process can be followed by an aerobic process for effluent polishing to utilize the benefits of both processes. Series reactors of anaerobic-aerobic processes have been shown feasible for treating municipal wastewaters in both temperate and warmer climates resulting in less energy needs and less sludge production (Lew et al., 2003; Chong et al., 2012). More recently, as discussed subsequently, a number of integrated combined single tank anaerobic-aerobic reactors have also been developed.

Summary Assessment

In general, for municipal wastewaters with lower concentrations of degradable COD, lower temperatures, higher effluent quality needs, and nutrient removal requirements, aerobic processes are favored at present. For industrial wastewaters with much higher degradable COD concentrations and elevated temperatures, anaerobic processes may be more economical. In the future, with further developments in anaerobic treatment processes, it is anticipated that their use will become more widespread in a variety of applications, because of the overwhelming advantages from energy savings and less sludge production.

10–2 DEVELOPMENT OF ANAEROBIC TECHNOLOGIES

The earliest engineered anaerobic technologies were designed for and applied to the treatment of wastewater. At the time of their development in the late 1800s and early 1900s, a community's wastewater was an unhealthy combination of untreated sanitary wastes, animal manure, and various local industrial discharges. The historical development of the early anaerobic technologies, the application of anaerobic treatment for sludges, use of anaerobic treatment for high strength wastes, and some thoughts on the future are considered in this section. The types of anaerobic technologies currently available are considered in the following section.

Historical Developments in Liquefaction

Some of the noteworthy developments in the early stages of anaerobic treatment technology are summarized in Table 10–2. Schematic diagrams of some of the early treatment process developments are illustrated on Fig. 10–2. The early developments in anaerobic treatment were focused on liquefying the solids in wastewater to reduce or eliminate the need for sludge management and make the effluent suitable for subsequent treatment and or reuse for irrigation. The automatic scavenger developed by Mouras in France and patented in the 1880s [see Fig. 10–2(a)] was perhaps the first purposeful attempt to liquefy

Table 10–2

Important milestones in the development of anaerobic technologies[a]

Period	Event
Early developments	
1852	Henry Austin in England designed and built a tank that allows accumulation of solid matter layer on the bottom and scum layer on the top, with liquid draw off between layers. Closely resembles modern septic tanks (Kinnicutt et al., 1913).
1881	Jean-Louis Mouras obtained a French patent for an "automatic scavenger—an automatic and odorless cesspit" to treat wastewater anaerobically, a development that became one of the earliest known domestic wastewater treatment systems [see Fig. 10–1(a)]. Perhaps the first purposeful attempt to liquefy sludge. (Moigno, 1881,1882; Kinnicutt et al., 1913).
1887	The first Dortmund tank was designed and built by Kniebuhler in Germany. The advantage of the Dortmund tank was that sludge could be removed without stopping the flow. Dortmund tanks are still being built today [see Fig. 10–1(b)] (Kinnicutt et al., 1913).
1887	Lawrence Experimental Station established on the bank of the Merrimac River at Lawrence, MA. In 1890, the first report of the work at the Lawrence Station was published, which Winslow considered the "the most important single document in the history of sewage treatment" (Winslow, 1938).
1887	A sand bed, upflow anaerobic filter was constructed by the Lawrence Experimental Station to treat domestic wastewater and was operated for about 14 y (McCarty, 2001).
1891	Scott-Moncrieff of England constructed a two-tiered tank (empty lower level sludge compartment and upper level upflow anaerobic rock filter) to treat domestic wastewater anaerobically followed by an aerobic coke tray trickling filter [see Fig. 10–1(c)] (Kinnicutt et al., 1913). The complete treatment system comprised of the anaerobic rock filter and aerobic treatment unit is perhaps the first hybrid system ever built (McCarty, 2001).
Developments in the treatment of wastewater sludges	
1895	In Exeter, England, Donald Cameron installed a water-tight, covered basin to treat wastewater anaerobically, naming the device a "septic tank" [see Fig. 10–1(d)] (Kinnicutt et al., 1913).
1899	H. W. Clark at the Lawrence Experimental Station, noted that sludge should be fermented in a separate tank. Sludge lagoons had been used up to that time and later (Imhoff, 1938; Winslow, 1938).
1904	Travis developed a two story tank for the liquefaction of sludge [see Fig. 10–1(e)]. In the original design about one sixth of the flow passed through the lower chamber) (Kinnicutt et al., 1913). In one configuration effluent was directed to anaerobic filters [see Fig. 10–1(f)].
1906	Dr. Karl Imhoff of Germany patented a wastewater treatment device (the Imhoff tank) that anaerobically treated sewage while separating solids from the liquid phase prior to discharge [see Fig. 10–1(g)]. The Imhoff tank was based on earlier work by Travis, but avoided the flow through the liquefaction chamber (Imhoff, 1938).
1909–1913	Production of combustible gas by methane fermentation of strawboard was demonstrated at working scale in Netherlands in 1909. The gas was utilized for power generation. Gas utilization occurred at treatment plants for a diary and slaughterhouse in 1912, and at a wastewater treatment plant in 1914. Both fixed and floating gasholders were used (Kessener, 1938).
1914	Early experiments were conducted on the collection and heating of gas at Emschergenossenschaft in Germany (Imhoff, 1938).
1915	Experiments in heating digesters were done to increase gas production in the Netherlands (Kessener, 1938).
1927	The Ruhrverband, a German water management association, constructed a separate heated digestion tank at Essen—Rellinghausen to anaerobically digest treatment plant sludge and utilize the generated biogas for power and heating (Imhoff, 1938).
1929	A long rectangular digester with paddles on a horizontal shaft for seeding, stirring, and scum destruction was built in the Netherlands (Kessener, 1938).

(*continued*)

Table 10–2 (*Continued*)

Period	Event
1930 and 1932	Buswell of the Illinois State Water Survey started a series of reports on the fundamentals of anaerobic digestion of solids (Buswell and Neave, 1930; Buswell and Boruff, 1932).
1950	Stander of South Africa demonstrated the full-scale process benefits obtained by separating anaerobic solids externally and returning them to the digester tank (Stander, 1950; Standar and Snyders, 1950).
Early 1950s	Morgan and Torpey both demonstrated through their research the increased process performance achievable by adding mixing to an anaerobic biosolids digester (Morgan, 1954; Torpey, 1954).
Developments in the treatment of high strength wastes	
1955	Schroepfer and others were involved in the first full-scale application of the anaerobic contact process at a meat packing plant in Minnesota (Schroepfer et al., 1955).
1969	Young and McCarty developed the anaerobic filter process to make attached growth (fixed-film) anaerobic biomass available for high strength wastewater treatment (Young and McCarty, 1969; Young, 1991).
1978	Grethlein experimented with the anaerobic treatment of wastewater using a septic tank and an external cross-flow membrane (Grethlein, 1978).
Late 1970s, early 1980	Lettinga developed the upflow anaerobic sludge (UASB) process [see Fig. 10–1(h)] using waste from the sugar beet industry (Lettinga et al., 1980). His work on anaerobic processes has been instrumental in the development of many commercial anaerobic technologies, especially for the treatment of high strength wastes (see Table 10–3).
1980	Switzenbaum and Jewell developed the anaerobic fluidized bed process, particularly useful in the treatment of high strength wastewater (Switzenbaum and Jewell, 1980).

[a] Adapted in part from Totzke (2012), McCarty (2001), Metcalf & Eddy (1915).

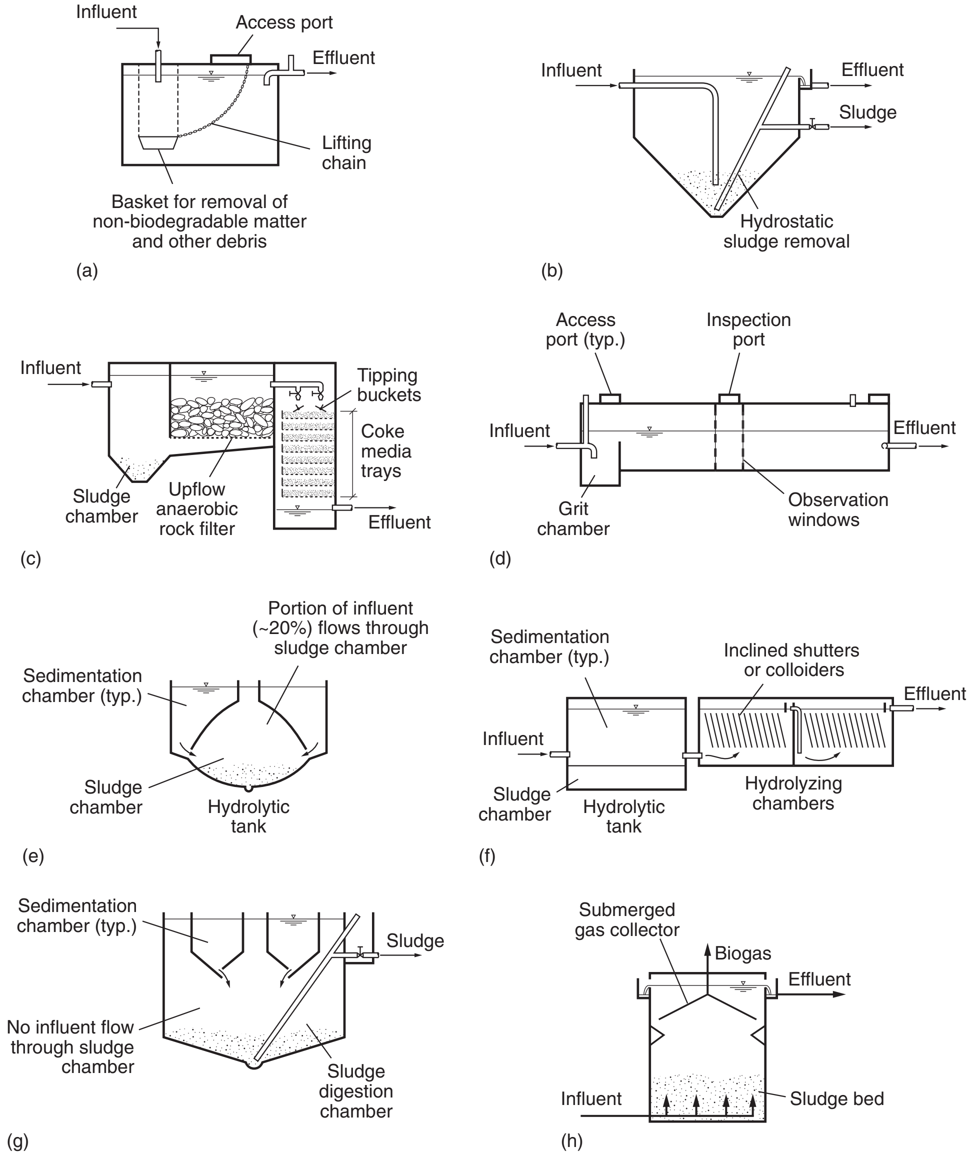
sludge. In the Dortmund tank [see Fig. 10–2(b)], sludge could liquefy and residual matter could be removed without stopping the process. In the Scott Moncrieff tank and filter [see Fig. 10–2(c)], the first tank was known as the liquefying tank. Referring to Fig. 10–2(c) wastewater entered the first compartment, which served as both a grease trap and sedimentation tank, and from there flowed into the space below the anaerobic rock filter. The wastewater then flowed up through the anaerobic rock filter. Bacteria attached to the rocks brought about the liquefaction of the colloidal material in the wastewater passing through the bed. Wastewater from above the stone bed then flowed and was distributed with tilting buckets over the uppermost series of nine perforated trays contain coke. The reactor was defined as anaerobic and the coke tray filter as aerobic. The time for the wastewater to pass through the nine trays was about 10 min.

Treatment of Wastewater Sludges

The first tank to be identified as a *septic tank* was built by Donald Cameron in England in 1895 [see Fig. 10–2(d)]. The next significant development in anaerobic technology was the Travis hydrolytic tank [see Fig. 10–2(e)] developed by W. O. Travis. As early as 1899, W. H. Clark, a chemist at the Lawrence laboratory, had suggested that sludge should be fermented in a separate tank. Travis partially implemented Clark's idea in the hydrolytic tank with the exception that in the original design a portion of the influent wastewater flowed through the liquefaction chamber. The Travis hydrolytic tank was followed by a series of hydrolyzing chambers containing an early form of inclined settlers to bring about additional treatment [see Fig. 10–2(f)]. It is interesting to note that the Imhoff tank, shown on Fig. 10–2(g), was basically an improvement of the Travis hydrolytic tank. K. Imhoff, who knew of Clark's idea, also recognized that the effluent quality was deteriorated by allowing a portion of the flow to pass through the liquefying chamber of the hydrolytic tank.

Figure 10–2

Evolution of anaerobic technology for wastewater treatment in process schematics: (a) Mouras automatic scavenger (1881), (b) Dortmund tank (1887), (c) Scott-Moncrieff two-tiered tank (1891), (d) Cameron septic tank (1895, first use of the name septic tank), (e) Travis two story hydrolytic tank (1904), (f) Travis two story hydrolytic tank with hydrolyzing chambers (1904), (g) Imhoff tank (1906), and (h) upflow anaerobic sludge blanket reactor (1980).



Imhoff tanks are still in common use at the present time. To increase gas production, experimental work on the collection, combustion, and utilization of digester gas was conducted in both Germany and the Netherlands in the early 1900s. The first heated digester constructed in Germany in 1927 evolved from early experimental work.

Treatment of High Strength Wastes

Following the stock market crash of the 1920s and the depression of the 1930s the rate of development in the anaerobic treatment of wastes slowed. Interest in wastewater treatment increased following the Second World War and considerable work was carried out in the 1950s by Stander (1950), Morgan (1954), and Torpey (1954). Concomitant with the work of Stander, Morgan, Torpey, and others in the 1950s, the principles of anaerobic degradation began to be applied to the private marketplace, a unique repository of high-strength, readily biodegradable wastes. Important technological developments in the anaerobic treatment of high strength wastes include the work of Schroepfer in the treatment of meat packing waste with the anaerobic contact process (Schroepher et al., 1955); the development of the anaerobic filter by Young and McCarty in the late 1960s (Young and McCarty, 1969; Young, 1991); and the development of the upflow anaerobic sludge blanket treatment process by Lettinga and his associates at Wageningen University in the Netherlands in the 1970s (Lettinga et al., 1980). Lettinga's work was motivated by the publications of Young and McCarty and McCarty.

The upflow anaerobic sludge blanket (UASB) reactor developed by Lettinga in 1980s [see Fig. 10–2(h)], is the most significant modern development in anaerobic process technology. Lettinga's work on the UASB and other anaerobic processes has been instrumental in the development of the many commercial anaerobic technologies discussed in the following section. Since these seminal advances, numerous researchers, consulting engineers, and manufacturers have pushed the development of anaerobic technologies to the point where there are many available suppliers and thousands of full-scale applications (Totzke, 2012).

Future Developments

In the evolution of anaerobic technologies it is interesting to note the significant amount of physical experimentation that took place in the late 1800s and early 1900s. One of the most interesting examples is the glass model [essentially the same as Fig. 10–2(f)] of the hydrolytic tank constructed by Travis to observe what was occurring in the process. The inclined glass plates, called *colloiders,* in the second and third chamber were used to remove colloidal material by interception and sedimentation, a precursor of the modern day lamella or tube settler described in Chap. 5. It should also be noted that the use of rock, coke, lath and slate filters are cited often in the literature from the late 1800s through the early 1900s. From this brief review, it is clear that many of the early process developments or variants thereof are in use today. Also, it is important to recognize that just as much or more research is going on today, but the primary focus is on understanding the fundamental process biochemistry, molecular microbiology, and physiology.

10–3 AVAILABLE ANAEROBIC TECHNOLOGIES

Currently, anaerobic treatment technology can be classified as public or proprietary and commercial. Public technologies are those technologies available to any experienced designer. Proprietary and commercial technologies are those technologies supplied as a complete package with little or no input from the designer. The available types of anaerobic technologies and their application are discussed below.

Types of Anaerobic Technologies

The principal types of anaerobic technologies used for the treatment of wastes, with the exception of the conventional complete-mix digester used for the treatment of municipal sludge's, are illustrated and described in Table 10–3. The digestion of municipal sludge is considered in detail in Chap. 13. The technologies identified in Table 10–3 are listed in their approximate order of application prevalence. In reviewing the technologies in Table 10–3, the lineage to Lettinga's UASB [see Table 10–3(b)] is apparent. The expanded granular sludge blanket [EGSB, see Table 10–3(c)] process is a modified UASB process with effluent recycle and higher upflow velocity to fluidize the granules within the reactor. The EGSB process was introduced by Lettinga and coworkers for the treatment of low strength brewery wastewater but it can handle both lower and higher

Table 10–3

Description of the principal types of commercially available anaerobic treatment technologies[a]

Process	Description
(a) Low loaded anaerobic lagoon system (ANL)  	Generally unmixed reactor system employing suspended/flocculating anaerobic biomass and settled anaerobic solids with hydraulic retention times of 20 to 50 d and average SRTs of 50 to 100 d. Can handle a wider range of wastes including solids and soluble wastewaters. Designed for a total chemical oxygen demand (COD) loading of less than 2 kg/m^3·d. Systems can be covered with synthetic membranes for gas collection.
(b) Upflow anaerobic sludge blanket (UASB)  	An upflow reactor with a bottom sludge bed and dense, granular anaerobic biomass with good mixing provided by the upflow velocity and biogas generation. The reactor effective anaerobic sludge concentration may be in the range of 35 to 40 kg/m^3. A gas-liquid-solid separator at the top separates granular solids from the effluent and collects biogas. The sludge blanket has SRTs in excess of 30 d with hydraulic retention times in the range of 4 to 8 h. Designed for a COD loading of 5 to 20 kg/m^3·d. Upflow velocities can vary from 1 to 6 m/h and reactor heights of 5 to 20 m have been used.
(c) Expanded granular sludge blanket (EGSB)  	The EGSB is a commonly used modification of the UASB by employing a higher upflow velocity, a greater height to diameter ratio, and recirculation of effluent. Upflow velocities may be the range of 4 to 10 m/h and reactor heights up to 25 m have been used. The higher velocity provides a more efficient reactor for treatment of soluble substrates by improving mixing, reducing dead volume, and increasing diffusion rates from the bulk liquid to the granular biofilm. Was originally developed to treat low strength wastes but has been used for high strength as well and at low temperatures of 10°C. Organic loading rates as high as 35 kg/m^3·d have been used. Not as effective as the UASB for colloidal and particulate solids capture.
(d) Internal circulation UASB (IC)  	An IC reactor consists of two stacked UASB reactors in series, each with a gas separator at the top. The system uses a down comer pipe from a top chamber to the bottom inlet and a riser pipe from the first gas separator to induce recirculation and high upflow velocities in the lower granular sludge blanket reactor. Gas produced from the lower reactor is captured in the first separator and creates a gas lift for water and biosolids in the riser pipe. The gas is separated (released) from the biosolids in the chamber above the second reactor gas separator. From there the biosolids/water mixture enters the down comer pipe to provide internal recirculation to the bottom compartment. The high recirculation ratio results in high upflow velocities in the bottom chamber, 8 to 20 times higher than in conventional UASB unit, to provide good mixing and a very efficient reactor operation. The upper reactor provides a second stage anaerobic treatment for more efficient overall COD removal and the lower upflow velocity and lower biogas production rate improves effluent solids and biomass capture. Reactor heights of up to 25 m have been used.

(*continued*)

Process	**Description**
(e) Fluidized bed (FB) 	These systems are based on the development of a dense anaerobic biomass on small size (0.10 to 0.30 mm) inert particles of fine sand, basalt, pumice, or plastic. The particles are kept in suspension and mixed by a high upward velocity. The higher velocities leads to what is called a fluidized bed with 25 to 300 percent bed expansion and the expanded fluidized bed refers to operation at lower velocity with 15 to 25 percent bed expansion. These reactors are applicable for soluble wastes or easily degraded small particulates, such as whey. Upflow velocities may be in the range of 10 to 20 m/h and COD loadings of 20 to 40 kg/m^3·d have been used.
(f) Anaerobic contact process (ANCP) 	A completely mixed reactor system employing suspended anaerobic biomass, a mixing/flocculator degassing chamber, liquid-solids separation, and solids recycle so that the SRT is longer than the hydraulic retention time. Designed for a COD loading of in the range of 2 to 5 kg/m^3·d.
(g) Anaerobic filter (ANF) 	An anaerobic filter (ANF) system is an unmixed reactor system employing fixed film anaerobic biomass attached to supporting media, so that a large anaerobic biomass and long SRT can be maintained to allow treatment at hydraulic retention times in the range of 1 to 3 d and designed for a COD loading of 5 to 20 kg/m^3·d. It is available in upflow (ANFU) and downflow (ANFD) configurations.
(h) Anaerobic hybrid process (ANHYB) 	A combination of stand-alone anaerobic technologies employing a combination of an upflow anaerobic sludge blanket reactor and anaerobic filter to provide a high biomass concentration and high volumetric organic removal rates in the lower portion and further removal of volatile fatty acids and capture of suspended solids in the upper anaerobic filter portion.
(i) Anaerobic membrane process (ANMBR) 	A mixed reactor system employing suspended/flocculating anaerobic biomass and a synthetic membrane solids-liquid separation with solids recycle to provide a long SRT with the short hydraulic retention time. Designed for a COD loading of 5 to 15 kg/m^3·d.

(*continued*)

Process	Description
(j) Anaerobic baffled reactor (ABR)  	Baffles are used to direct the flow of wastewater in an upflow mode through a series of upflow anaerobic sludge blanket reactors. The sludge in the reactor rises and falls with gas production and flow, but moves through the reactor at a slow rate. Reactor volatile solids concentrations vary from 2 to 10 percent. Systems have been operated with τ values in the range of 6 to 24 h and SRTs in excess of 30 d. Designed for a COD loading of 5 to 10 kg/m^3·d. The main limitations with the ABR process are that many studies have been limited do laboratory- and pilot-scale treatment units.
(k) Anaerobic migrating blanket reactor (AMBR)  	Process is similar to the ABR with the added features of mechanical mixing in each stage and an operating approach to maintain the sludge in the system without resorting to packing or settlers for additional solids capture. When a significant quantity of solids accumulates in the last stage, the influent feed point is changed to the effluent side, which helps to maintain a more uniform sludge blanket. Organic loading rates from 1.0 to 3.0 kg COD/m^3·d with hydraulic retention times ranging from 4 to 12 h are possible.
(l) Anaerobic sequencing batch reactor (ANSBR)  	A mixed suspended growth anaerobic process with reaction and solids-liquid separation in the same vessel, much like that for aerobic sequencing batch reactors (SBRs) (see Chap. 8). The operation of SBRs consists of four steps: (1) feed, (2) react, (3) settle, and (4) decant/effluent withdrawal. The settling velocity of the sludge during the settle period before decanting the effluent is critical. Settling times used are about 30 min. After sufficient operating time, a dense granulated sludge develops that improves the liquid-solids separation. At τ values from 6 to 24 h, the SRT may range from 50 to 200 d, respectively. At 25°C, 92 to 98 percent COD removal was achieved at volumetric organic loadings of 1.2 to 2.4 kg COD/m^3·d. At 5°C, COD removal ranged from 85 to 75 percent for COD loadings from 0.9 to 2.4 kg/m^3·d, respectively.
(m) Continuously stirred tank anaerobic reactor (ANCSTR)  	A completely mixed reactor system treating semi-solids wastes with suspended anaerobic biomass. The reactor detention time equals the SRT, which may range from 15 to 30 d, with resulted COD loadings typically less than 4 kg/m^3·d.
(n) Plug flow anaerobic system (ANPF)  	Generally an unmixed rectangular reactor system treating semi-solids waste with high (10 to 18 percent) total solids concentration. In some cases the rectangular reactor is slightly inclined. Recycle of effluent solids may be done to seed the influent feed. The feed retention time equals the SRT, which may range from 20 to 30 d with COD loadings generally less than 4 kg/m^3·d.

strength wastewaters (Kato et al., 1999). Similarly, the internal recycle (IC) reactor [see Table 10–3(d)] is essentially two UASB reactors in series with internal recycle and it has also been successful for the treatment of low and very high strength wastewaters. The principal advantages in the development of EGSB and IC processes has been to increase the volumetric organic loading and treatment efficiency. Other anaerobic processes have been developed to treat wastes with specific characteristic (e.g., colloidal and particulate wastes).

Combined Processes. Process additions to the upflow granular sludge blanket have been made to improve treatment performance to approach or meet secondary treatment levels. These include hybrid anaerobic processes and a combined anaerobic-aerobic process. Hybrid processes typically involve two stages of anaerobic treatment, such as the one shown in Table 10–3(h) which involves an anaerobic sludge blanket process in the lower portion of the reactor followed by anaerobic attached growth process for polishing in the upper portion. A sequential anaerobic-aerobic process was reported as early as 1992 (Garuti et al., 1992) to provide a secondary effluent quality for anaerobic treatment in warm climates. More recently the aerobic process has been incorporated as an integral part of a combined anaerobic-aerobic process in a single tank (Tauseef, et al., 2013). Although there are a number of combined aerobic-anaerobic process the focus of this chapter is on the anaerobic processes.

Commercial Technologies. Compiling a list of commercially available anaerobic technologies is beyond the scope of this book task, and is complicated by the wide range of technical descriptions, trade names, and research descriptions that are available in the literature and in the marketplace. Most of the technologies listed in Table 10–3 can be defined by (1) the organic loading criteria, (2) the methods used to condition the influent waste (e.g., dilution, pH adjustment, nutrient addition), (3) the method used to introduce and distribute the influent into the reactor; (4) the method used to contact the waste to be treated with the biomass, (5) the method used to retain and separate the anaerobic biomass, a key factor in a successful operation of an anaerobic treatment process, (6) the characteristics of the biological reactor, (7) the gas management system, and (8) the ultimate management of the residual solids. Because so many new processes are coming on the market it is important to review the current literature. Pilot-plant testing is recommended for new designs and for wastewater with no full-scale treatment experience. Fundamental considerations for anaerobic treatment are presented and discussed in the following section.

Application of Anaerobic Technologies

The technologies described in Table 10–3 are used for (1) the treatment of high-strength wastes from a variety of industries, (2) the pretreatment of high-strength wastes, (3) the treatment of domestic wastewater in combination with other aerobic processes, and (4) treatment of domestic wastewater. Of these applications, most of the activity has been for the treatment of high-strength and specialized industrial wastes, but there are also a number of installations for anaerobic treatment of domestic wastewater.

Applications for High Strength Wastes. In the last 25 to 30 y, the number of industrial anaerobic installations worldwide has increased by nearly an order-of-magnitude and is as of 2013 close to 4750 (see Table 10–4). A representative listing of the industries in which anaerobic technologies are now used is presented in Table 10–5. Different types of anaerobic processes may be employed for the same type of industrial wastewater as indicated in Table 10–6. Because of their relatively small footprint, the EGSB and

Table 10–4

Estimated number of anaerobic process installations by type as of mid 2013[a] (exclusive of conventional anaerobic digesters used for wastewater sludges)

Process category	Installation
Anaerobic lagoon	>50,000
UASB	2000
EGSB	1500
Anaerobic contact process	500

IC processes have become quite popular for the treatment of industrial wastewaters. Typical views of EGSB and IC reactors are shown on Fig. 10–3. The use of UASB process for the treatment of high strength waste and domestic wastewater is considered below.

To meet current water quality requirements for most effluent discharges, an anaerobic process used for the treatment of high strength wastes may need to be followed by an aerobic process. A variety of aerobic processes have been used for post treatment of effluent from high rate anaerobic industrial pretreatment processes. These include conventional or biological nutrient removal activated sludge, sequencing batch reactors. trickling filters, biological aerated filters, rotating biological contactors, and wetlands (Chong et al., 2012). An example is shown on Fig. 10–4 in which a UASB reactor, located at a municipal wastewater treatment, is used to treat high strength food processing wastewater from a dedicated pipeline from the industry. The UASB effluent is directed to a biological nutrient removal activated sludge process receiving the municipal wastewater. The residual volatile fatty acids in the UASB effluent are expected to help the performance of the enhanced biological phosphorus removal process in the municipal plant.

Applications for Domestic Wastewater. In many parts of the world, especially in less developed countries with warm climates, anaerobic treatment may be the

most attractive option for domestic wastewater treatment. The USAB process is the most common anaerobic process used for treatment of domestic wastewater. Following its development for the treatment of high-strength wastewaters, it was successfully demonstrated for treating domestic wastewater at 25°C in a tropical climate during the early 1980s in Columbia (Gomec, 2010). The first full-scale facility was installed in

1989 in Kanpur, India, and is still in operation with a treatment capacity of 5000 m^3/d. As of 2006, Aiyuk et al. (2006) reported that over 200 facilities were in operation worldwide. Many of these are in warm climates, but the UASB process had been applied for the treatment of domestic wastewaters at temperatures as low as 10°C. In a summary of UASB installations by Gomec (2010), 9 out of 35 facilities were operating at temperatures below 15°C. The hydraulic retention times in 75 percent of these facilities ranged from 2 to 10 h. A low energy wastewater treatment system employing a UASB reactor with a trickling filter treating the UASB effluent is shown on Fig. 10–5. The trickling filter effluent is used for crop irrigation following sedimentation. In the future, it is anticipated that many more combined anaerobic/aerobic treatment systems will be used and new ones developed, based on energy concerns and evolving treatment objectives.

The high rate anaerobic treatment process can be an attractive alternative for domestic wastewater treatment because of the relatively small size and low construction costs, low excess sludge production, low energy demand, and potential for biogas recovery. For countries with low water use and more concentrated wastewater, the advantages for the process increase. However, where a secondary effluent treatment quality is required, the anaerobic treatment process must be followed by an aerobic system for post treatment to further remove colloids, suspended solids and soluble BOD (Lew et al., 2002). Another emerging alternative is the use of synthetic membranes with a suspended growth anaerobic treatment process operated with a long SRT [see Table 10–3(i)]. The membrane separation can result in greater than 99 percent suspended solids removal to meet secondary treatment levels (Visvanathan and Abeynayaka, 2012). A number of processes that may be used after anaerobic treatment for nutrient removal, such as the Anammox process, are currently under investigation.

10–4 FUNDAMENTAL CONSIDERATIONS IN THE APPLICATION OF ANAEROBIC TREATMENT PROCESSES

The type of wastewater and its characteristics are important in the evaluation, design, and implementation of anaerobic processes. The wastewater characteristics affect the economics of selecting an anaerobic process over an aerobic treatment process, the type of anaerobic treatment process preferred, and the operational costs and concerns for using an anaerobic treatment process. The focus of the discussion in this section is on the effect of the wastewater characteristics on (1) important anaerobic process design issues, (2) the need for pretreatment and alkalinity and/or nutrient addition, and (3) the gas production and amount of energy that can be gained by treating the wastewater with an anaerobic treatment process. The topics discussed apply to the granular sludge blanket, suspended growth, attached growth, and membrane separation anaerobic processes presented in Table 10–3.

Characteristics of the Wastewater

As shown in Table 10–5, a wide variety of wastewaters have been treated by anaerobic processes. Due to the energy savings by eliminating aeration and minimal sludge production, anaerobic processes become more attractive with increasing organic concentration and temperature. Food processing and distillery wastewaters can have COD concentrations ranging from 3000 to 30,000 g/m^3. Other considerations within the type of wastewater are potential toxic streams, daily flowrate and loading variations, inorganic concentrations, and seasonal load variations.

Flowrate and Loading Variations. Wide variations in influent flowrate and organic loads can upset the balance between acid fermentation and methanogenesis in anaerobic processes. The acidogenic reactions can be much faster to possibly depress the pH and increase VFA and hydrogen concentration to levels that inhibit methanogenesis. A more conservative design or flow equalization must be considered for such situations. Flow equalization tanks can store wastewaters from batch wasting in industrial process operations and then allow a more uniform feed flowrate and feed strength to the anaerobic treatment process. More uniform feeding provides a more stable anaerobic process operation and also allows higher average organic loading rates. Anaerobic processes have been shown to be able to respond quickly to incremental increases in wastewater feed after long periods without substrate addition.

Organic Concentration and Temperature. As discussed in Sec. 10–1, the wastewater strength and temperature greatly affect the economics and choice of anaerobic treatment over aerobic treatment. Reactor temperatures of 25 to 35°C are generally preferred to support more optimal biological reaction rates and to provide more stable treatment. Generally, biodegradable COD concentrations greater than 1500 to 2000 mg/L are needed to provide sufficient methane production to heat the wastewater assuming it is at ambient temperature.

Anaerobic treatment can be applied at lower temperatures and has been sustained at 10 to 20°C in granular sludge blanket, suspended growth, and attached growth reactors. At the lower temperatures slower reaction rates occur and longer SRTs, larger reactor volumes, and lower organic COD loadings are needed (Banik et al., 1996; Collins et al., 1998; and Alvarez et al., 2008).

When higher SRTs are needed, the solids loss in an anaerobic reactor can become a critical limiting factor. Anaerobic reactors generally produce more dispersed, less flocculent solids than aerobic systems with effluent TSS concentrations for suspended growth processes in the 100 mg/L range.

For dilute wastewaters, the effluent TSS concentration will limit the possible SRT of the process and treatment potential. Either a lower treatment performance occurs or it is necessary to operate the reactor at a higher temperature. Thus, the method to retain solids in the anaerobic reactor is important in the overall process design and performance. The maximum SRT possible is when biomass lost via the effluent is equal to the solids produced, which can be calculated from Eq. 8–20.

$$Q(\text{VSSe}) = \frac{QY_{\text{H}}(b\text{CODr})}{1 + b_{\text{H}}(\text{SRT})} + \frac{(f_d)(b_{\text{H}})QY_{\text{H}}(b\text{CODr})\text{SRT}}{1 + b_{\text{H}}(\text{SRT})} \tag{10–1}$$

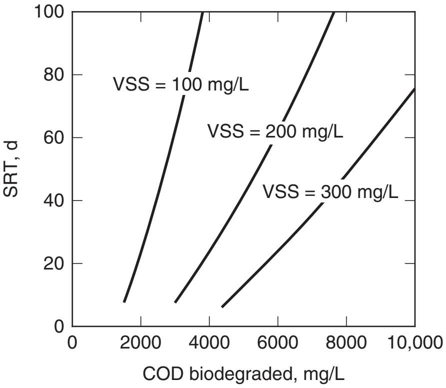
Where VSSe = effluent volatile suspended solids, g/m^3
bCODr = COD degraded in anaerobic reactor, g/m^3

Solving for SRT as a function of effluent volatile suspended solids concentration, biodegradable COD removed, and growth and decay coefficients yields

$$\text{SRT} = \frac{Y_{\text{H}}(b\text{CODr}) - \text{VSSe}}{(b_{\text{H}})(\text{VSSe}) - (f_d)(b_{\text{H}})(Y_{\text{H}})(b\text{CODr})} \tag{10–2}$$

Figure 10–6

Estimate of biomass SRT in an anaerobic reactor as a function of the amount of COD degraded and effluent biomass VSS concentration. (Based on assumptions of a synthesis yield coefficient of 0.08 g VSS/g CODr and specific endogenous decay rate coefficient of 0.03 g VSS/g VSS·d from Table 10–13 and an f_d value of 0.10.)



The maximum SRT as a function of bCOD removed and effluent VSS concentration is shown on Fig. 10–6. To achieve an SRT of 40 d, which would be desirable at a temperature of about 30°C, the amount of COD that must be degraded increases from about 2400 mg/L for an effluent VSS concentration of 100 mg/L to about 7400 mg/L if the effluent VSS concentration is 300 mg/L. For operation at lower temperatures much higher SRT values are needed, which requires a very low effluent VSS concentrations for weaker wastewaters or a higher biodegradable COD in the influent.

Fraction of Non-Dissolved Organic Matter. The composition of the wastewater in terms of its particulate and soluble fractions affects the type of anaerobic reactor selected and its design. Wastewaters with high solids concentrations are treated more appropriately in suspended growth and UASB reactors than by upflow or downflow attached growth processes. Where more particulate conversion is required, longer SRT values may be needed if solids hydrolysis is the rate limiting step as compared to acid fermentation or methanogenesis in anaerobic treatment. In such cases, it may be appropriate to use a two phase anaerobic treatment process with hydrolysis and acid fermentation in a sludge bed or stirred reactor, followed by UASB reactor or other type of reactor for methanogenesis (Shuizhou and Zhou, 2005; Alvarez et al., 2008).

Wastewater Alkalinity. During anaerobic treatment gas bubbles containing a high CO_2 content (25 to 35 percent) are produced in the liquid from fermentation reactions, which results in an elevated dissolved CO_2 concentration in the liquid. A high alkalinity concentration, in the range from 2000 to 4000 mg/L as $CaCO_3$, is typically needed to offset the dissolved carbonic acid and maintain the pH at or near neutral. For wastewaters low in alkalinity, proteins or amino acids can be metabolized and deaminated during anaerobic treatment to produce alkalinity as $NH_4(HCO_3)$. Where lacking, the purchase of alkalinity for pH control is necessary, which can have a significant impact on the economics of anaerobic treatment.

The relationship between pH and alkalinity as outlined in Appendix F is controlled by the bicarbonate chemistry as follows:

$$\frac{[HCO_3^-][H^+]}{[H_2CO_3]} = K_{a1} \tag{10–3}$$

where K_{a1} = first acid dissociation constant, which is a function of ionic strength and temperature

The carbonic acid (H_2CO_3) concentration is determined using Henry's law [Eq. (2–46)] and the partial pressure of the CO_2 in the atmosphere above the water.

$$x_g = \frac{P_T}{H} p_g \tag{2–46}$$

where x_g = mole fraction of gas in water, mole gas/mol water

$$= \frac{\text{mole gas } (n_g)}{\text{mole gas } (n_g) + \text{mole water } (n_w)}$$

P_T = total pressure, usually 1.0 atm

H = Henry's las constant, $\dfrac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}$

P_g = mole fraction of gas in air, mole gas / mole of air (Note: The mole fraction of a gas is proportional to the volume fraction)

Once the carbonic acid concentration is known, the bicarbonate (HCO_3^-) alkalinity needed to maintain the required pH can be estimated. The use of the above equations is illustrated in Example 10–1.

EXAMPLE 10–1 **Alkalinity and pH in Anaerobic Process** Determine the alkalinity required in kg $CaCO_3$/d to maintain a pH value of 7.0 in an anaerobic suspended growth process at 35°C, with a 30 percent CO_2 content in the gas phase. The influent wastewater flowrate is 2000 m^3/d and the alkalinity is 400 mg/L as $CaCO_3$. At 35°C, the Henry's constant for CO_2, computed using Eq. (2–28) and the data given in Table 2–8, is 2092 atm and the value of K_{a1} is 4.85×10^{-7} (see Appendix F).

Solution

1. Determine the concentration of HCO_3^- required to maintain the pH at or near a value of 7.0.
   a. Determine the concentration of H_2CO_3 using Eq. (2–46)

$$x_{H_2CO_3} = \frac{P_T}{H} P_g = \frac{(1 \text{ atm})(0.30)}{2092 \text{ atm}} = 1.434 \times 10^{-4}$$

Because one liter of water contains 55.6 moles [1000 g/(18 g/mole)], the mole fraction of H_2CO_3 is equal to

$$x_{H_2CO_3} = \frac{\text{mole gas } (n_g)}{\text{mole gas } (n_g) + \text{mole water } (n_w)}$$

$$1.434 \times 10^{-4} = \frac{[H_2CO_3]}{[H_2CO_3] + (55.6 \text{ mole/L})}$$

Because the number of moles of dissolved gas in a liter of water is much less than the number of moles of water,

$$[H_2CO_3] \approx (1.434 \times 10^{-4})(55.6 \text{ mole/L}) \approx 7.97 \times 10^{-3} \text{ mole/L}$$

   b. Determine the concentration of HCO_3^- required to maintain the pH at or near a value of 7.0 using Eq. (10–1)

$$[HCO_3^-] = \frac{(4.85 \times 10^{-7})(7.97 \times 10^{-3} \text{ mole/L})}{(10^{-7} \text{ mole/L})}$$

$$= 0.03863 \text{ mole/L}$$

$$HCO_3^- = 0.03863 \text{ mole/L } (61 \text{ g/mole})(10^3 \text{ mg/1 g}) = 2356 \text{ mg/L}$$

2. Determine the amount of alkalinity required per day

$$\text{Equivalents of } HCO_3^- = \frac{(2356 \text{ g/L})}{(61 \text{ g/eq})} = 0.03863$$

$$1 \text{ eq. } CaCO_3 = \frac{\text{m.w.}}{2} = \frac{(100 \text{ g/mole})}{2} = 50 \text{ g } CaCO_3/\text{eq}$$

$$\text{Alkalinity as } CaCO_3 = (0.03863 \text{ eq/L})\,(50 \text{ g/eq})(10^3 \text{ mg/1 g})$$

$$= 1931 \text{ mg/L as } CaCO_3$$

$$\text{Alkalinity needed} = (1931 - 400) \text{ mg/L}$$

$$= 1531 \text{ mg/L as } CaCO_3$$

Daily alkalinity addition:

$$= (1531 \text{ g/m}^3)\,(2000 \text{ m}^3\text{/d})\,(1 \text{ kg}/10^3 \text{ g})$$

$$= 3062 \text{ kg/d}$$

Comment Based on the results of the above analysis, it is clear that the quantity of alkalinity required can be significant, and, as a consequence, a significant cost can be incurred.

The results of similar calculations to those presented in Example 10–1 for different temperatures and gas phase CO_2 concentrations are reported in Table 10–7. The data presented in Table 10–7 were derived using the bicarbonate dissociation constants given in Table F–2 in Appendix F and Henry's constants derived from the data given in Table 2–8 in Chap. 2. The values presented in Table 10–7 can be used to estimate the alkalinity requirements. For wastewaters with a higher total dissolved solids concentration and ionic strength, the alkalinity requirements will generally be much greater.

Nutrients. Though anaerobic processes produce less sludge and thus require less nitrogen and phosphorus for biomass growth, many industrial wastewaters may lack sufficient nutrients. Thus, the addition of nitrogen and/or phosphorus may be needed.

Macronutrients. The presence of the iron, nickel, cobalt, and molybdenum at trace concentrations are needed for the growth of methanogenic bacteria in anaerobic processes (Demirel and Scherer, 2011). The addition of trace metals has been shown in a number of cases to increase COD removal efficiency in anaerobic processes including granular

sludge reactors (Osuna et al., 2003; Fermoso et al., 2008) and a suspended growth process for the digestion of food waste (Evans et al., 2012). Digester studies by Takashima et al. (2011) led to a recommendation of having the following ratios available for iron, nickel, cobalt, and zinc in mg/g COD removed, respectively for efficient anaerobic degradation: 0.20, 0.0063, 0.017, and 0.049 in a mesophilic system and 0.45, 0.049, 0.054, and 0.24 in a thermophilic system.

The exact amounts of trace metals needed can vary for different wastewaters and, thus, successive trials are used to assess their benefit for high rate anaerobic processes.

Inorganic and Organic Toxic Compounds. Proper waste analysis and treatability studies are needed to assure that a chronic or serious transient toxicity does not exist for wastewater treated by anaerobic processes. At the same time, the presence of a toxic substance does not mean the process cannot function. Some toxic compounds inhibit anaerobic methanogenic reaction rates, but with a high biomass inventory and low enough loading, the process can be sustained. Toxic and inhibitory inorganic and organic compounds of concern for anaerobic processes are presented in Tables 10–8 and 10–9, respectively. Acclimation to toxic concentrations has also been shown (Speece, 1996) but it may be necessary to apply pretreatment steps to prevent toxicity problems in the anaerobic degradation process.

Pretreatment of Wastewater

Wastewater pretreatment requirements depend on the waste source, the type of anaerobic treatment process employed, and the need to prevent an anaerobic treatment process failure or unstable operation. Pretreatment considerations include screening, solids conditioning or reduction, pH and temperature adjustment, nutrient addition, and fats, oil, and grease (FOG) control, and toxicity reduction.

Table 10–9

[a] From Parkin and Owen (1986).

Screening. Some form of screening is normally used to removed objectionable material that could cause interference with the flow distribution in a granular sludge reactor, mixing problems in suspended growth reactors, or plugging of attached growth reactors. Fine screening, in the range of 2 to 3 mm, should be considered for anaerobic membrane reactors to prevent membrane fouling problems.

Solids Conditioning or Reduction. A solids conditioning pretreatment step may be considered in the processing of wastes that are high in solids content and/or lignin material, such as agriculture waste or certain pulp and paper mill streams, to enhance methane production and anaerobic degradation reaction rates. These may include mechanical, chemical, thermal, and biological processes or a combination of them (Sambusiti et al., 2013). Solids conditioning technology is addressed in Chap. 13 for anaerobic digestion of wastewater treatment plant sludges.

Solids reduction by a two-step process with solids removal or solids removal and hydrolysis in the first step before downstream granular sludge and attached growth anaerobic processes can be beneficial to COD removal performance and operational stability. High suspended solids concentration in the influent to a granular sludge anaerobic process may cause clogging and channeling in the sludge blanket to reduce treatment effectiveness. In addition the adsorption and incorporation of suspended and colloidal solids may impair the sludge granulation process and the density of the granules. Minimal influent solids concentrations are desired for the operation of packed bed anaerobic treatment processes to prevent plugging and channeling of the wastewater flow. One option is to provide gravity settling for solids removal and thickening with the settled solids treated in a separate sludge digester and another option is to provide solids reduction by anaerobic hydrolysis in the first step.

A two-step processes with solids contact and hydrolysis in the first step was proposed by van Haandel and Lettinga (1994) and has been used for both industrial and domestic wastewater treatment with downstream UASB, EGSB, and packed bed anaerobic processes (Seghezzo et al., 1998). A hydrolysis upflow sludge blanket (HUSB) reactor or alternatively referred to as an upflow anaerobic solids removal (UASR) reactor provides solids capture and hydrolysis prior to a downstream anaerobic process. It has been demonstrated in domestic wastewater treatment applications at temperatures from 14 to 26°C and with hydraulic retention times from 3 to 10 h (Alvarez et al., 2008; Zeeman et al., 1997). A greater solids accumulation occurs under cold temperature operation due to the slower hydrolysis rates and may require solids wasting and further treatment elsewhere.

pH Adjustment. The ability to operate the anaerobic process with little variation in the reactor pH and temperature leads to a more stable operation and better process efficiency. Based on knowledge of the wastewater characteristics and the anaerobic reactor operating conditions the amount of alkalinity, if needed, can be determined and provided in the operational protocols. For more dilute wastewaters with lower gas production rates relative to the wastewater flowrates, the percent CO_2 can be minimal compared to the amount when treating a wastewaters with high COD concentrations, such that the alkalinity demands are none or modest. The influent alkalinity should be controlled to maintain reactor operating pH values between 6.8 and 7.8 for which stable methanogenic activity occurs (Leitão et al., 2006).

Temperature Adjustment. Operation at constant temperature provides a more stable and more efficient process performance. A decrease in the reactor temperature is more detrimental than an increase. A sudden temperature drop of 1 to 2°C results in a slower acetate uptake rate by the methanogenic bacteria and accumulation of VFAs. Depending on the system alkalinity and buffer capacity, this could result in a pH decrease that could further slow down the methanogenic activity leading to a path of digester instability and potential failure if not adjusted soon enough. Sudden temperature drops can also affect the integrity of granular sludge in UASB, EGSB, and IC reactors.

Nutrient Addition. Many high strength wastewaters, such as those from food processing, brewery, beverage, and distillery operations, will require the addition of nitrogen and phosphorus to support growth of the anaerobic bacteria. The amount needed is higher during start up due to more rapid growth and less supply of nutrients within the reactor by endogenous decay. An influent COD:N:P ratio of 600:5:1 is recommended during start up and 300:5:1 during long term operation (Annachhatre, 1996).

Fats, Oil, and Grease (FOG) Control. The presence of FOG in wastewaters fed to anaerobic processes can be of concern for two reasons: (1) inhibition of methanogenesis due to inhibition by long chain fatty acids (LCFAs) and (2) sludge flotation due to the hydrophobicity and lower density of FOG components. The inhibition is thought to be due to sorption of LCFAs on the methanogenic organism's cell wall and membranes to interfere with cell substrate transport functions (Hanaki et al., 1981). Further, the presence of FOG can also be detrimental to the integrity of granular sludge particles in UASB and EGSB reactors and can cause fouling of the synthetic membranes used in anaerobic membrane reactors.

Anaerobic biodegradation of FOG has been demonstrated in the treatment of rendering waste with sustained FOG loadings of less than 1.0 kg FOG/m^3·d, but unacceptable solids loss occurred due to flotation at higher loadings (Jeganathan et al., 2006). Upon initial exposure, FOG inhibition of methanogenic activity occurs at much lower loadings until FOG degradation occurs following an acclimation period (Evans et al., 2012). Thus, intermittent or variable FOG loadings can cause methanogenic inhibition and unstable operation of the anaerobic process. Source control and dissolved air flotation pretreatment must be considered for wastewater with high FOG concentration.

Toxicity Reduction. As shown in Tables 10–8 and 10–9 a wide range of inorganic and organic substances can be toxic to anaerobic processes, including certain heavy metals, high dissolved solids, chlorinate organic compounds, high nitrogen concentration from ammonia, amino acids, and or proteins, and industrial chemical products. Control of toxicity for anaerobic processes requires a careful evaluation of the wastewater and its sources. Source control is a first step and where necessary pretreatment steps for toxicity reduction may include for example dilution, air stripping, and chemical precipitation processes. Air stripping was found for example to be effective for the reduction of high ammonia concentration toxicity in piggery wastes (Zhang and Jahng, 2010).

A two step process in the anaerobic treatment system may be used to remove or biodegrade toxic substances before a final methanogenic treatment step. A first step solids removal/hydrolysis or acid phase anaerobic treatment may remove the toxin to a sufficient level before exposure of the more sensitive methanogenic bacteria to the toxic compound (Lettinga and Hulshoff Pol, 1991).

Expected Gas Production

Higher strength wastewaters will produce a greater amount of methane per volume of liquid treated to provide a relatively higher amount of energy to raise the liquid temperature if needed. Gas composition and volume relationships for methane are discussed below.

Gas Composition. Anaerobic degradation of organic substances results in the production of a gaseous product with the conversion of carbon to methane (CH_4) and carbon dioxide (CO_2), nitrogen to ammonia (NH_3), and sulfur to hydrogen sulfide (H_2S). The energy value of the gas produced is proportional to its methane content. Buswell and Boruff (1932) were the first to recognize that the composition of the gaseous product is a function of the organic compound type and composition. Buswell and Mueller (1952) later developed a molar stoichiometric relationship between the carbon, hydrogen, and oxygen in an organic compound to the volume of methane, and carbon dioxide produced in anaerobic degradation. Their relationship was further modified to include the organic compound nitrogen and sulfur content and the volume of ammonia and hydrogen sulfide produced (Parkin and Owen, 1986; Tchobanoglous et al., 2003):

$$\begin{aligned} &C_vH_wO_xN_yS_z + \left(v - \frac{w}{4} - \frac{x}{2} + \frac{3y}{4} + \frac{z}{2}\right)H_2O \rightarrow \\ &\quad \left(\frac{v}{2} + \frac{w}{8} - \frac{x}{4} - \frac{3y}{8} - \frac{z}{4}\right)CH_4 + \left(\frac{v}{2} - \frac{w}{8} + \frac{x}{4} + \frac{3y}{8} + \frac{z}{4}\right)CO_2 + yNH_3 + zH_2S \end{aligned} \tag{10–4}$$

The gaseous ammonia (NH_3) that is formed will react with the carbon dioxide to form the ammonium ion and bicarbonate according to the following relationship.

$$NH_3 + H_2O + CO_2 \rightarrow NH_4^+ + HCO_3^- \tag{10–5}$$

The reaction given by Eq. (10–5) is representative of the formation of alkalinity under anaerobic conditions, due to the conversion of organic compounds containing proteins, peptides or amino acids (i.e., nitrogen). The expected mole fractions of methane and carbon dioxide, and hydrogen sulfide are given by the following three expressions, respectively. Ammonia gas production from Eq. (10–4) is not included as most of it will remain in solution as ammonium bicarbonate. In general, the mole fraction of hydrogen sulfide will be somewhat less because of metal complexation/precipitation.

$$f_{CO_2} = \frac{4v - w + 2x + 2z}{8(v + z)} \tag{10–6}$$

$$f_{CH_4} = \frac{4v + w - 2x - 2z}{8(v + z)} \tag{10–7}$$

$$f_{H_2S} = \frac{z}{(v + z)} \tag{10–8}$$

Using approximate formulas for lipid, carbohydrate, and protein compounds of $C_{18}H_{33}O_2$, $C_6H_{10}O_5$, and $C_{11}H_{24}O_5N_4$, the percent methane in the anaerobic process gas calculated from Eq. (10–7) are 70, 50, and 66, respectively. These values compare well to respective values of 70, 50, and 68 percent in studies by Li et al. (2002). For carbohydrate, starch, and FOG wastes, alkalinity will be a problem due to the lack of ammonia production.

Volume of Methane Gas. As derived by Eq. (7–142) in Sec. 7–14 in Chap. 7, the amount of methane (CH_4) produced from anaerobic oxidation of COD is equal to 0.35 L CH_4/g COD at standard conditions (0°C and 1 atm). The quantity of methane at other than standard conditions is determined by using the universal gas law [Eq. (2–44)] to determine the volume of gas occupied by one mole of CH_4 at the temperature in question.

$$V = \frac{nRT}{P} \tag{2–44}$$

Where V = volume occupied by the gas, L, m^3
n = moles of gas, mole
R = universal gas law constant, 0.08205 atm·L/g mole·K
= 0.08205 atm·L/g mole·K
T = temperature, °K (273.15 + °C)
P = absolute pressure, atm

Thus, for 35°C the volume occupied by one mole of CH_4 is:

$$V = \frac{(1\text{ mole})(0.082056\text{ atm·L/g mole·K})(273.15 + 35)}{1.0\text{ atm}} = 25.29\text{ L/mole}$$

Because the COD of one mole of CH_4 is equal to 64 g, the amount of CH_4 produced per unit of COD converted under anaerobic conditions at 35°C is equal to 0.40 L as determined below.

$$(25.29\text{ L/mole})/(64\text{ g COD/mole }CH_4) = 0.40\text{ L }CH_4\text{/g COD}$$

The total gas production rate is commonly estimated by calculating the methane production rate and dividing it by the fraction of methane in the gas phase, typically assuming a value in the range of 60 to 65 percent methane.

Table 10–10

Comparison of energy balance for aerobic and anaerobic processes. Wastewater at 20°C, 100 m^3/d and 10,000 g/m^3 COD concentration

Energy	Value, kJ/d	
	Anaerobic	Aerobic
Aeration		-1.9×10^6
Methane produced	12.5×10^6	
Increase wastewater temperature to 30°C	-5.3×10^6	
Net energy, kJ/d	7.2×10^6	-1.9×10^6

Energy Production Potential

In contrast to aerobic biological treatment very little electrical energy is used for anaerobic biological treatment, being limited to energy for pumping and tank mixing, depending on the anaerobic process. The methane produced in the anaerobic process is often used to heat the wastewater or sludge where required. In some cases for larger installations, the methane may be used in reciprocating engine or microturbine equipment to produce electricity. When the heat generated during electrical generation is captured and used for heating, the energy producing process is called cogeneration.

An energy balance comparison for aerobic and anaerobic treatment of a high strength wastewater at 20°C is presented in Table 10–10. For the conditions given, the aerobic process requires 1.9×10^6 kJ/d of energy. On the other hand, the anaerobic process produces a total of 12.5×10^6 kJ/d. Of the total energy produced anaerobically, about 5.3×10^6 kJ/d is required to raise the wastewater temperature from 20 to 30°C, assuming an 80 percent energy utilization efficiency after accounting for losses in the boiler and heat exchanger and reactor heat losses. Thus, the potential net energy production that can be achieved with anaerobic treatment is on the order of 7.2×10^6 kJ/d, or about 3.8 times the energy required for aerobic treatment. General considerations used for the energy balance are shown as follows.

A large portion of the energy demand for an aerobic activated sludge process is for aeration to supply oxygen and can be calculated as follows:

$$E_{\mathrm{AER}}(\mathrm{kJ/d}) = Q(\mathrm{CODr})(A_n)(3600\ \mathrm{kJ/kWh})/\mathrm{AOTE} \tag{10–9}$$

Where E_{AER} = daily energy demand for oxygen transfer, kJ/d
Q = wastewater flowrate, m^3/d
CODr = COD removed by biodegradation, kg/m^3
A_n = net oxygen required, kg O_2/kg CODr
AOTE = actual oxygen transfer efficiency, kg O_2/kWh

The value for A_n can be calculated for a given activated sludge design SRT using Eq. (8–67). The anaerobic process produces energy in the form of methane but may use some portion of the methane produced to heat the wastewater to a more optimal operating temperature, typically in the range of 30 to 35°C. The net energy production, accounting for the energy from methane production and energy used for heating is as follows:

$$\begin{aligned} E_{\mathrm{ANAER}},\ \mathrm{kJ/d} &= (Q)(\mathrm{CODr})\left(\frac{0.35\ \mathrm{m^3\ CH_4}}{\mathrm{kg\ CODr}}\right)\left(\frac{35{,}846\ \mathrm{kJ}}{\mathrm{m^3\ CH_4}}\right) \\ &\quad -(Q)(\Delta T)(C_p)\left(\frac{10^3\ \mathrm{kg}}{\mathrm{m^3\ H_2O}}\right)\left(\frac{1}{\mathrm{Eff_{heat}}}\right) \end{aligned} \tag{10–10}$$

Where: E_{ANAER} = net energy available, kJ/d
ΔT = temperature increase for influent wastewater, °C
C_p = specific heat of water, 4.2 kJ/°C·kg
Eff_{heat} = fraction of heat available after losses from vessel and heat exchanger

The effect of the wastewater strength on the net energy consumption or production between aerobic and anaerobic treatment is illustrated in Example 10–2. The same assumptions used to generate the comparison in Table 10–10 are used in the example.

EXAMPLE 10–2 **Comparison of Energy Consumption and Production in Aerobic and Anaerobic Treatment** Compare the energy needed for aeration for treatment of a high strength wastewater by an activated sludge aerobic treatment process to the net energy production for an anaerobic treatment process. The net energy production for anaerobic treatment accounts for the energy produced by methane generation minus the energy used to heat the wastewater from 20 to 30°C.

a. Express the net energy as a positive or negative production in kJ/m^3 of wastewater treated and tabulate the results for aerobic and anaerobic treatment to achieve a COD biodegradation of 3800, 4200, 6000, 8000, and 10,000 mg/L. Include the volume of methane produced in m^3/d for a wastewater flowrate of 400 m^3/d.
b. Using similar calculations as for the above, prepare a graph that can be used to illustrate the net energy for anaerobic treatment in terms of kJ/m^3 for three wastewater conditions that require heating from 25 to 30°C, 20 to 30°C and 10 to 30°C. Use an influent wastewater COD biodegradation range of 1500 to 10,000 mg/L. Where the net energy production is negative limit the *Y* axis to –5000 kJ/m^3.

The following assumptions apply:

1. A_n = 0.80 g O_2/g COD removal
2. Aeration actual oxygen transfer efficiency (OTE) = 1.52 kg O_2/kWh
3. Net heat loss for methane utilization for heating = 20 percent
4. Heat capacity of water = 4.2 kJ/°C·kg
5. Energy content of methane at standard conditions = 38,846 kJ/m^3
6. Methane production rate at standard conditions = 0.35 m^3 CH_4/kg CODr (ignore COD to biomass, which is about 3 to 4 percent of total COD degraded)

Solution

1. Determine the energy needed for aeration per unit flow in the aerobic treatment process using Eq. 10–9 for a CODr of 3800 mg/L (3.8 kg/m^3).

$$\frac{E_{\text{AER}}}{Q} = (\text{CODr})(A_n)(3600 \text{ kJ/kWh})/\text{AOTE}$$

$$\frac{E_{\text{AER}}}{Q} = (3.8 \text{ kg COD/m}^3)(0.8 \text{ kg O}_2\text{/kg COD})\left[\frac{1}{(1.52 \text{ kg O}_2\text{/kWh})}\right](3600 \text{ kJ/kWh})$$

$$= 7200 \text{ kJ/m}^3$$

The aeration energy needed for the other CODr removal levels is directly proportional to the COD concentration and is tabulated in the summary table in Step 4a.

2. Determine the net energy produced per unit flow from methane production and wastewater heating using Eq. (10–10) for a CODr = 3800 mg/L for heating the wastewater from 20 to 30°C (ΔT = 10°C). With a 20 percent heat loss, the methane utilization efficiency for heating is 80 percent.

a. Net energy for a CODr = 3800 mg/L

$$\frac{E_{\text{ANAER}}}{Q} = (3.8\text{ kg COD/m}^3)(0.35\text{ m}^3\text{ CH}_4\text{/kg COD})(35{,}846\text{ kJ/m}^3\text{ CH}_4)$$

$$-(10^\circ\text{C})(4.2\text{ kJ/}^\circ\text{C}\cdot\text{kg})(10^3\text{ kg/m}^3\text{ H}_2\text{O})\left(\frac{1}{0.80}\right)$$

$$= -4825\text{ kJ/m}^3$$

b. Net energy for a CODr = 4200 mg/L

$$\frac{E_{\text{ANAER}}}{Q} = (4.2\text{ kg COD/m}^3)(0.35\text{ m}^3\text{ CH}_4\text{/kg COD})(35{,}846\text{ kJ/m}^3\text{ CH}_4)$$

$$-(10^\circ\text{C})(4.2\text{ kJ/}^\circ\text{C}\cdot\text{kg})(10^3\text{ kg/m}^3\text{ H}_2\text{O})\left(\frac{1}{0.80}\right)$$

$$= 194\text{ kJ/m}^3$$

Similarly for a CODr of 6000, 8000 and 10,000 mg/L, the specific net energy production is 22,777, 47,869, and 72,961 kJ/m^3, respectively.

3. Determine the volume of methane produced for a flowrate of 400 m^3/d as a function of temperature using the ideal gas law.

a. Methane volume for a CODr = 3800 mg/L at a temperature of 30°C
From the ideal gas law, $V_2 = (V_1/T_1)\,T_2$

$$\text{CH}_4\text{ production at }30^\circ\text{C} = (\text{CODr})Q(0.35\text{ m}^3\text{ CH}_4\text{/kg COD})\left(\frac{273.15^\circ\text{C} + 30^\circ\text{C}}{273.15^\circ\text{C}}\right)$$

$$= (3.8\text{ kg/m}^3)(400\text{ m}^3\text{/d})(0.35\text{ m}^3\text{ CH}_4\text{/kg COD})(1.1098)$$

$$= 590.4\text{ m}^3\text{ CH}_4\text{/d}$$

b. Methane volume for a CODr = 4200 mg/L at a temperature of 30°C

$$\text{CH}_4\text{ production at }30^\circ\text{C} = (\text{CODr})Q(0.35\text{ m}^3\text{ CH}_4\text{/kg COD})\left(\frac{273.15^\circ\text{C} + 30^\circ\text{C}}{273.15^\circ\text{C}}\right)$$

$$= (4.2\text{ kg/m}^3)(400\text{ m}^3\text{/d})(0.35\text{ m}^3\text{ CH}_4\text{/kg COD})(1.1098)$$

$$= 652.6\text{ m}^3\text{ CH}_4\text{/d}$$

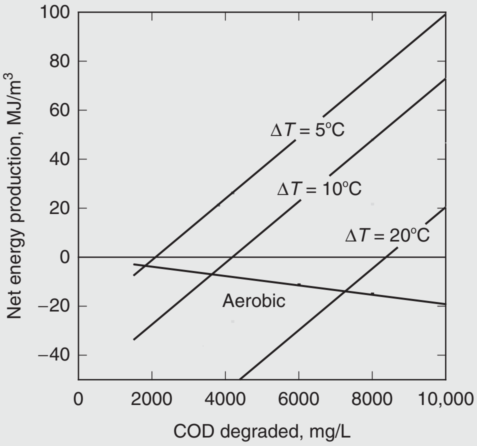
Similarly for a CODr of 6000, 8000 and 10,000 mg/L, methane production is 930, 1240, and 1550 m^3/d, respectively.

4. Prepare a summary table and a graphic plot to illustrate the results.

a. Prepare summary table

CODr, mg/L	Aeration energy, kJ/m^3	Net anaerobic treatment energy, kJ/m^3	Methane production, m^3/d
3800	−7200	−4830	590
4200	−7960	190	650
6000	−11,370	22,780	930
8000	−15,160	47,870	1240
10,000	−18,950	72,960	1550

b. Similar calculations used in Step 2a were prepared for $\Delta T = 5^\circ$C and 10°C. The net energy produced from an anaerobic process as a function of the wastewater temperature increase needed to bring the temperature up to 30°C and the amount of COD degraded is shown on the following plot.



Comment The wastewater strength and temperature is important for comparing energy balances for aerobic and anaerobic processes, where the wastewater temperature must be increased. Based on the results presented in the summary table, both the aerobic and anaerobic processes require energy input for the degradation of a wastewater with a COD of 3800 mg/L COD. It can be shown that if the amount of COD degraded is 3640 mg/L. the energy input is equal for both systems. At lower COD concentrations, the aerobic process requires less energy and the anaerobic process has less methane production.

The effect of the influent wastewater temperature and the amount of COD that can be degraded on the net energy produced by anaerobic treatment is shown in the above figure. A net positive energy production for the anaerobic process requires biodegrading 2100, 4200, and 8400 mg/L COD if it is necessary to raise the influent wastewater temperature 5, 10, and 20°C, respectively. However, heat recovery from the anaerobic effluent stream can modify these values. Even at a break even net energy production, the lower biomass yield discussed below is still a major advantage offered by anaerobic treatment. Consideration should also be given to whether alkalinity addition is necessary for the anaerobic process.

Sulfide Production

Oxidized sulfur compounds, such as sulfate, sulfite, and thiosulfate, may be present in significant concentrations in various industrial wastewaters and to some degree in municipal wastewaters. These compounds can serve as electron acceptors for sulfate-reducing bacteria, which consume organic compounds in the anaerobic reactor and produce hydrogen sulfide (H_2S). For example, using methanol as the electron donor and an f_s value of 0.05 (see Sec. 7–4 in Chap. 7), the overall reaction for the reduction of sulfate to H_2S can be illustrated by the following expression:

$$0.119\ SO_4^{2-} + 0.167CH_3OH + 0.010CO_2 + 0.003NH_4^+ + 0.003\ HCO_3^- +$$
$$0.178H^+ = 0.003C_5H_7NO_2 + 0.060H_2S + 0.060HS^- + 0.331H_2O \qquad (10–11)$$

From Eq. (10–11), the amount of COD used for sulfate reduction is 0.89 g COD/g sulfate which is higher than the reported value of 0.67 g COD/g sulfate reduced (Arceivala, 1998) and is due to the lower biomass yield coefficient associated with methanol oxidation. Based on the following stoichiometry for H_2S oxidation, 2 moles of oxygen are required per mole of H_2S, as was the case for methane oxidation,

$$H_2S + 2O_2 \rightarrow H_2SO_4 \qquad (10–12)$$

Thus, the amount of H_2S produced per unit COD is the same as that for methane (0.40 L H_2S/g COD used at 35°C).

Hydrogen sulfide is malodorous and corrosive to metals. In contrast to methane, H_2S is highly soluble in water with a solubility of 2650 mg/L at 35°C, for example.

The concentration of oxidized sulfur compounds in the influent wastewater to an anaerobic treatment process is important as high concentrations can have a negative effect on anaerobic treatment. Sulfate reducing bacteria compete with the methanogenic bacteria for COD, and, thus, can decrease the amount of methane gas production. While low concentrations of sulfide (less than 20 mg/L) are needed for optimal methanogenic activity, higher concentrations can be toxic Speece (1996, 2008). Methanogenic activity has been decreased by 50 percent or more at H_2S concentrations ranging from 50 to 250 mg/L (Arceivala, 1998). A comprehensive evaluation of the dynamics of competition between sulfate-reducing and methanogenic bacteria and toxicity effects is given in Maillacheruvu et al. (1993).

Because unionized H_2S is considered more toxic than ionized sulfide, pH is important in determining H_2S toxicity. The degree of H_2S toxicity is also complicated by the type of anaerobic biomass present (granular versus dispersed), the particular methanogenic population, and the feed COD/SO_4 ratio. With higher COD concentrations, more methane gas is produced to dilute the H_2S and transfer more of it to the gas phase. Hydrogen sulfide exists in aqueous solution as either the hydrogen sulfide gas (H_2S), the ion (HS^-) or as the sulfide ion (S^{2-}), depending on the pH of the solution, in accordance with the following equilibrium reactions:

$$H_2S \rightleftarrows HS^- + H^+ \tag{10–13}$$

$$HS^- \rightleftarrows S^{2-} + H^+ \tag{10–14}$$

Applying the law of mass action [Eqs. (10–13)] to Eq. (10–14) yields

$$\frac{[HS^-][H^+]}{[H_2S]} = K_{a1} \text{ and } \frac{[S^{2-}][H^+]}{[HS^-]} = K_{a2} \tag{10–15}$$

where K_{a1} = first acid dissociation constant, 1×10^{-7}
K_{a2} = second acid dissociation constant, $\sim 10^{-19}$ (value uncertain)

The percentage H_2S as a function of the pH can be determined using the following relationship:

$$H_2S, \% = \frac{[H_2S](100)}{[H_2S] + [HS^-]} = \frac{100}{1 + [HS^-]/H_2S} = \frac{100}{1 + [H^+]/K_{a1}} \tag{10–16}$$

Dissociation constants for hydrogen sulfide as a function of temperature are presented in Table 10–11, along with values for ammonia. As illustrated on Fig. 10–7, at a pH value of 7, at 30°C, about 60 percent of the total H_2S is present as gaseous H_2S.

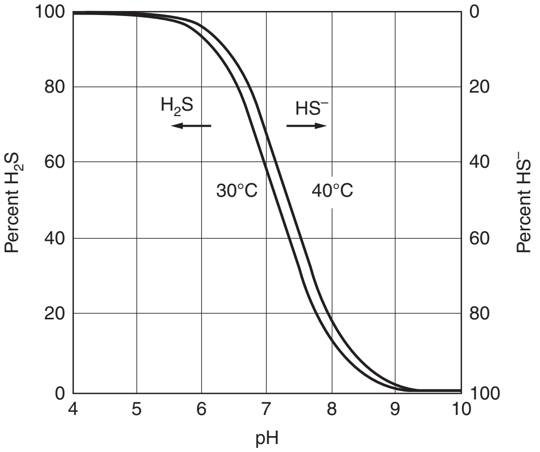
Table 10–11

Acid equilibrium constants for ammonia (NH_3) and hydrogen sulfide (H_2S)

Temperature, °C	$K_{NH_3} \times 10^{10}$, mole/L	$K_{H_2S} \times 10^7$, mole/L
0	7.28	0.262
10	6.37	0.485
20	5.84	0.862
25	5.62	1.000
30	5.49	1.480
40	5.37	2.440

Figure 10–7

Fraction of hydrogen sulfide in H_2S form as function of pH.



Ammonia Toxicity

Ammonia toxicity may be of concern for anaerobic treatment of wastewaters containing high concentrations of ammonium or proteins and/or amino acids, which can be degraded to produce ammonium. Free ammonia (NH_3), at high enough concentrations, has been found to be toxic to aceticlastic methanogens (Angelidaki and Arhing, 1994; Steinhaus et al., 2007; Lu et al., 2008), but the hydrogenotrophic organisms appear to be less sensitive (Sprott and Patel, 1986). As described in Chap. 2, ammonia is a weak acid and dissociates in water to form ammonium (NH_4^+) and hydroxyl ions. The amount of free ammonia is a function of temperature and pH. Dissociation constants for NH_3 as a function of temperature are given in Table 10–11. Based on the constants in Table 10–11, the free ammonia content decreases from 1.8 to 1.7 percent at a pH of 7.5 as the temperature increases from 20 to 35°C. At a pH of 7.8, the range is from 3.5 to 3.3 percent. Thus, the total ammonium- plus ammonia-N concentration (TAN) that can be tolerated is a function of the free ammonia toxicity concentration. Reported values for the threshold of NH_3-N toxicity range from 100 mg/L (McCarty, 1964) to 250 mg/L (Garcia and Angenent, 2009; Wilson et al., 2012). The higher values have been observed with more acclimation time, which may be due to acclimation by the aceticlasts or changes in the anaerobic process population with a shift to organisms more tolerant of free ammonia. These observations suggest that TAN concentrations of 3000 to 7000 mg/L may be tolerated in anaerobic treatment processes. With long-term acclimation non-inhibitory TAN concentrations of about 4000 mg/L have been reported by Garcia and Angement (2009) and 5000 to 8000 mg/L by van Velsen (1977) and Parkin and Miller (1982).

10–5 DESIGN CONSIDERATIONS FOR IMPLEMENTATION OF ANAEROBIC TREATMENT PROCESSES

Design of anaerobic treatment processes involves identification of process elements, determination of organic loading rate and other design parameters, and considerations for the conditions specific to anaerobic processes. When proprietary processes are considered, engineers must identify the quality and quantity of the waste stream to be treated, as well as the treatment goals. The purpose of this section is to provide a brief review of design parameters and considerations necessary to implement anaerobic treatment processes. The topics covered are (1) treatment efficiency needed, (2) general process design parameters and anaerobic degradation kinetics, and (3) other implementation issues.

Treatment Efficiency Needed

Anaerobic treatment processes are capable of very high COD conversion efficiency to methane production with minimal biomass production and relatively short hydraulic retention time reactors compared to aerobic treatment. Operation at high SRT values, greater than 20 to 50 d is possible with granular sludge, packed bed, and anaerobic membrane reactors, to provide maximum conversion of solids at temperatures above 25°C. However, the ability to meet secondary effluent discharge standards by anaerobic treatment alone is limited by high effluent suspended solids (50 to 150 mg/L) and a residual volatile fatty acid concentration that are common for anaerobic processes. These issues are magnified for anaerobic treatment at temperatures below 20°C. Some form of aerobic treatment is necessary to provide effluent polishing, either attached growth or suspended growth processes (Chong et al., 2012). For high strength wastewaters the combination of anaerobic and aerobic treatment can be very economical in terms of both capital and operating costs (Obayashi et al., 1981).

General Process Design Parameters

In the introduction to this chapter it was noted that the anaerobic digestion of wastewater treatment plant sludges is considered in Chap. 13. The material presented below is provided to serve as general guidance for comparing commercially available anaerobic technologies. Important design parameters used to size anaerobic processes include organic loading rate, hydraulic loading rate, and SRT. Biological kinetics and stoichiometric relationships between substrate removal and biomass growth are also useful for determining excess solids production and soluble substrate concentrations.

Organic Loading Rate. The volumetric organic loading rate (OLR) is the key design parameter used to determine the reactor volume for granular sludge and attached growth anaerobic treatment processes. Generally, organic loading rates for anaerobic treatment processes are significantly higher than those used for aerobic processes. Organic loading rates used in anaerobic processes can vary from 1 to 50 kg COD/m^3·d, whereas typical volumetric organic loading rates used for aerobic processes will vary from 0.5 and 3.2 kg COD/m^3·d.

Organic loading rates are affected by the type of anaerobic process used, type of wastewater, and temperature. A range of organic loading rates are included with the process descriptions for commonly used anaerobic processes in Table 10–3. The wide range of organic loading rates reported for a given anaerobic treatment technology is illustrated in a comparison of organic loading rates for the UASB, EGSB, and anaerobic contact processes on Fig. 10–8. The values for the UASB and EGSB processes are of a similar

Figure 10–8

Range of organic loading rates reported for anaerobic treatment of various wastewaters with UASB, EGSB, and anaerobic contactor processes. (Data from Tauseef et al., 2013.)

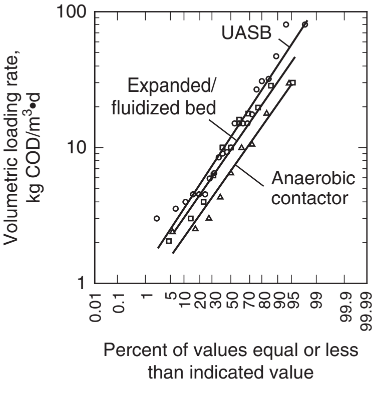


Table 10–12

Recommended UASB reactor SRTs for stable operation for treatment of domestic wastewater (van Lier et al., in Henze et al., 2011)

Temperature, °C	SRT, d
35	25
30	30
25	60
20	100
15	140

magnitude and generally higher than that used for anaerobic contactor reactors. The use of higher loadings for the granular sludge systems are in part due to the ability to carry a very high biomass concentration in the reactor as a result of the high biomass density developed in the granular sludge. The mixing regime for the EGSB and IC granular sludge systems also promote higher mass transfer of soluble substrate into the biofilm. The lower loading rates for the anaerobic contactor process may also be related to the more frequent application of this process for wastewaters with high solids concentration. The solids can limit the sludge concentration possible in the anaerobic reactor to thus require a larger reactor volume for a sufficient SRT for the necessary solids destruction, which then results in a lower organic loading rate.

Solids Retention Time. The solids retention time is a fundamental parameter for all anaerobic processes. The performance of an anaerobic treatment process is related to SRT in three ways: (1) from the basic biological kinetics discussed in Sec. 7–6, soluble substrate concentration is lower with increased SRT; (2) a higher SRT provides a greater mass of methanogenic organisms in the reactor, which is then better able to handle variations in process operating conditions to maintain a stable balance between volatile fatty acid production and utilization; and (3) the hydrolytic destruction efficiency of solids fed to an anaerobic reactor is increased at higher SRTs. At 30°C, SRT values greater than 20 d are needed for anaerobic processes for effective treatment performance. At lower temperatures much longer SRT values are needed. Recommended SRT values as a function of temperature for stable treatment of domestic wastewater by a UASB process are given in Table 10–12. Lower SRTs can be used for wastewaters that contain mainly soluble substrates.

Because of the nature of the biomass accumulation in granular sludge and attached growth anaerobic systems, it is impossible to predict the biomass concentration and SRT accurately. In addition, the substrate removal rate is not just a function of SRT as in a completely-mixed suspended growth reactor, but is also a function of substrate diffusion, mass transfer, and biofilm characteristics. Thus, the organic loading rate is the primary design parameter used for these systems, with the recognition that longer SRTs are commensurate with lower OLR values.

The use of SRT as design parameter is feasible for completely-mixed reactors such as the anaerobic contact process [see Table 10–3(f)] and the anaerobic membrane reactor [see Table 10–3(i)]. In such cases, the effect of the SRT on the effluent soluble substrate concentrations can be determined using Eq. (7–56) and appropriate biokinetic coefficients. The final step in anaerobic processing of organic material is the conversion of acetate and hydrogen to methane. The reactor acetate concentration is affected by the SRT and biokinetics of the acetoclastic methanogenic organisms. Biokinetic information for methanogenesis is summarized in Table 10–13 for different temperatures. Values for synthesis yield and specific endogenous decay coefficient coefficients for fermentation and methanogenesis

Table 10–13

Summary of biokinetic coefficients and methane stoichiometry for anaerobic treatment reactions[a]

Parameter	Unit	Value Range	Value Typical
Synthesis yield, Y_H			
Fermentation	g VSS/g COD	0.06–0.12	0.10
Methanogenisis	g VSS/g COD	0.02–0.06	0.04
Overall combined	g VSS/g COD	0.05–0.10	0.08
Decay coefficient, b_H			
Fermentation	g/g·d	0.02–0.06	0.04
Methanogenisis	g/g·d	0.01–0.04	0.02
Overall combined	g/g·d	0.02–0.04	0.03
Maximum specific growth rate, μ_m			
35°C	g/g·d	0.03–0.38	0.35
30°C	g/g·d	0.22–0.28	0.25
25°C	g/g·d	0.18–0.24	0.20
Half-velocity constant, K_S	mg COD/L	60–500	120
Methane			
Production at std. conditions	m^3/kg CODr	—	0.35
Content of gas	%	60–70	65
Energy content at std.conditions	kJ/m^3	—	38,846

[a] Tchobanoglous et al. (2003); Batstone et al. (2002).

are also included in Table 10–13. The methanogenic biokinetic values shown are based on *Methanosaeta* as the dominant organisms for acetoclastic methanogenesis, which are very common. However, under certain conditions, such as highly loaded anaerobic reactors, *Methanosarcina* may dominate. It has been shown that the maximum growth rate of *Methanosarcina* is about 2.5 times that for *Methanosaeta* at 35°C and its half-velocity coefficient for acetate utilization is about 3.5 times greater (Conklin et al., 2006).

The information given in Table 10–13 can also be used to approximate the amount of biomass and excess sludge production for completely-mixed anaerobic reactors, and for other types of anaerobic processes, if the SRT values can be estimated The use of SRT for the design of an anaerobic contact process is illustrated in Example 10–4 in Sec. 10–6.

Hydraulic Retention Time. The hydraulic retention time is directly related to the anaerobic process organic loading rates and wastewater strength:

$$\tau = S_o/\text{OLR} \tag{10–17}$$

Wastewaters with higher substrate concentration will require a longer hydraulic retention time for a given design OLR.

Process Implementation Issues

In addition to the process design consideration discussed above a number of other issues must be addressed when considering the implementation of anaerobic treatment technologies. Important issues include: solids separation, temperature management, corrosion control, and odor management. Additional issues are identified in Table 10–14.

Table 10–14

Design issues for anaerobic treatment of industrial wastewaters[a]

Design issue	Remarks
Flow equalization	
Pretreatment	TSS removal, FOG removal
Anaerobic process	
Corrosion control	Material selection
Temperature control	Preheating of waste stream, reactor heating
Chemical addition	Alkalinity control, nutrient, struvite control
Odor control	Odor removal processes (Chap. 16)
Sludge wasting	
Gas collection	Gas storage, cleaning, utilization (Chap. 17)

[a] Adapted, in part, from Totzke (2012).

Liquid-Solids Separation. Solids separation is a critical element in the application of anaerobic processes. With respect to energy intensity, liquid sludge separation processes can vary from simple evaporation and/or decanting in sludge lagoons to centrifugation and electro-dewatering, depending on the application. A range of dewatering options for digested wastewater sludge, as well as other types of sludge, is considered in Sec. 14–2 in Chap. 14. Other solids separation processes that are an integral part of one or more of the processes identified in Table 10–3 are conventional sedimentation and membranes. Where sedimentation is used some form of degasification will be needed.

Temperature Management. Anaerobic microorganisms responsible for the anaerobic treatment processes are in general temperature sensitive and anaerobic processes are often maintained at a significantly higher temperature than the ambient temperature, in the range of 30 to 36°C, or higher. Heating of the influent and the reactor may be achieved by using a heater directly in the reactor vessel, or using heat exchangers to preheat the influent. Heat in the effluent flow is used commonly to preheat the influent through a heat exchanger. Digester heating is considered in detail in Sec. 13–9 in Chap. 13.

Corrosion Control. Anaerobic treatment usually generates hydrogen sulfide and H_2S, both of which can causes corrosion of various materials. Hydrogen sulfide in the anaerobic conditions can be converted biologically to sulfuric acid in the presence of moisture, also resulting in corrosion from sulfuric acid (U.S. EPA, 1991). Appropriate materials must be used for the equipment exposed to the anaerobic condition and the pipes to convey biogas containing hydrogen sulfide. Hydrogen sulfide removal in the gas phase is practiced commonly for odor control, and it is considered in Chap. 16. The use of materials such corrosion resistant concrete, fiber-reinforced plastic (FRP), polyvinyl chloride (PVC), high density polyethylene (HDPE) and a variety of similar materials and coatings in parts of the process exposed to corrosive gases must be considered to minimize the potential risk of corrosion and minimize the use of chemicals for corrosion control.

Odor Management. Much of the early impetus for contained anaerobic process applications was related to complying with waste discharge regulations and minimizing odor complaints. With development of techniques to contain and remove odorous gases, odor has become less of the impetus but the odor control unit is a critical process element for the anaerobic treatment processes. As with the issue of corrosion, hydrogen sulfide is the most common odorous compound found in anaerobic processes, although a variety of mercaptan based odors have also been reported. The threshold values for a variety of odors are given in Sec. 16–3 in Chap. 16.

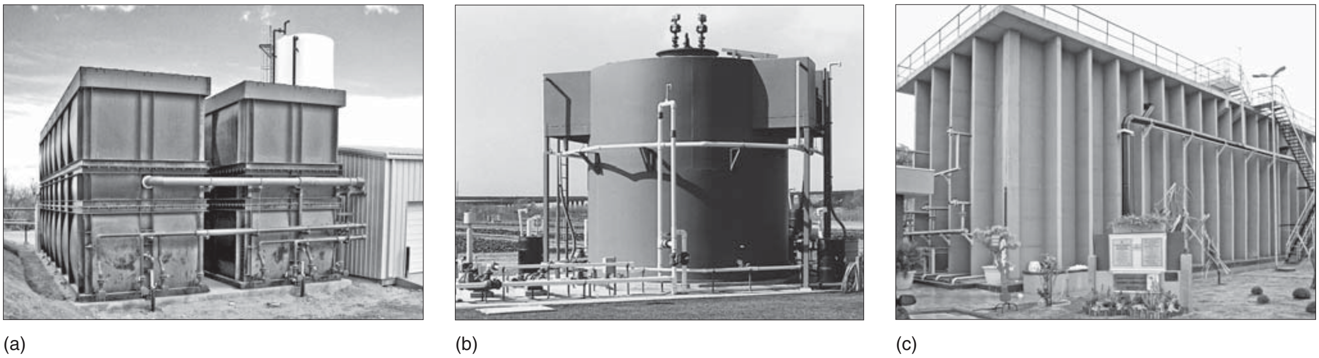
The principal methods used for the control of odors from anaerobic processes include the use of compost filters (biofilters), direct oxidation, carbon adsorption, acid scrubbing, and biotrickling filters. Relatively inexpensive, compost filters are generally used for smaller plants. In some wastewater treatment plants, odorous gases are oxidized by introducing them into sparged aeration diffusers in the activated sludge process. Views of carbon adsorption, acid scrubbing, and biotrickling filter facilities are shown on Fig. 9–9 in Chap. 9. All of these options for odor control are considered in greater detail in Sec. 16–3 in Chap. 16.

10–6 PROCESS DESIGN EXAMPLES

With the exception of the anaerobic lagoon process and anaerobic digesters used for wastewater treatment sludge, the three most common types of commercial anaerobic processes are: (1) the upflow anaerobic sludge blanket process, (2) the expanded granular sludge blanket process, and (3) the anaerobic contact process (see Table 10–4). The complete mix process which corresponds to anaerobic digestion of wastewater treatment plant sludges is considered separately in Chap. 13, along with sludge processing in Chap. 14. The purpose of this section is to illustrate the design of the upflow anaerobic sludge blanket process and the anaerobic contact process. It should be noted that because most commercial anaerobic processes illustrated in Table 10–3 are proprietary, there is little opportunity for individual process design as the treatment units are provided as a package.

Upflow Anaerobic Sludge Blanket Process

The UASB process and its evolution to the EGSB and IC processes have been described in Sec. 10–3. Some commercial and domestic installations have been illustrated previously on Figs. 10-3, 10–4, and 10–5. Some additional UASB and UASB type installations are illustrated on Fig. 10–9. The purpose of this section is to discuss key process elements



(a) (b) (c)

Figure 10–9

Granular sludge blanket anaerobic treatment systems: (a) UASB process in modular steel tanks, before insulation and hookup (courtesy of Robert Pharmer of Pharmer Engineering); (b) view of hybrid reactor equipped with internal packing above the granular sludge blanket [see Table 10-3(h)]. The exterior physical appearance of a UASB reactor without and with internal packing is similar; and (c) combined anaerobic-aerobic single-tank reactor treatment system (courtesy of Paques BV).

and process design considerations for granular sludge treatment systems. Important topics addressed are (1) the development and maintenance of the granular sludge, (2) physical design components, and (3) process design considerations.

Process Description. The heart of the UASB, EGSB, and IC, and similar processes is the development and maintenance of the dense granular sludge particles, which results in a high reactor biomass concentration. Because of the high biomass concentration these anaerobic processes can be operated at high organic loading rates. The granular sludge particle size is generally in the range of 1 to 2 mm but may range from 0.10 to 8 mm depending on the waste treated and hydraulic and gas shear forces. Particle densities are in the range of 1.0 to 1.05 g/L with settling velocities of 15 to 50 m/h (Henze et al., 2011). Because of the granulated floc formation, the solids concentration at the bottom of the reactor may range from 50 to 100 kg/m^3. Above the sludge blanket, a more diffused layer forms containing particles with lower settling velocities. The solids concentration in this layer may range from 10 to 30 kg/m^3 (Aiyuk et al., 2006).

From studies on the microbial composition of the granules it appears that the surface is made up of coccid bacteria, while rod-shaped *Methanosaeta* are dominant in the interior and provide a filamentous structural backbone for the granulation (O'Flaherty et al., 2006). The physical characteristics of the granules provide a complex microbial ecology with methane-producing organisms in close proximity to hydrogen- and acetic acid-producers. A specific methane production activity of 0.10 g COD/VSS·d in the granular particles has been reported by Seghezzo et al. (2001).

Development of Granular Sludge. Schmidt and Ahring (1996) describe a four-step process for the development of granular sludge: (1) attachment of cells to an uncolonized inert material or other cells, (2) initial adsorption of other colloidal or bacteria particles by reversible physiochemical forces, (3) irreversible attachment of microbial organisms due to microbial extracellular polymers, and (4) multiplication of cells from substrate diffusion into the granular structure. The substrate removal kinetics and mass transfer characteristics of the granular particles are similar to that described for biofilms in Sec. 7–7.

The development of a granular sludge bed can take many months, but this is normally avoided today by seeding with granular sludge wasted from other UASB reactors. The sludge blanket development is more rapid at higher temperatures (above 20°C) and with the presence of readily degradable soluble COD in the feed. The high upflow velocities washout unattached organisms and favor the growth of the dense granular particles.

Impact of Wastewater Characteristics. The development and maintenance of granular sludge is affected by the wastewater characteristics. Granulation is very successful with high carbohydrate or sugar wastewaters, but less so with wastewaters high in protein resulting in a more fluffy floc instead (Thaveesri et al., 1994). Other factors affecting the development of granulated solids are pH, divalent cations and nutrient addition (Annachhatre, 1996). The pH should be maintained near 7.0 and a recommended COD/N/P ratio during startup is 300:5:1, while a lower ratio, 600:5:1, can be used during steady-state operation. Studies have shown that within certain concentrations, ferrous iron and calcium can enhance granular sludge formation; about 300 mg/L for Fe^{2+} and about 250 mg/L for Ca^{2+} (Yu et al., 2000; Yu et al., 2001).

The presence of suspended solids in the wastewater can adversely affect granular sludge formation and density, and the affects are more pronounced at lower temperatures

Table 10–15

Recommended design considerations for the gas-solids separators for UASB reactors[a]

1. The slope of the settler bottom, i.e., the inclined wall of the gas collector, should be between 45 to 60°.
2. The surface area of the apertures between the gas collectors should not be smaller than 15 to 20 percent of the total reactor surface area.
3. The height of the gas collector should be between 1.5 to 2 m at reactor heights of 5 to 7 m.
4. A liquid gas interface should be maintained in the gas collector in order to facilitate the release and collection of gas bubbles and to combat scum layer formation.
5. The overlap of the baffles installed beneath the apertures should be 100 to 200 mm to avoid upward flowing gas bubbles entering the settler compartment.
6. Generally scum layer baffles should be installed in front of the effluent weirs.
7. The diameter of the gas exhaust pipes should be sufficient to guarantee the easy removal of the biogas from the gas collection cap, particularly also in the case where foaming occurs.
8. Anti-foam spray nozzles should be installed in the upper part of the gas cap where the treatment of the wastewater is accompanied by heavy foaming.

[a] Adapted from Malina and Pohland (1992).

due to slower solids hydrolysis rates and solids accumulation (Letting and Hulshoff-Pol, 1991; Elmitwalli et al., 2002). For wastewaters with higher influent suspended solids and with lower temperatures, a two-step process, with a UASB reactor at a lower upflow velocity for solids capture and hydrolysis prior to a final UASB reactor, may provide more stable performance and operation flexibility. At certain feed solids concentrations (above 6 g TSS/L), an anaerobic contract process may be more appropriate.

Physical Design Considerations. The main physical design considerations are the feed inlet, gas separation, gas collection, and effluent withdrawal. The gas separation and effluent withdrawal functions are done with specifically designed gas-solids separators. Specific design features of these components are provided by the suppliers of proprietary upflow granular sludge anaerobic treatment processes. Gas-solids separator designs are located at the top of the liquid layer overlying the sludge blanket zone. Designs are employed to direct and trap the rising gas bubbles into hoods or collection zones [see Table 10–3(b) and (c)], and to capture the effluent from quiescent zones that allow solids settling and return to the reactor process volume below. Methods applied to improve effluent solids capture include a UASB-hybrid design with plastic packing at the top of the reactor (Tauseef et al., 2013) and the use of lamella-type plates in the effluent settling zone (Gomec, 2010). Design considerations for gas-solids separators are listed in Table 10–15.

The feed inlet designs must provide uniform flow distribution across the bottom of the granular sludge treatment process column to avoid channeling or formation of dead zones. The distribution is even more critical for designs with lower organic loading rates, as there would be less gas production to help mix the reactor contents. As shown in Table 10–16, the recommended bottom area served by individual feed pipes is a function of the bottom sludge layer density and the organic loading rate.

Process Design Considerations. Specific process designs will be influenced by the type of upflow granular sludge process used and the experience with the particular wastewater by the anaerobic treatment system supplier. Selection of the upflow granular sludge process reactor volume will be controlled by either (1) the allowable upflow velocity

Table 10–16

Guidelines for area served by feed inlet pipes for UASB reactors as a function of sludge density and organic loading rate[a]

Sludge type	COD loading, kg/m³·d	Area per feed inlet, m²
Dense flocculent sludge, (> 40 kg TSS/m³)	< 1.0	0.5–1
	1–2	1–2
	> 2	2–3
Medium flocculent sludge, (20 to 40 kg TSS/m³)	< 1–2	1–2
	> 2	2–5
Granular sludge	1–2	0.5–1.0
	2–4	0.5–2.0
	> 4	> 2.0

[a] Adapted from Lettinga and Hulshoff Pol (1991).

or (2) the organic loading rate (OLR). Limiting values for these parameters are affected by temperature and the type of wastewater being treated.

Upflow Velocity. The upflow velocity, based on the influent flowrate, is a critical design parameter. Design upflow velocities recommended for UASB reactors are shown in Table 10–17. Upflow velocities would be much higher in EGSB and IC reactors, which are more likely applied for higher strength industrial wastewaters. When the UASB reactor is applied for domestic wastewater treatment or for wastewater with higher influent solids concentrations, a lower velocity is needed to better retain the solids to provide sufficient time for solids capture and reduction by hydrolysis. The maximum allowable upflow velocity determines the cross-sectional area of the reactor, which is the feed rate divided by the upflow velocity:

$$A = \frac{Q}{v} \tag{10–18}$$

where v = maximum design upflow superficial velocity, m/h
A = reactor cross-section area, m^2
Q = influent flowrate, m^3/h

The reactor process volume is equal to the cross-sectional area times the process reactor height (H) where V_v = reactor volume controlled by the maximum upflow velocity, m^3.

$$V_v = H(A) \tag{10–19}$$

The total reactor height is greater than this, as additional depth is added at the top for the gas-solids separator zone. The process volume must be large enough so that the allowable

Table 10–17

Design upflow velocities and reactor heights recommended for UASB reactors[a]

	Upflow velocity, m/h		Reactor height, m	
Wastewater type	Range	Typical	Range	Typical
COD near 100% soluble	1.0–3.0	1.5	6–10	8
COD partially soluble	1.0–1.25	1.0	3–7	6
Domestic wastewater	0.8–1.0	0.7	3–5	5

[a] Adapted from Lettinga and Hulshoff Pol (1991).

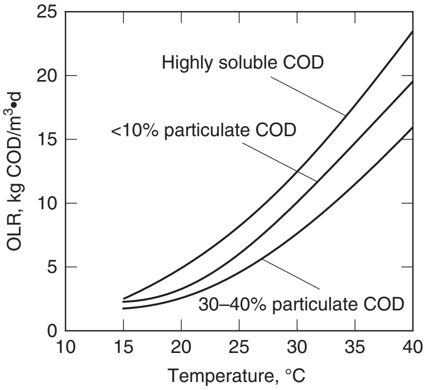


Figure 10–10

Effect of temperature on organic loading rate for UASB process (Henze et al., 2011).

reactor organic loading rate is not exceeded. The reactor design is ultimately controlled by either the maximum allowable upflow velocity or by the required organic loading rate. For weaker wastewaters the upflow velocity will be the controlling parameter.

Organic Loading Rate. As discussed in Sec. 10–5, a wide range of organic loading rates have been applied for upflow granular sludge processes, depending on the wastewater characteristics, reactor type, and temperature. In addition, Lettinga and Hulshoff-Pol (1991) point out that higher organic loadings can be used if higher effluent TSS concentrations are acceptable and also that higher loadings can be used for wastewaters with a lower fraction of particulate COD. As shown in Table 10–3, organic loading rates for UASB systems may range from 5 to 15 kg COD/ m^3·d and from 10 to 40 kg COD/ m^3·d for EGSB systems. An example of the effect of temperature on organic loading rate is shown on Fig. 10–10. For a highly soluble wastewater the organic loading rate is reduced by a factor of 5.0 for operation at 15 versus 30°C and by a factor of 4.3 for a wastewater with 30–40% particulate COD.

The reactor process volume is related to the organic loading rate as follows:

$$V_{\mathrm{OLR}} = \frac{Q(S_o)}{\mathrm{OLR}} \tag{10–20}$$

where V_{OLR} = reactor process volume controlled by the organic loading rate, m^3. The process design for a UASB treatment process is illustrated in Example 10–3.

EXAMPLE 10–3 **UASB Treatment Process Design** Determine the following for a UASB treatment process used to treat a sugar beet wastewater, with the characteristic given below, to achieve 90 percent COD removal:

a. Reactor process volume
b. Process hydraulic retention time
c. Reactor dimensions
d. Reactor SRT
e. Daily sludge production rate in kg VSS/d
f. Excess sludge waste volume in m^3/d
g. Methane gas production rate in m^3/d
h. Total gas production rate in m^3/d
i. Energy available from methane production in kJ/d
j. Alkalinity requirements

Wastewater characteristics:

Item	Unit	Value
Flowrate	m^3/d	500
COD	g/m^3	12,000
TSS	g/m^3	600
nbVSS	g/m^3	500
Alkalinity	g/m^3 as $CaCO_3$	500
Temperature	°C	25

Use the design parameters given below and typical values from Table 10–13:

1. From Table 10–14
   $Y_H = 0.08$ g VSS/g COD
   $b_H = 0.03$ g VSS/g VSS·d,
2. $f_d = 0.10$ g VSS cell debris/g VSS biomass decay
3. Methane production at 0°C = 0.35 L CH_4/g COD
4. Energy content of methane at 0°C = 38,846 kJ/m^3
5. Percent methane in gas phase = 65%
6. Height of reactor process volume = 8 m
4. Height of clear zone above the sludge blanket = 0.50 m
8. Height of gas-solids separator = 2.5 m
9. Reactor length:width ratio = 2.0
10. Maximum reactor upflow velocity = 1.0 m/h
11. Average solids concentration in process volume = 30 kg VSS/m^3

Based on data from the treatment of sugar beet wastewater in other UASB facilities, 90 percent COD removal at 25°C, can be achieved with a design organic loading rate of 8.0 kg COD/m^3·d. The wastewater is mainly soluble containing carbohydrate compounds, and a granular sludge is expected. Assume an effluent VSS concentration of 120 g/m^3.

Solution

1. Determine the reactor process volume.
   a. Determine the reactor volume based on the maximum upflow velocity Eq. (10–18) and Eq. (10–19)

$$A = \frac{Q}{v} = \frac{(500\ \text{m}^3/\text{d})}{(1.0\ \text{m/h})(24\ \text{h/d})} = 20.8\ \text{m}^2$$

$$V_v = A(H) = 20.8\ \text{m}^2(8\ \text{m}) = 166.7\ \text{m}^3$$

   b. Determine the reactor volume based on the organic loading rate.
   From Eq. (10–20)

$$V_{\text{OLR}} = \frac{Q\,S_o}{\text{OLR}} = \frac{(500\ \text{m}^3/\text{d})(12\ \text{kg COD/m}^3)}{(8.0\ \text{kg COD/m}^3\cdot\text{d})} = 750\ \text{m}^3$$

   The organic loading rate controls the reactor volume design.
2. Determine the process hydraulic retention time.

$$\frac{V}{Q} = \frac{750\ \text{m}^3}{(500\ \text{m}^3/\text{d})} = 1.5\ \text{d}$$

3. Determine the reactor dimensions.
   a. Reactor area = $(L)(W) = 2W(W) = 2W^2$

$$\text{Area} = \frac{V}{H} = \frac{750\ \text{m}^3}{8\ \text{m}} = 93.75\ \text{m}^2$$

$2W^2 = 93.75\ \text{m}^2$, $W = 6.85$ m, $L = 13.7$ m

b. Total reactor height

H_T = processing hgt + clear zone hgt + separator hgt

$H_T = 8\ \text{m} + 0.5\ \text{m} + 2.5\ \text{m} = 11\ \text{m}$

Reactor dimensions = 13.7 m × 6.85 m × 11 m

4. Determine the reactor SRT.

a. From Eq. (7–56), $X(V) = P_x\ \text{SRT}$

b. From Eq. (8–20),

$$P_x = \frac{Q(Y_\text{H})(S_o - S)}{1 + b_\text{H}(\text{SRT})} + \frac{f_d b_\text{H}(Q)(Y_\text{H})(S_o - S)(\text{SRT})}{1 + b_\text{H}(\text{SRT})} + (\text{nbVSS})Q$$

c. Substituting Eq. (8–20) into Eq. (7–56),

$$X_\text{VSS}(V) = \frac{Q(Y_\text{H})(S_o - S)(\text{SRT})[1 + f_d b_\text{H}(\text{SRT})]}{1 + b_\text{H}(\text{SRT})} + (\text{nbVSS})\text{Q}(\text{SRT})$$

$$S_o - S = 0.90\ S_o = 0.90(12{,}000\ \text{g COD/m}^3)$$

$$S_o - S = 10{,}800\ \text{g COD/m}^3$$

$$(30{,}000\ \text{g VSS/m}^3)(750\ \text{m}^3) =$$

$$\frac{(500\ \text{m}^3/\text{d})(0.08\ \text{g VSS/g COD})(10{,}800\ \text{g COD/m}^3)(\text{SRT})[1 + 0.10(0.03\ \text{g/g}\cdot\text{d})(\text{SRT})]}{1 + (0.03\ \text{g/g}\cdot\text{d})(\text{SRT})}$$

$$+\ 500\ \text{g VSS/m}^3\ (500\ \text{m}^3/\text{d})\text{SRT}$$

Solving: SRT = 50.2 d

5. Determine the daily sludge production rate from Eq. (7–56).

$$P_{X,\text{VSS}} = \frac{X_\text{VSS}(V)}{\text{SRT}}$$

$$= \frac{(30{,}000\ \text{g VSS/m}^3)(750\ \text{m}^3)(1\ \text{kg}/10^3\ \text{g})}{50.2\ \text{d}}$$

$$P_{X,\text{VSS}} = 448.2\ \text{kg VSS/d}$$

6. Determine the excess sludge daily waste volume.

$$P_{X,\text{VSS}} = Q(X_e) + (X)Q_W$$

$$Q_W = \frac{P_{X,\text{VSS}} - Q(X_e)}{X}$$

$$= \frac{(448{,}200\ \text{g VSS/d}) - (500\ \text{m}^3/\text{d})(0.120\ \text{g VSS/m}^3)}{(30{,}000\ \text{g VSS/m}^3)}$$

$$Q_W = 14.9\ \text{m}^3/\text{d}$$

7. Determine the methane gas production rate by COD balance.

COD removal = methane COD + biomass COD

$$P_{X,\text{bio}} = P_{X,\text{VSS}} - \text{nbVSS(Q)}$$

$$P_{X,\,\text{bio}} = 448{,}200 \text{ g VSS/d} - 500 \text{ g VSS/m}^3 \text{ (500 m}^3\text{/d)}$$

$$P_{X,\,\text{bio}} = 448{,}200 \text{ g VSS/d} - 250{,}000 \text{ g VSS/d}$$

$$= 198{,}200 \text{ g VSS/d}$$

Methane COD = COD removed − biomass COD

CH_4 COD/d

$$= 500 \text{ m}^3\text{/d}(10{,}800 \text{ g COD/m}^3) - 1.42 \text{ g COD/g VSS (198,200 g VSS/d)}$$

$$CH_4 \text{ COD} = 5{,}118{,}556 \text{ g } CH_4 \text{ COD/d}$$

At standard conditions, methane production rate =

$$(5{,}118{,}556 \text{ g } CH_4 \text{ COD/d})(0.35 \text{ L } CH_4\text{/g COD})(1 \text{ m}^3/10^3 \text{ L})$$

$$= 1719.5 \text{ m}^3 \text{ } CH_4\text{/d at } 0°\text{C}$$

methane production rate at 25°C =

$$(1719.5 \text{ m}^3 \text{ } CH_4\text{/d})\frac{(273.15 + 25)°\text{C}}{273.15°\text{C}} = 1955 \text{ m}^3 \text{ } CH_4\text{/d}$$

8. Determine the total gas production rate; Percent methane = 65%

$$\text{Total gas production rate} = \frac{(1955 \text{ m}^3 \text{ } CH_4\text{d})}{(0.65 \text{ m}^3 \text{ } CH_4\text{/m}^3 \text{ gas})} = 3008 \text{ m}^3 \text{ gas/d}$$

9. Energy content of methane production

$$\text{Energy} = (38{,}846 \text{ kJ/m}^3)(1719.5 \text{ m}^3 \text{ } CH_4\text{/d}) = 66.8 \times 10^6 \text{ kJ/d}$$

10. Determine alkalinity requirements.

Assume pH = 7.0

From Table 10–7 at pH = 7.0, T = 25°C,

percent CO_2 = 35%, alkalinity = 2678 g/m^3 as $CaCO_3$

Influent alkalinity = 500 g/m^3 as $CaCO_3$

$$\text{Alkalinity needed} = (2678 - 500)\text{g/m}^3 \text{ as } CaCO_3$$

$$= 2178 \text{ g/m}^3 \text{ as } CaCO_3$$

$$\text{Alkalinity in kg/d} = (2178 \text{ g/m}^3)(500 \text{ m}^3\text{/d})(1 \text{ kg}/10^3 \text{ g})$$

$$= 1098 \text{ kg/d}$$

11. Summary of results.

Parameter	Unit	Value
Reactor process volume	m^3	750.0
Reactor total height	m	11.0
Reactor LxW	m	13.7 × 6.85
Hydraulic retention time	d	1.5

(continued)

Parameter	Unit	Value
SRT	d	50.2
Excess waste sludge	m^3/d	14.9
Total gas production rate	m^3/d	3008
Methane production rate	m^3/d	1955
Energy production rate	kJ/d	66.8×10^6
Alkalinity needed as $CaCO_3$	kg/d	1089

Comment A significant amount of energy is produced daily in the form of methane gas. If the gas can be used as an energy source by the industrial facility, it could help to offset the cost of adding a considerable amount of alkalinity to maintain the anaerobic reactor pH near 7.

Anaerobic Contact Process

The anaerobic contact process is a completely-mixed reactor system with suspended/flocculating anaerobic biomass and a liquid-solids separation step for biomass capture and recycle.

Process Description. The process flow diagram for the ANCP is illustrated in Table 10–3(f). As shown, the anaerobic contact process overcomes the disadvantages of equal values of hydraulic retention time and SRT in the completely mixed process. Biomass is separated and returned to the completely mixed or contact reactor so that the process SRT is longer than the hydraulic retention time. By separating the hydraulic retention time and SRT, the anaerobic reactor volume can be reduced. Gravity separation is the most common approach for solids separation and thickening prior to sludge recycle, however, the success is dependent on the settling properties of the anaerobic reactor solids.

Because the reactor sludge contains gas produced in the anaerobic process and gas production can continue in the separation process, solids-liquid separation can be inefficient and unpredictable. Various methods have been used to minimize the effect of trapped gas bubbles in the sludge settling step. These include gas stripping by agitation or vacuum degasification, inclined plate separators, and the use of coagulant chemicals. Clarifier hydraulic application rates range from 0.5 to 1.0 m/h. Practical reactor MLVSS concentrations are 4000 to 8000 mg/L (Malina and Pohland, 1992). Organic loading rates are typically $\leq$ 4.0 kg COD/m^3·d and SRTs range from 15 to 30 d as indicted in Table 10–3(f).

Design Considerations for Anaerobic Contact Process. The anaerobic contact process may be designed in a manner similar to completely mixed aerobic activated sludge processes, because the hydraulic regime and biomass concentration can be reasonably defined. The design procedure is as follows:

1. Select an SRT to achieve a given effluent concentration and percent COD removal.
2. Determine the daily solids production and mass of solids in the system to maintain the desired SRT.
3. Select the expected solids concentration in the reactor and determine the reactor volume.
4. Determine the gas production rate.
5. Determine the amount of excess sludge wasted and the nutrient needs.
6. Check the volumetric organic loading rate.
7. Determine alkalinity needs.

These same design considerations apply to other types of anaerobic treatment processes, with the main difference being the need to rely on using organic loading rates instead of SRT to size the reactor volume.

Information in Table 10–13 provides a summary of kinetic coefficients and other design values that may be used to design an anaerobic contactor process treating wastewater that is comprised of mostly soluble biodegradable COD. For wastewater with high solids concentrations, the design methods presented in Chap. 13 for anaerobic digestion may be applicable. Laboratory treatability studies or pilot plant testing is normally recommended for wastewater containing soluble and particulate constituents that are significantly different from past experience with anaerobic degradation of other wastewaters. The design of an anaerobic contact process is presented in Example 10–4.

EXAMPLE 10–4 **Suspended Growth Anaerobic Contact Reactor Process** Determine the reactor volume and hydraulic retention time, the gas production rate and energy available, the solids production rate, and the amount of alkalinity and nutrient addition needed for an anaerobic contact process [see Table 10–3(f)] treating the following wastewaters to achieve 90 percent COD removal.

Wastewater characteristics:

Item	Unit	Value
Flowrate	m^3/d	500
COD	g/m^3	6000
Soluble COD	g/m^3	4000
COD/VSS ratio	g/g	1.8
Degradable fraction of VSS	%	80
Nitrogen	g/m^3	10
Phosphorus	g/m^3	20
Alkalinity	g $CaCO_3/m^3$	500
Temperature	°C	25

Design assumptions:

1. Effluent VSS concentration = 150 g/m^3.
2. Factor of safety for design SRT = 3.0
3. f_d = 0.15 g VSS cell debris /g VSS biomass decay
4. At SRT $\geq$ 30, >99% of degradable VSS is transformed
5. MLVSS = 6000 g/m^3
6. Settling rate = 24 m/d
7. Gas composition = 65% CH_4 and 35% CO_2
8. Use kinetic coefficients and methane production assumptions from Table 10–13.
9. Biomass nutrient content = 12% N and 2.4% P

Solution

1. Determine design SRT at 25°C.

   At 90 percent COD removal the effluent COD is:

   = (1.0 – 0.90) (6000 mg/L) = 600 g/m^3

   The assumed effluent VSS concentration equals 150 g/m^3.

Effluent COD from VSS = (150 g/m^{3}L) 1.8 g COD/g VSS

= 270 g/m^3

Allowable effluent soluble COD = (600 – 270) g/m^3

= 330 g/m^3

Solving for SRT in Eq. (7–46) and substituting $\mu_{\max} = Y_H k$;

$$S = \frac{K_s[1 + b_H(\text{SRT})]}{\text{SRT}(\mu_{\max} - b_H) - 1}$$

$$\text{SRT} = \left[\frac{\mu_{\max}(S)}{K_s + S} - b_H\right]^{-1}$$

Use kinetic coefficients from Table 10–13,

$\mu_{\max}$ = 0.20 g/g·d

K_s = 120 g/m^3

b_H = 0.03 g/g·d

$$\text{SRT} = \left[\frac{(0.20\text{ g/g·d})(330\text{ g COD/m}^3)}{(120 + 330)\text{g COD m}^3} - (0.03\text{ g/g·d})\right]^{-1} = 8.6\text{ d}$$

With a safety of 3.0

Minimal design SRT = 3.0 (8.6) = 25.7 d

Use SRT = 30 d to complete degradable VSS transformation

2. Determine sludge production rate.

Calculate nondegraded VSS concentration

Nonsoluble COD = (6000 − 4000) g/m^3

= 2000 g/m^3

Nonsoluble COD as VSS = (2000 g/m^3 COD) / (1.8 g COD/g VSS)

= 1110 g/m^3 VSS

Degradable fraction of VSS = 0.8 (given)

Nondegraded VSS = 0.20 (1110) = 222 g VSS/m^3

Use Eq. (8–20) to determine solids production:

$$P_{X,\text{VSS}} = \frac{Q(Y_H)(S_o - S)}{1 + b_H(\text{SRT})} + \frac{f_d b_H(Q)(Y_H)(S_o - S)(\text{SRT})}{1 + b_H(\text{SRT})} + (\text{nbVSS})Q$$

$S_o - S$ = COD degraded

= Influent COD − nondegraded VSS COD − effluent soluble COD

= 6000 g COD/m^3 − 222 g VSS/m^3 −330 g COD/m^3 = 5270 g COD/m^3

Use following coefficients from Table 10–14 and assume $f_d = 0.15$

Y_H = 0.08 g VSS/g COD

b_H = 0.03 g/g·d

$$P_{X,\text{VSS}} = \frac{Q(Y_H)(S_o - S)[1 + f_d b_H(\text{SRT})]}{1 + b_H(\text{SRT})} + (\text{nbVSS})Q$$

$$P_{X,\text{VSS}} = \frac{(500\ \text{m}^3/\text{d})(0.08\ \text{g VSS/g COD})(5270\ \text{g COD/m}^3)[1 + 0.15(0.03\ \text{g/g}\cdot\text{d})(30.0\ \text{d})]}{[1 + (0.03\ \text{g/g}\cdot\text{d})(30.0\ \text{d})]}$$

$$+ (222\ \text{g VSS/m}^3)(500\ \text{m}^3/\text{d})$$

$$P_{X,\text{VSS}} = 125{,}925\ \text{g VSS/d} + 111{,}000\ \text{g VSS/d} = 236{,}925\ \text{g VSS/d}$$

3. Determine reactor volume and τ.
   a. Determine the volume using Eq (7–56).

$$V = \frac{(P_{X,\text{VSS}})\text{SRT}}{\text{MLVSS}} = \frac{(236{,}925\ \text{g VSS/d})(30\ \text{d})}{6000\ \text{g/m}^3} = 1184.6\ \text{m}^3$$

   b. Determine the hydraulic detention time, τ.

$$\tau = \frac{V}{Q} = \frac{1184.6\ \text{m}^3}{(500\ \text{m}^3/\text{d})} = 2.4\ \text{d}$$

4. Determine the methane and total gas production rate and energy production rates.
   a. Determine the methane gas production rate.

From Table 10–13, 0.35 $\text{m}^3\ \text{CH}_4$/kg COD at 0°C

COD removal = methane COD + biomass COD

biomass COD = (1.42 g COD/g VSS)($P_{x,\text{bio}}$)

$P_{x,\text{bio}}$ = first term in $P_{X,\text{VSS}}$ calculation = 125,925 g VSS/d

Methane COD = COD removed − biomass COD

CH_4 COD/d

$= 500\ \text{m}^3/\text{d}\ (5270\ \text{g COD/m}^3) - 1.42\ \text{g COD/g VSS}\ (125{,}925\ \text{g VSS/d})$

$= 2{,}456{,}186\ \text{g CH}_4\ \text{COD/d}$

At standard conditions, methane production rate =

$(2{,}456{,}186\ \text{g CH}_4\ \text{COD/d})(0.35\ \text{L CH}_4/\text{g COD})(1\ \text{m}^3/10^3\ \text{L})$

$= 859.7\ \text{m}^3\ \text{CH}_4/\text{d}$ at 0°C

Methane production rate at 25°C =

$$(859.7\ \text{m}^3\ \text{CH}_4/\text{d})\frac{(273.15 + 25)^\circ\text{C}}{273.15^\circ\text{C}} = 938.3\ \text{m}^3\ \text{CH}_4/\text{d}$$

   b. Determine the total gas production rate.

Gas composition = 65% methane (given)

$$\text{Total gas production rate at 25°C} = \frac{(938.3\ \text{m}^3\ \text{CH}_4/\text{d})}{(0.65\ \text{m}^3\ \text{CH}_4/\text{m}^3\ \text{gas})} = 1443.6\ \text{m}^3\ \text{gas/d}$$

(Note gas rate = 1443.6/500 = 2.9 times liquid flowrate.)

c. Determine the energy production rate.

From Table 10–13, energy content of methane = 38,846 kJ/m^3 at 0°C.

Energy production rate = (859.7 m^3 CH_4/d)(38,846 kJ/m^3) = 33.4 × 10^6 kJ/d

5. Determine nutrient requirements.

Biomass production rate = 125,925 gVSS/d

Given: biomass N = 12% and P = 2.4% of VSS

N required = (125,925)(0.12) = 15,111 g/d

P required = (125,925)(0.024) = 3022 g/d

Influent nutrients:

N = (10 g/m^3)(500 m^3/d) = 5000 g/d

P = (20 g/m^3)(500 m^3/d) = 10,000 g/d

There is sufficient phosphorus in the influent, but nitrogen must be added.

N addition = (15,111 – 5000) g N/d

= 10,111 g N/d

= 10.1 kg N/d

6. Determine alkalinity requirement.
From Table 10–7 at pH = 7.0, T = 25°C, percent CO_2 = 35, alkalinity = 2678 g/m^3 as $CaCO_3$

Influent alkalinity = 500 g/m^3 as $CaCO_3$

Alkalinity needed = (2678 − 500) g/m^3 as $CaCO_3$

= 2178 g/m^3 as $CaCO_3$

$$\text{As NaHCO}_3 = \left[\frac{(2178 \text{ g as CaCO}_3/\text{m}^3)}{(50 \text{ mg/meq CaCO}_3)}\right](84 \text{ mg NaHCO}_3/\text{meq}) = 3659 \text{ g NaHCO}_3/\text{m}^3$$

$NaHCO_3$/d = (3659 g/m^3)(500 m^3/d)(1 kg/10^3 g) = 1830 kg/d

7. Determine clarifier diameter.

(Assume degasifier used before clarifier)

$$\text{Area} = \frac{(Q, \text{m}^3/\text{d})}{(\text{settling rate, m/d})} = \frac{(500 \text{ m}^3/\text{d})}{(24 \text{ m/d})} = 20.83 \text{ m}^2$$

Diameter = 5.2 m

Comments A considerable amount of energy (i.e., kJ) is generated by the production of methane (CH_4). The methane could be used to heat the anaerobic process, which would provide more rapid degradation and, thus, reduce the anaerobic bioreactor size.

Use of Simulation Models

The relatively straightforward design procedures described above can be used to obtain a reasonable estimate of reactor volume requirements, effluent soluble bCOD concentration, and gas production. However, as discussed in Sec. 8–5, in Chap. 8, for aerobic activated sludge processes, computer aided mechanistic dynamic simulation models have been developed and applied for anaerobic reactors. The most common is the model developed for anaerobic sludge digestion, termed ADM1, by an International Water Association task group (Batstone et al., 2002a). ADM1 has also been applied to other wastes with high solids contents such as pig slurry wastes (Girault et al., 2011) and waste mixtures of biodegradable soluble and particulate COD (Batstone et al., 2002b; Fezzani and Cheikh, 2008).

The ADM1 model follows the fate of feed COD according to the schematic given on Fig. 7–26 and also accounts for inert nondegradable soluble COD and volatile solids. Changes in concentration of biodegradable solid and dissolved COD components of the waste and intermediate degradation products are determined by the application of biokinetic equations along the various degradation pathways that include the type of microorganisms involved and effects of pH and temperature. The particulate COD is considered to be a homogeneous mixture of carbohydrates, proteins, and lipids. Kinetic relationships described a disintegration rate of particles to a production rate of carbohydrate, protein and lipid components. Another set of equations is used to describe the rate of hydrolysis of carbohydrates, proteins and lipids to sugars, amino acids, and long chain fatty acids (LCFA), respectively. Monod-based biokinetic equations are then applied for acidogenesis of sugars and amino acids to volatile fatty acids (VFA) and hydrogen and acetogenesis of LCFA and VFAs to acetate. Separate Monod-based kinetics are used to describe methanogenesis by acetate and hydrogen utilizing organisms.

The model also includes physicochemical processes to (1) calculate the reactor pH as a function of alkalinity and VFA concentrations and gas phase carbon dioxide concentration and (2) gas-liquid transfer of carbon dioxide, methane and hydrogen sulfide generated in the process. The model is applied as a series of differential equations encompassing 32 dynamic concentration state variables. Application of the model is most useful for dynamic simulations to analyze changes in VFA and hydrogen concentrations following transient feed and loading variations to evaluate conditions that can result in an imbalance between VFA production rates and methanogenesis acetate utilization rates that could lead to digester instability (Straub et al., 2006).

10–7 CODIGESTION OF ORGANIC WASTES WITH MUNICIPAL SLUDGE

Codigestion refers to an anaerobic digestion process in which different types of wastes from at least two different sources are combined and treated in a common anaerobic reactor. The main practice of codigestion occurs in municipal anaerobic sludge digesters. If there is excess capacity in municipal facility anaerobic digesters, codigestion of other wastes in the community can be an attractive means for increasing the methane production and energy available for the facility or for other community uses such as gas powered vehicles. Typical applications of codigestion have been for processing FOG wastes and food wastes. Codigestion applications with municipal sludge digesters is discussed in Chap. 13.

Benefits of Codigestion. A major benefit of codigestion is the ability to turn a waste product into a source of energy, while at the same time reducing the region carbon footprint by the replacement of other fuels with methane from the anaerobic conversion of the waste material and curtailing the carbon dioxide release from the waste decomposition in other ways (Rosso and Stenstrom, 2008). A variety of wastes are available in local communities for processing in codigestion. Examples are given in the list of wastes shown in Table 10–18 from a modest sized community that were found to be highly amenable for codigestion (Muller et al., 2009).

Table 10–18

Example of types of highly biodegradable wastes evaluated for a municipal codigestion application[a]

Description of wastes	Comment
Flower and vegetable wastes	Requires nutrients and alkalinity
Blood product from animal processing	High in nitrogen
Dissolved air flotation sludge from rendering plant	High in nitrogen
Brown grease from grease traps	Difficult to degraded alone, requires nutrients and alkalinity
Chili, soup and salad dressing production wastes	Requires nutrients and alkalinity
Confectionary sugar wastes	Requires nutrients and alkalinity
Beer, wine, soda and juice production wastes	Requires nutrients and alkalinity

[a] Muller et al. (2009).

Codigestion can also be an attractive alternative for various food processing operations in lieu of constructing their own onsite anaerobic treatment process. The advantages include economies of scale for the facility, the elimination of onsite operational requirements, and the elimination of operating cost for the addition of alkalinity and nutrients for high carbohydrate wastes. Without a sufficient amount of protein or amino acids in the waste to produce ammonium bicarbonate at a level needed to maintain a proper pH in anaerobic treatment, the cost for alkalinity addition can be prohibitive.

Operation of Digestion Process. Alkalinity production in municipal anaerobic digesters is normally sufficient due to the degradation of organic nitrogen in primary sludge and waste activated sludge. In some cases, such as oily wastewaters (Jeganathan et al., 2006), the waste is difficult to treat by itself, but can be handled within proper proportions in municipal anaerobic digesters. The economical impact to the municipal facility must also be considered and includes costs for feed stock management, storage, and pretreatment such as screening or heating, and increased operational requirements for the codigestion operation.

PROBLEMS AND DISCUSSION TOPICS

10–1 The alkalinity concentration in an anaerobic suspended growth reactor operated at 30°C, is 2200, 2600, or 2800 mg as $CaCO_3$/L (value to be selected by instructor). Assuming equilibrium between the liquid and gas phase with a CO_2 content in the gas phase of 35 percent, determine the reactor pH.

10–2 An industrial wastewater with a flowrate of 4000 m^3/d has a soluble degradable COD concentration of 10,000, 5000, and 2500 mg/L (value to be selected by instructor), 20°C temperature, and 200 mg/L alkalinity concentration as $CaCO_3$. Determine and compare the net operating costs or revenue for anaerobic versus aerobic treatment based on the following key parameters and assumptions (labor and maintenance costs are omitted here) for each:

Anaerobic process:
Anaerobic operating cost items are related to raising the liquid temperature, and adding alkalinity, versus the revenue from methane production. The following assumptions apply:

1. Reactor temperature = 35°C
2. Heat exchanger recovery efficiency for raising liquid temperature = 80 percent
3. COD removal efficiency = 95 percent
4. CO_2 of gas phase = 35 percent and pH = 7.0

5. Value of methane $= \$5/10^6$ kJ
6. Alkalinity is provided as $NaHCO_3$ at \$0.90/kg

Aerobic

Major aerobic treatment operating cost items are energy for aeration and sludge processing and disposal. The following assumptions apply:

1. COD removal efficiency = 99 percent
2. gO_2/g COD removal = 1.2
3. Actual aeration efficiency = 1.2 kgO_2/kWh
4. Electricity costs = \$0.08/kWh
5. Net sludge production = 0.3 g TSS/g COD removed
6. Sludge processing/disposal cost = \$0.10/kg dry solids

10–3 A wastewater has a daily average flowrate of 1000, 2000, or 3000 m^3/d (value to be selected by instructor) and 4000 mg/L of an organic substance with the following approximate composition: $C_{50}H_{75}O_{20}N_5S$. For anaerobic treatment at 95 percent degradation determine (a) the alkalinity production in mg/L as $CaCO_3$; and (b) the approximate mole fraction of CO_2, CH_4, and H_2S in the gas phase.

10–4 An industrial wastewater has an average flowrate of 2000 m^3/d, an influent COD concentration of 4000, 6000, or 8000 mg/L (value to be selected by instructor), and influent sulfate concentration of 500 mg/L. The percent of COD degraded in an anaerobic treatment process at 35°C is 95 percent, and 98 percent of the sulfate is reduced. Determine (a) the amount of methane produced in m^3/d; (b) the amount of methane produced in m^3/d, if the sulfate reduction is not accounted for; and (c) the amount of H_2S in the gas phase at a reactor pH value of 7.0.

10–5 A suspended growth anaerobic reactor is operated at an SRT of 30 d at a temperature of 30°C. On a given day, the methane gas production rate (m^3/d) decreases by 30 percent. List at least four possible causes that should be investigated and briefly explain the mechanism behind each one.

10–6 A 100 percent soluble industrial wastewater is to be treated by an anaerobic contact process consisting of a mixed covered reactor, a degasifier, and gravity settling. The effluent TSS concentration from the clarifier is 120 mg/L. For the following wastewater characteristics and design assumptions, determine and compare the following design parameters for treatment at 25 and 35°C to meet an effluent soluble COD concentration of ≤ 50 mg/L.

a. The design SRT, d
b. The reactor volume, m^3
c. The reactor hydraulic detention time τ, d
d. The methane gas production rate, m^3/d
e. The total gas production rate, m^3/d
f. The amount of solids and to be manually wasted daily, kg/d
g. The nitrogen and phosphorus requirements, kg/d.

Wastewater characteristics:

Parameter	Unit	Value
Flowrate	m^3/d	2000
Degradable COD	mg/L	

(*continued*)

(*Continued*)

Parameter	Unit	Value
Wastewater 1		4000
Wastewater 2		6000
Wastewater 3		8000
Percent sCOD	%	100
Alkalinity	mg/L as $CaCO_3$	500

Note: Wastewater 1, 2 or 3 to be selected by instructor.

Other design assumptions:

1. Reactor MLSS concentration = 5000 mg/L
2. Factor of safety for SRT = 1.5
3. VSS/TSS ratio = 0.85
4. f_d = 0.15 g VSS cell debris/g VSS biomass decay
5. Gas phase methane = 65 percent
6. Nitrogen content of biomass = 0.12 g N/g VSS5
7. Phosphorus content of biomass = 0.02 g P/g VSS
8. Use the appropriate kinetic coefficients and design information provided in Table 10–13

10–7 An anaerobic process is being considered for the treatment of a soluble industrial wastewater at 30°C. A design SRT of 30 d is required to provide the desired level of 95 percent soluble COD degradation. An effluent VSS concentration of 100, 150 or 200 mg/L (value to be selected by instructor) from biomass growth is assumed. Using the appropriate kinetic coefficient values from Table 10–13, determine the influent COD concentration that must be present to allow operation at a 30-d SRT, if all the biomass wasted is via the effluent solids losses.

10–8 Design a single UASB reactor to treat an industrial wastewater at 30°C with the following wastewater characteristics and using the assumptions given below. Assume 97 percent degradation of the soluble COD, 60 percent particulate COD degradation, and an effluent VSS concentration of 200 mg/L. Using the given information, determine:

1. The reactor liquid volume, m^3
2. The reactor area (assume a circular reactor will be used), m^2
3. The reactor area diameter and total height, m
4. The hydraulic retention time, d
5. The average SRT, d
6. The amount of solids to be manually wasted daily, kg VSS/d
7. The methane gas production rate, m^3/d
8. The energy value of the gas, kJ/d
9. The alkalinity requirement, kg as $CaCO_3/d$

Design Assumptions:

1. Kinetic coefficients from Table 10–13.
2. f_d = 0.15 g VSS/g VSS biomass decayed
3. Maximum organic loading rate = 6.0 kg $COD/m^3 \cdot d$
4. Maximum upflow velocity = 0.50 m/h
5. pH = 7.0
6. CO_2 in gas phase = 35 percent
7. Process reactor liquid height = 8 m
8. Average solids concentration in process reactor = 50 g VSS/L

Wastewater characteristics:

Parameter	Unit	Value
Flowrate	m^3/d	500
Total bCOD	mg/L	
Wastewater 1		6000
Wastewater 2		7000
Wastewater 3		8000
Particulate COD	Percent	40
Particulate COD/VSS ratio	g/g	1.8
Particulate VSS/TSS ratio	g/g	0.85
Alkalinity	mg/L as $CaCO_3$	300

Note: Wastewater 1, 2, or 3 to be selected by instructor.

10–9 A domestic wastewater is to be treated using the UASB process at 25°C. The wastewater characteristics are given in the following table. Determine: (a) the reactor hydraulic retention time (hours); (b) the COD loading rate (kg COD/m^3•d); and (c) the process reactor liquid height (m) and diameter (m). What effluent BOD and TSS concentration may be expected from the UASB reactor? Describe an aerobic secondary treatment process you would select to add after the UASB process to meet an effluent BOD concentration of 20 mg/L or less. Would alkalinity have to be added to the UASB reactor to maintain the pH near 7.0? Explain the basis for your answer.

Wastewater characteristics:

Parameter	Unit	Value
Flowrate	m^3/d	
Wastewater 1		3000
Wastewater 2		4000
Wastewater 3		5000
COD	mg/L	450
BOD	mg/L	180
TSS	mg/L	180
Alkalinity	mg/L as $CaCO_3$	150

Note: Wastewater 1, 2, or 3 to be selected by instructor.

10–10 A brewery wastewater with a flowrate of 1000 m^3/d and COD (mainly soluble) of 4000 mg/L is to be treated at 35°C in a 4 m upflow attached growth anaerobic reactor, which contains cross-flow plastic packing, with the aim of 90 percent COD removal. Assume that the attached growth SRT is 30 d. Determine (a) the reactor volume (m^3) and dimensions; (b) the methane gas production rate (m^3/d); and (c) the effluent TSS concentration (mg/L).

10–11 An industrial wastewater has a degradable COD concentration of 8000 mg/L and 4000 mg/L VSS concentration with 50 percent of the VSS degradable. Briefly critique the compatibility of the following processes for treatment of this wastewater and describe the potential impact of the influent solids on the reactor operation and performance.

Processes:
- UASB
- Anaerobic fluidized bed reactor
- Anaerobic baffled reactor
- Upflow packed bed reactor
- Downflow attached growth reactor
- Anaerobic covered lagoon

10–12 From the literature within the past three years, identify and summarize an application of an anaerobic membrane process. Include a description of the wastewater treated, the reactor design, the organic loading rate, the temperature, the membrane fouling control strategy, the membrane flux rate over time, the reactor solids concentration, the membrane cleaning method or restoration method, and any significant operating and performance issues.

10–13 From a review of the literature summarize the wastewater type and characteristics, system design and operating conditions and the treatment performance of a UASB, EGSB, or anaerobic contact process (to be selected by the instructor).

Separation Processes for Removal of Residual Constituents

WORKING TERMINOLOGY

Term	Definition
Absorption	The process by which atoms, ions, molecules, and other constituents are transferred from one phase and are distributed uniformly in another phase (see also adsorption).
Activated carbon	A substance used commonly in adsorption processes for the removal of trace constituents from water and odor compounds from air. Activated carbon is derived from an organic base material, prepared using a high temperature pyrolysis process and activated at high temperature in the presence of steam resulting in properties conducive to mass transfer.

Term	Definition
Adsorption	The process by which atoms, ions, molecules, and other constituents are transferred from one phase and accumulate on the surface of another phase (see also absorption).
Backwash	The process of removing solids accumulated on or in a filtration medium by applying air and/or clean water in the opposing flow direction.
Brine	Concentrated liquid waste stream containing elevated concentrations of total dissolved solids
Depth filtration	The removal of particulate matter suspended from a liquid by passing the liquid through a granular medium such as sand or anthracite coal.
Electrodialysis (ED)	A process that moves ions (charged molecular species) from one solution to another by employing an electrical potential as the driving force and using a semipermeable membrane as a separator.
Flux	The mass or volume rate of transfer through the membrane surface, usually expressed as $m^3/m^2 \cdot h$ or $L/m^2 \cdot h$ ($gal/ft^2 \cdot d$).
Fouling	The accumulation of solid matter on the surface of or within the pores of a membrane that impedes the flow of permeate through the membrane.
Gas stripping	A process to remove a volatile constituent from a liquid phase, such as in the removal of ammonia from water in a packed column using air as the gas phase.
Ion exchange	A process used for the removal of dissolved ionic constituents where ions of a given species are displaced from a solid phase material by ions of a different species from solution.
Isotherm	A function used to relate the amount of a given constituent adsorbed from water per concentration of adsorbent at a given temperature.
Membrane	A device, usually made of an organic polymer, that allows the passage of water and certain constituents, but rejects others above a certain physical size or molecular weight.
Microfiltration (MF)	A membrane separation process used typically to remove particulate material from the feed water; microfiltration pore sizes range approximately from 0.05 to 2 μm.
Nanofiltration (NF)	A pressure-driven membrane separation process used to remove colloidal and dissolved material as small as approximately 0.001 μm.
Residuals	Waste streams produced by wastewater treatment processes. For depth and surface filtration, the residual waste stream is filter waste washwater. For membrane systems, residual waste streams include waste washwater, concentrate, and chemical cleaning wastes.
Reverse osmosis (RO)	The rejection of dissolved constituents by preferential diffusion using a pressure-driven, semipermeable membrane.
Semipermeable membrane	A membrane that is permeable to some components in a feed solution and impermeable to other components.
Separation processes	Physical and chemical processes used in water reclamation that bring about treatment by the isolation of particular constituents. The isolated constituents are concentrated into a waste stream that must be managed.
Sodium adsorption ratio (SAR)	A measure of the sodicity of the soil; the SAR is the ratio of the sodium cation to the calcium and magnesium cations.
Surface filtration	The removal of particulate matter suspended in a liquid by passing the liquid through a thin septum, usually a cloth or metal medium.
Synthetic organic compounds (SOCs)	Compounds of synthetic origin used extensively in industrial processes and contained in numerous manufactured consumer products. The presence of SOCs in drinking water as well as reclaimed water is of concern due to toxicity and unknown effects.
Ultrafiltration (UF)	A membrane separation process similar to MF except the membrane pore sizes can range from approximately 0.005 to 0.1 μm. Generally, UF membranes are able to achieve higher levels of separation than MF, particularly for bacteria and viruses.

The effluent from conventional secondary treatment contains varying amounts of residual suspended, colloidal, and dissolved constituents. Suspended and colloidal matter can reduce the effectiveness of downstream disinfection processes or make the effluent unsuitable for discharge or reuse. Dissolved constituents may range from relatively simple inorganic ions, such as calcium, potassium, sulfate, nitrate, and phosphate to an ever-increasing number of highly complex synthetic organic compounds. Research is ongoing to determine (1) the environmental effects of potentially toxic and biologically active substances found in wastewater and (2) how these substances can be removed by both conventional and advanced wastewater treatment processes. In recent years, the effects of many of these substances on the environment have become understood more clearly. As a result, wastewater treatment requirements are becoming more stringent in terms of limiting effluent concentrations of many of these substances.

To meet new treatment requirements, many of the existing secondary treatment facilities will have to be retrofit and new advanced wastewater treatment facilities will have to be constructed. The purpose of this chapter is to present an introduction to the unit processes used for the removal and/or treatment of residual particulate, colloidal, and dissolved constituents in treated wastewater. However, before discussing the individual unit processes, it will be helpful to review the need for additional wastewater treatment and the reasons that specific constituents are of concern.

11–1 NEED FOR ADDITIONAL WASTEWATER TREATMENT

Residual constituents found in secondary effluent can be grouped into four broad categories: (1) organic and inorganic suspended and colloidal particulate matter, (2) dissolved organic constituents, (3) dissolved inorganic constituents, and (4) biological constituents. Constituents within each category are reported in Table 11–1, along with the reasons for their removal. The potential impacts of the residual constituents identified in Table 11–1 will vary considerably depending on local conditions. The list of constituents presented in Table 11–1 is not meant to be exhaustive; rather, it is meant to highlight that a wide variety of substances must be considered in establishing and meeting discharge requirements. Also, based on the accumulation of scientific knowledge concerning the impacts of the residual constituents found in secondary effluent, derived from laboratory studies and environmental monitoring, it is anticipated that many of the treatment methods now classified as tertiary or advanced will be considered conventional within the next 10 to 20 years. For example, effluent filtration has become more commonplace within the past 20 years.

11–2 OVERVIEW OF TECHNOLOGIES USED FOR REMOVAL OF RESIDUAL PARTICULATE AND DISSOLVED CONSTITUENTS

Over the past 20 years, a wide variety of treatment technologies have been studied, developed, and applied for the removal of the residual constituents found in secondary and tertiary effluent. The unit processes used for the removal of residual constituents from water may be classified as (1) mass transfer separation processes and (2) chemical and biological transformation processes.

Separation Processes Based on Mass Transfer

The removal of constituents by the transfer of mass from one phase to another or by the concentration of mass within a phase is accomplished with various unit processes.

Table 11–1

Typical residual constituents found in treated wastewater effluents and reasons that additional treatment may be required

Residual constituent	Effect and/or need for additional treatment
Inorganic and organic suspended and colloidal particulate matter	
Suspended solids	• Can impact disinfection by shielding organisms • May cause sludge deposits or interfere with receiving water clarity • May affect effluent turbidity
Colloidal solids	• May affect effluent turbidity
Organic matter (particulate)	• May shield bacteria during disinfection, may deplete oxygen resources
Dissolved organic matter	
Total organic carbon	• May deplete oxygen resources
Refractory organics	• Toxic to humans; carcinogenic
Volatile organic compounds	• Toxic to humans; carcinogenic; form photochemical oxidants
Pharmaceutical compounds	• Impacts to aquatic species (e.g., endocrine disruption)
Surfactants	• Cause foaming and may interfere with coagulation
Dissolved inorganic matter	
Ammonia	• Increases chlorine demand • Can be converted to nitrates and, in the process, can deplete oxygen resources • With phosphorus, can lead to the development of undesirable aquatic growth • Toxic to fish
Nitrate	• Can stimulate algal and other aquatic growth • Can cause methemoglobinemia in infants (blue babies)
Phosphorus	• Can stimulate algal and other aquatic growth • Increases chemical requirements • Interferes with lime-soda softening
Calcium and magnesium	• Increase hardness and total dissolved solids • Can affect sodium adsorption ratio
Chloride and sulfate	• Can impart salty taste
Total dissolved solids	• Interfere with agricultural and industrial processes • Can interferes with coagulation
Biological	
Bacteria	• Can cause disease
Protozoan cysts and oocysts	• Can cause disease
Viruses	• Can cause disease

The principal mass transfer processes used for the separation (removal) of residual constituents are summarized in Table 11–2. It is important to note that a key characteristic of most separation processes is the generation of a waste stream that will require subsequent management (e.g., processing, disposal, reuse). The particular waste stream generated will depend on the type and effectiveness of the separation process used. For example,

Table 11–2

Unit processes based on mass transfer used for the removal of particulate and dissolved constituents in wastewater treatment and water reclamation[a]

Unit process	Phase	Application
Absorption	Gas → liquid	Aeration, O_2 transfer, SO_2 scrubbing, chlorination, chlorine dioxide and ammonia addition, ozonation
Adsorption	Gas → solid Liquid → solid	Removal of inorganic and organic compounds using activated carbon, activated alumina, granular ferric hydroxide, or other adsorbent material
Distillation	Liquid → gas	Demineralization of water, concentrating of waste brines
Electrodialysis	Liquid → liquid	Removal of dissolved species, removal of salts
Filtration, depth	Liquid → solid	Removal of particulate material
Filtration, surface	Liquid → solid	Removal of particulate material
Flotation	Liquid → solid	Removal of particulate constituents
Gas stripping	Liquid → gas	Removal of NH_3 and other volatile inorganic and organic chemicals
Ion exchange	Liquid → solid	Demineralization of water, removal of specific constituents, softening
Microfiltration ultrafiltration	Liquid → liquid	Removal of particulate and colloidal species
Nanofiltration	Liquid → liquid	Removal of dissolved and colloidal species; softening
Precipitation, chemical	Liquid → solid	Removal of particulate and dissolved species; softening
Reverse osmosis	Liquid → solid	Removal of dissolved constituents
Sedimentation	Liquid → solid	Removal of particulate constituents

[a] Adapted in part from Crittenden et al. (2012).

adsorption results in a medium saturated with removed constituents, chemical precipitation produces a sludge containing both the precipitated constituents as well as the chemical(s) added to cause the precipitation, and reverse osmosis produces a liquid waste (brine) containing concentrated rejected constituents. In many cases, the management of waste streams resulting from separation processes, as discussed in Chap. 15, can present a significant technological challenge and cost.

Transformation Based on Chemical and Biological Processes

The second group of processes used for the removal of residual constituents make use of chemical and biological reactions to transform or destroy trace constituents in water, typically through oxidation and reduction reactions. Conventional chemical oxidants that have been used for constituent transformation include hydrogen peroxide, ozone, chlorine, chlorine dioxide, and potassium permanganate. Chemical oxidation processes that utilize hydroxyl radical species, referred to as advanced oxidation processes (AOPs), or photons generated through UV photolysis, are particularly effective for the transformation and destruction of trace constituents, often resulting in the complete mineralization of trace constituents to carbon dioxide and mineral acids. Chemical treatment processes including advanced oxidation and photolysis are considered in Chap. 6. Chemical disinfection of wastewater is considered separately in Chap. 12. Biological treatment and conversion processes are considered in Chaps. 7 through 10.

Application of Unit Processes for Removal of Residual Constituents

Information on the application of the unit processes identified in Table 11–2 is presented in Table 11–3. Selection of a given unit process or combination thereof depends on (1) the use to be made of the treated effluent; (2) the constituent(s) of concern; (3) the compatibility of the various operations and processes; (4) the available means for management of any process residuals; and (5) the environmental and economic feasibility of the various systems. Specific factors that should be considered in the selection of treatment processes were identified and discussed previously in Table 4–2 in Chap. 4. It should be noted that in some situations, economic feasibility may not be a controlling factor in the design of advanced wastewater treatment systems, especially where specific constituents must be removed to protect the environment and/or to meet discharge requirements. Because of the variations in performance observed in the field, bench-scale and pilot-plant testing is recommended for the development of local treatment performance data and design criteria. Representative performance data for the processes identified in Table 11–3 are presented in the discussion of the individual technologies that follows and in the indicated sections in other chapters.

11–3 UNIT PROCESSES FOR THE REMOVAL OF RESIDUAL PARTICULATE AND DISSOLVED CONSTITUENTS

The principal unit processes used for the removal of residual particulate matter discussed in this chapter include (1) depth filtration (passing the liquid through a filter bed comprised of a granular or compressible filter medium); (2) surface filtration (the removal of particulate material suspended in a liquid by mechanical sieving by passing the liquid through a thin septum); and (3) membrane filtration (passing the liquid through porous material to exclude particles ranging in size from 0.005 to 2.0 μm). Each of these processes is illustrated and described in Table 11–4. Flotation (attaching air bubbles to particulate matter to provide buoyancy so the particles can be removed by skimming) is included in Table 11–4 for completeness, but has been considered previously in Chap. 5.

The principal unit processes used for the removal of dissolved constituents, as discussed in this chapter, include (1) reverse osmosis (passing the liquid through semipermeable membranes to exclude particles ranging in size from 0.0001 to 0.001 μm), (2) electrodialysis (transport of ionic species through an ion-selective membranes), (3) adsorption (the accumulation of constituents on a solid phase), (4) gas stripping (transfer of a constituent from a liquid to a gas phase), (5) ion exchange (the exchange of ionic species), and (6) distillation (constituents are separated by evaporation).

Typical Process Flow Diagrams

Typical treatment process flow diagrams that incorporate the unit processes discussed above are illustrated on Fig. 11–1. The combination of unit processes will depend on the treatment objective. For example, in the flow diagram shown on Fig. 11–1(b), electrodialysis is used to remove salts to reduce the total dissolved solids in the treated effluent. On Fig. 11(d), a number of unit processes have been combined to produce a potable water. Where reverse osmosis is used, some form of membrane filter will be used upstream to mitigate the effects of particulate matter that tends to clog the membrane. On Fig. 11–1(f), two stages of reverse osmosis have been combined to produce water suitable for use in

high-pressure boilers. Clearly, a wide variety of treatment process flow diagrams can be developed, depending on the specific requirements. Other examples of process flow diagrams are presented and discussed throughout this chapter.

Process Performance Expectations

It is important to know what typical mean effluent constituent values can be expected and the variability in those values for a given unit process. Information on the constituent values and variability is of importance in meeting effluent requirements and in the selection of technologies that might be used to further process the treated effluent. Typical mean

Table 11–4

Description of commonly used processes for the removal of residual suspended and colloidal solids

Unit process	Description
(a) Depth filtration  	Depth filtration was developed originally for the treatment of surface water for potable uses and later adapted for wastewater treatment applications. Depth filtration is used in to achieve supplemental removal of suspended solids (including particulate BOD) from wastewater effluents for the following purposes: (1) to allow more effective disinfection; (2) as a pretreatment step for subsequent treatment steps such as carbon adsorption, membrane filtration, or advanced oxidation; and (3) to remove chemically precipitated phosphorus.
(b) Surface filtration  	Surface filtration is used to remove the residual suspended solids from secondary effluents and stabilization pond effluents, and as an alternative to depth filtration. Surface filtration, a relatively new technology, involves a sieving action similar to a kitchen colander.
(c) Membrane filtration  	Membrane filtration with microfiltration (MF) and ultrafiltration (UF) membranes is being used increasingly for water and wastewater applications. Microfiltration and UF membrane filters are also surface filtration devices but are differentiated on the basis of the sizes of the pores in the filter medium; the pore size can vary from 0.005 to 2.0 μm. In water reuse applications, MF and UF usually follow biological treatment and are used to remove particulates, including pathogens; organic matter; and some nutrients, not removed by secondary clarification. Product water from MF and UF may be used directly for a variety of reuse applications (after disinfection) or used as pretreated feed water for further treatment by nanofiltration (NF) or reverse osmosis (RO).
(d) Dissolved air flotation  	Dissolved air flotation is a gravity separation process in which gas bubbles attach to solid particles to cause the density of the bubble-solid agglomerates to be lighter than water. For water reuse applications, DAF has been used principally for treating pond effluents containing algae and for low density particles that are difficult to remove by gravity sedimentation, as a replacement for conventional primary sedimentation, and as a pretreatment step for depth or surface filtration. Dissolved air flotation is considered in Sec. 5–7 in Chap. 5.

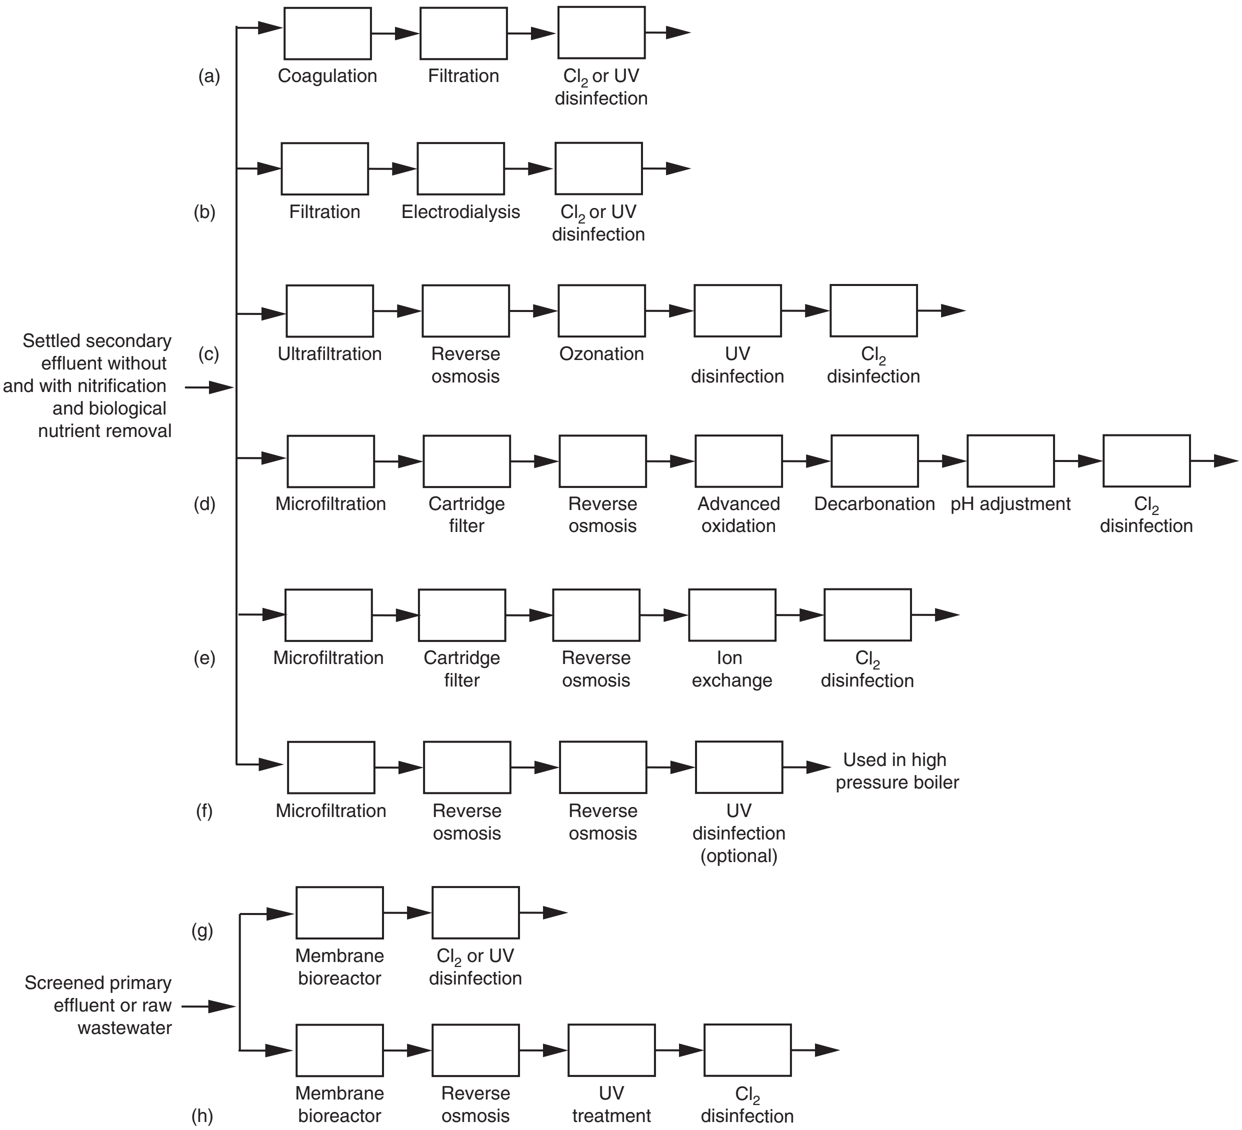

Figure 11–1

Typical process flow diagrams for wastewater treatment employing advanced treatment processes. All of the flow diagrams have been used at one time or another. For example, in flow diagram number (d) advanced oxidation is used for the destruction of NDMA. In flow diagram number (e) ion exchange is used for the removal of nitrate.

effluent constituent values that can be achieved with depth, surface, and membrane filtration following various forms of biological treatment are reported in Table 11–5. The variability observed in the performance of various particulate removal processes with respect to TSS and turbidity in the treated effluent is discussed in the sections which deal with depth, surface, and membrane filtration.

11–4 INTRODUCTION TO DEPTH FILTRATION

Depth filtration with a non-compressible filter medium or media is one of the oldest unit process used in the treatment of potable water and is commonly used for the filtration of effluents from wastewater treatment processes, especially in low-level nutrient removal and water reuse applications. Depth filtration is used most commonly to (1) achieve supplemental removals of residual suspended solids (including particulate BOD and phosphorus), (2) reduce the mass discharge of solids, and (3) perhaps more importantly, as a conditioning step that will allow for the effective disinfection of the filtered effluent, especially with UV disinfection (see Chap. 12). Single- and two-stage filtration is used to remove chemically precipitated phosphorus. The relationship between depth filtration and other forms of filtration is illustrated on Fig. 11–2. In the past, depth filtration was used almost exclusively for effluent filtration. However, with the development of modern surface filtration technologies, as discussed in Sec. 11–5, depth filtration is no longer the dominant filtration technology.

To introduce the subject of depth filtration, the purpose of this section is to present (1) a general introduction to the depth filtration process, (2) an introduction to filter clean-water hydraulics, and (3) an analysis of the filtration process. The types of filters that are available and issues associated with their selection and design, including a discussion of the need for pilot-plant studies, are considered in the following section.

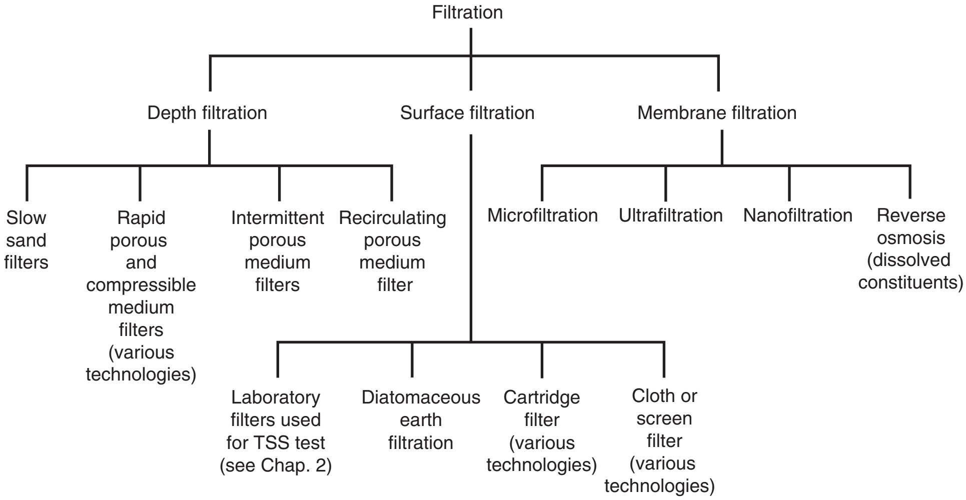
Description of the Filtration Process

The basics of the depth filtration can be understood by considering the (1) physical features of a conventional granular medium depth filter, (2) characteristics of the filter-medium, (3) the process by which suspended material is removed from the liquid, and (4) the backwash process in which material retained within the filter is removed.

Physical Features of a Depth Filter. The general features of a conventional granular medium depth filter are illustrated on Fig. 11–3. As shown, the filtering medium (sand in this case) is supported on a gravel layer, which, in turn, rests on the filter underdrain system. The water to be filtered enters the filter from an inlet channel. Filtered water

Figure 11–2

Classification of filtration processes used in wastewater management. Note: Intermittent and recirculating porous medium filters are used for small systems and are not considered in this text.



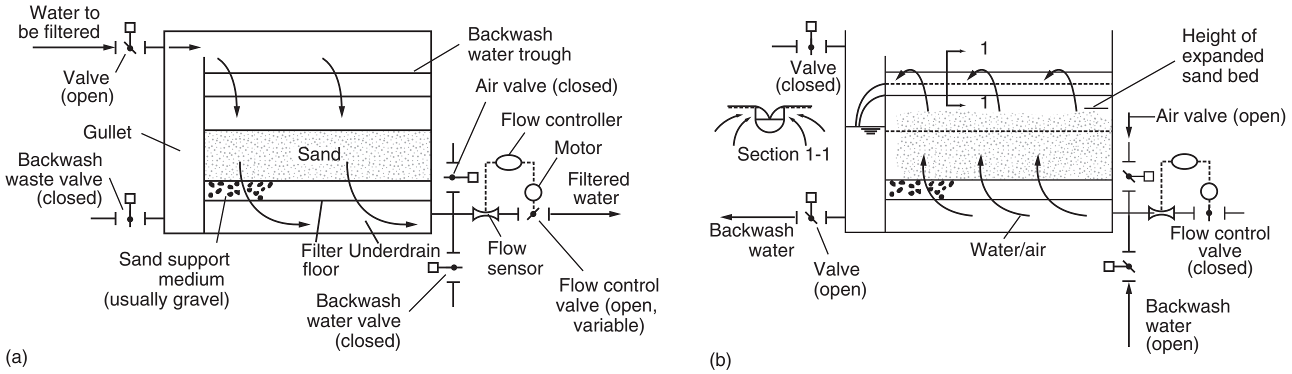


Figure 11–3

General features and operation of a conventional rapid granular medium depth filter: (a) flow during filtration cycle, and (b) flow during backwash cycle. (From Tchobanoglous and Schroeder, 1985.)

is collected in the underdrain system which is also used to reverse the flow to backwash the filter. Filtered water typically is disinfected before being discharged to the environment. If the filtered water is to be reused, it can be discharged to a storage reservoir or to the reclaimed water distribution system.

Characteristics of the Filter Medium. Grain size is the principal filter-medium characteristic that affects the filtration operation including the removal of suspended and colloidal material, the clear-water headloss, and the buildup of headloss during the filter run. If the size of the filtering medium is too small, much of the driving force will be wasted in overcoming the frictional resistance of the filter bed. If the size of the medium is too large, many of the small particles in the influent will pass directly through the filter bed. Thus, the selection of media size must balance the need for a target filtered water quality with an acceptable rate of filter headloss development. The size distribution of the filter material is usually determined by sieve analysis using a series of decreasing sieve sizes. The designation and size of opening for U.S. sieve sizes are given in Table 11–6. The results of a sieve analysis are usually analyzed by plotting the cumulative percent passing a given sieve size on arithmetic-log or probability-log paper (see Example 11–1).

The effective size of a filtering medium, $d_{10,}$ is defined as the 10 percent size based on weight. For sand, it has been found that the 10 percent size by weight corresponds approximately to the 50 percent size by count. The uniformity coefficient (UC) is defined as the ratio of the 60 percent size to the 10 percent size ($\mathrm{UC} = d_{60}/d_{10}$). Sometimes it is advantageous to specify the 99 percent passing size and the 1 percent passing size to define the gradation curve for each filter medium more accurately. Additional information on filter medium characteristics is presented in the following section dealing with the design of depth filters.

The Filtration Process. During filtration in a conventional downflow depth filter, wastewater containing suspended and colloidal material is applied to the top of the filter bed [see Fig. 11–3(a)]. As the water passes through the filter bed, the suspended matter (measured as turbidity) in the wastewater is removed by a variety of removal mechanisms,

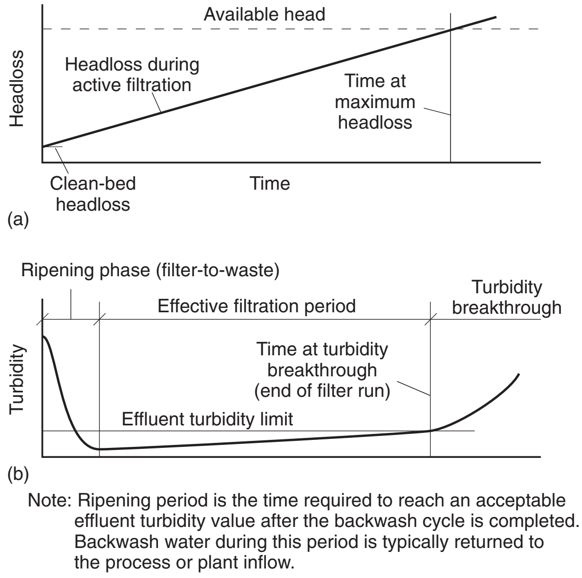
[b] Size does not follow the ratio $(2)^{0.5}$.

as described below. With the passage of time, as material accumulates within the interstices of the granular medium, the headloss through the filter starts to build up beyond the initial value, as shown on Fig. 11–4.

Headloss and Turbidity Considerations. After some period of time, the operating headloss or effluent turbidity reaches some predetermined headloss or turbidity value, and the filter must be cleaned. Under ideal conditions, the time required for the headloss buildup to reach the preselected terminal value should correspond to the time when the turbidity or suspended solids in the effluent reach the preselected terminal value for acceptable quality. Turbidity breakthrough occurs when the interstitial spaces within the filter bed fill to a point where the shearing force of the liquid passing through the filter exceeds the strength of the bond formed between the material being filtered and the accumulated material. At breakthrough, accumulated material will dislodge only to be replaced by new material so



Note: Ripening period is the time required to reach an acceptable effluent turbidity value after the backwash cycle is completed. Backwash water during this period is typically returned to the process or plant inflow.

Figure 11–4

Definition sketch for length of filter run based on: (a) headloss buildup and (b) effluent turbidity breakthrough.

that an equilibrium condition is maintained. In actual practice, one or the other event will govern the backwash cycle.

Particle Removal Mechanisms. The principal particle-removal mechanisms, believed to contribute to the removal of material within a granular medium filter, are identified and described in Table 11–7. The major removal mechanisms (the first five listed in Table 11–7) are illustrated pictorially on Fig. 11–5. Straining has been identified as the principal mechanism that is operative in the removal of suspended solids during the filtration of settled secondary effluent from biological treatment processes (Tchobanoglous and Eliassen, 1970; Tchobanoglous, 1988).

Other mechanisms including interception, impaction, and adhesion are also operative even though their effects are small and, for the most part, masked by the straining action. The removal of the smaller particles found in wastewater (see Fig. 11–5) must be accomplished in two steps involving (1) the transport of the particles to or near the surface where they will be removed and (2) the removal of particles by one or more of the operative removal mechanisms. This two-step process has been identified as transport and attachment (O'Melia and Stumm, 1967).

Conventional down-flow filters, dual- and multi-media and deep-bed mono-medium depth filters (see Fig. 11–6) were developed to allow the suspended solids in the liquid to be filtered to penetrate further into the filter bed, and thus use more of the solids-storage capacity available within the filter bed. The deeper penetration of the solids into the filter bed also permits longer filter runs because the buildup of headloss is reduced. By comparison, in shallow mono-medium beds, most of the removal occurs in the upper few millimeters of the bed.

Backwash Process. The end of the filter run (filtration phase) is reached when the suspended solids in the effluent start to increase (breakthrough) beyond an acceptable level, or when a limiting headloss occurs across the filter bed (see Fig. 11–4). Once either of these conditions is reached, the filtration phase is terminated, and the filter must be cleaned (backwashed) to remove the material (suspended solids) that has accumulated within the granular medium filter bed. Backwashing is accomplished by reversing the flow

Table 11–7

Principal mechanisms and phenomena contributing to removal of material within a granular medium depth filter

Mechanism/phenomenon	Description
1. Straining	
a. Mechanical	Particles larger than the pore space of the filtering medium are strained out mechanically.
b. Chance contact	Particles smaller than the pore space are trapped within the filter by chance contact.
2. Sedimentation or impaction	Heavy particles that do not follow the flow streamlines settle on the filtering medium within the filter.
3. Interception	Many particles that move along in the streamline are removed when they come in contact with the surface of the filtering medium.
4. Adhesion	Particles become attached to the surface of the filtering medium as they pass by. Because of the force of the flowing water, some material is sheared away before it becomes firmly attached and is pushed deeper into the filter bed. As the bed becomes clogged, the surface shear force increases to a point at which no additional material can be removed. Some material may break through the bottom of the filter, causing the sudden appearance of turbidity in the effluent.
5. Flocculation	Flocculation can occur within the interstices of the filter medium. The larger particles formed by the velocity gradients within the filter are then removed by one or more of the above removal mechanisms.
6. Chemical adsorption	Once a particle has been brought in contact with the surface of the filtering medium or with other particles, either one of these mechanisms, or both, may be responsible for holding it there.
a. Bonding	
b. Chemical interaction	
7. Physical adsorption	
a. Electrostatic forces	
b. Electrokinetic forces	
c. van der Waals forces	
8. Biological growth	Biological growth within the filter will reduce the pore volume and may enhance the removal of particles with removal mechanisms 1 through 5.

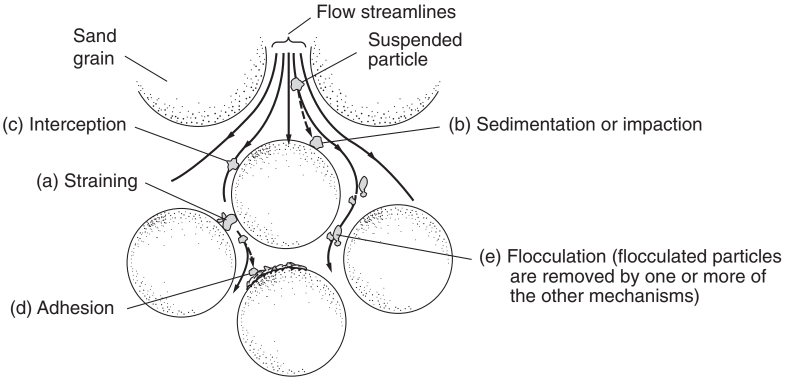


Figure 11–5

Removal of suspended particulate matter within a granular filter by: (a) straining, (b) sedimentation or inertial impaction, (c) interception, (d) adhesion, and (e) flocculation with subsequent removal by one or more of the previous mechanisms. (Adapted from Tchobanoglous and Schroeder, 1985.)

Figure 11–6

through the filter [see Fig. 11–3(b)]. A sufficient flow of washwater is applied until the granular filtering medium is fluidized (expanded), causing the particles of the filtering medium to abrade against each other. The backwash water flow requirements are related to water temperature and the desired bed expansion during high-rate washing. Unless the filter bed is cleaned properly, fine material, grease, and bacterial slimes can accumulate within the bed, ultimately leading to the formation of mudballs.

The suspended matter retained within the filter is removed by the shear forces created by backwash water as it moves up through the expanded bed and by abrasion as the grains of the filter medium interact with each other. The material that has accumulated within the bed is then washed away. Surface washing with water and air scouring are often used in conjunction with the water backwash to enhance the cleaning of the filter bed. Air scour in particular will often reduce the required backwash duration and, therefore, will reduce the amount of washwater required. Following backwashing, the practice of filter-to-waste is often used to prevent any residual backwash particles from entering the filtered water. In most wastewater treatment plant flow diagrams, the washwater containing the suspended solids that are removed from the filter is returned either to the primary settling facilities or to the biological treatment process. Increasingly, especially at larger treatment plants, separate treatment facilities are provided to remove the solids from the backwash water.

Filter Hydraulics

During the past 60 years considerable effort has been devoted to the modeling of the filtration process. The models fall into two general categories: those models used to predict the clean-water headloss through a granular medium filter bed (*clean water* referring to water absent of suspended particles that would otherwise create headloss) and the filter backwash expansion, and those models used to predict the performance of filters for the removal of suspended solids. Headloss and backwash hydraulics are considered in the following discussion.

Clean-Water Headloss. Over the years a number of equations have been proposed to describe the flow of clean-water through a porous medium (Darcy, 1856; Hazen, 1905; Fair and Hatch, 1933; Kozeny-Carman, 1937; Rose, 1945; Ergun, 1952). The equations developed by these early researchers are summarized in Table 11–8. In most cases, the equations for the flow of clean water through a porous medium are derived from a consideration of the Darcy-Weisbach equation [Eq. (5–78)] for flow in a closed conduit and from dimensional analysis.

Application of Headloss Equations. The equations given in Table 11–8 apply to different flow regimes. All of the equations presented in Table 11–8 can be used for laminar flow conditions, with Reynolds numbers typically below 6. However, only the Rose and Ergun equations apply to the laminar, transitional, and turbulent flow regimes. The equations for

N_R = See Eq.(11–8)	

C = coefficient of compactness (varies from 600 for very closely packed sands that are not quite clean to 1200 for very uniform clean sand)
C_d = coefficient of drag
d = grain size diameter, m (ft)
d_g = geometric mean diameter between sieve sizes d_1 and d_2, $\sqrt{d_1 d_2}$, mm (in.)
d_{10} = effective medium size diameter, mm (in.)
f = friction factor
g = acceleration due to gravity, 9.81 m/s^2 (32.2 ft/s^2)
h = headloss, m (ft)
k = filtration constant, 5 based on sieve openings, 6 based on size of separation
L = depth of filter bed or layer, m (ft)
N_R = Reynolds number
p = fraction of particles (based on mass) within adjacent sieve sizes
S = shape factor (varies between 6.0 for spherical particles and 6/ψ for nonshperical particles)
S_v = specific surface area (A_p/V_p) is equal to 6/d for spheres and 6/d ψ for nonshperical particles
T = temperature, °C [°F in Eq. (11–10)]
υ_h = superficial (approach) filtration velocity, m/d (ft/d)
υ_s = superficial (approach) filtration velocity, m/s (ft/s)
α = porosity
μ = viscosity, N·s/m^2 (lb·s/ft^2)
ν = kinematic viscosity, m^2/s (ft^2/s)
ρ = density, = kg/m^3 (slug/ft^3, lb·s^2/ft^4)
ψ = sphericity, often identified as ϕ in the literature (1.0 for spheres, 0.94 for worn sand, 0.81 for sharp sand, 0.78 for angular sand, 0.70 for crushed coal and sand)

[a] Although known as the Kozeny-Carman equation, Blake (1922) should also be credited with its development.

the transitional or turbulent flow regimes are important because many of the newer filters are deeper with larger filter media and operate at higher filtration rates. In the Rose equation [Eq. (11–5)], use of the coefficient of drag, C_d [Eq. (11–7)], makes it possible to capture the affect of varying flow regimes from viscous to inertial. Similarly, in the Ergun friction equation [Eq. (11–10)], the first term accounts for viscous energy losses and the second term accounts for inertial energy losses. Based on a review of the literature, Trussell and Chang (1999) proposed some different coefficients for sand and anthracite for use in the Ergun equation [Eq. (11–10)].

The summation term in Eqs. (11–3) and (11–6) is included to account for the stratification that occurs in filters. To account for stratification, the mean size of the material retained between successive sieve sizes is assumed to correspond to the mean size of the successive sieves (see Table 11–6), assuming that the particles retained between sieve sizes are substantially uniform (Fair and Hatch, 1933). The Ergun equation [Eq. (11–9)] can also be applied to successive layers in a stratified filter.

Sphericity, Specific Surface Area, and Shape Factor. In applying the equations given in Table 11–8, some confusion exists over the definition of sphericity, ψ, specific surface area, S_v, and shape factor, S. The sphericity factor is defined as the ratio of the surface area of a sphere with the same volume as a given particle to the surface area of the particle and is given by the following formula (Wadell, 1935).

$$\psi = \frac{\pi^{1/3}(6V_p)^{2/3}}{A_p} \tag{11–11}$$

where ψ = sphericity, dimensionless
V_p = equivalent volume sphere, L^3 (m^3)
A_p = actual surface area of particle, L^2 (m^2)

Thus, for a spherical particle, the sphericity factor is equal to 1.0. Typically, sphericity factors can be applied to discrete particles and can vary from 1.0 for spheres to 0.70 for crushed sand. Further, because sphericity is difficult to measure, typical values are derived from experimental observations (Carman, 1937).

The specific surface area, S_v, defined as the area to volume ratio, is given by the following expressions for spherical and nonspherical particles.
For spherical particles

$$S_v = \frac{A_p}{V_p} = \frac{\pi d^2}{(\pi d^3/6)} = \frac{6}{d}, \text{ and} \tag{11–12a}$$

For nonspherical (irregular) particles

$$S_v = \frac{A_p}{V_p} = \frac{6}{\psi d} \tag{11–12b}$$

where S_v = specific surface area, m, mm
A_p = surface area of filter medium particle, m^2, mm^2
V_p = volume of filter medium particle, m^3, mm^3
d = diameter of filter medium particle, m, mm
ψ = sphericity, dimensionless

In the literature, the number 6 that appears in the above equations has been identified as a shape factor S for spherical particles and $6/\psi$ for nonspherical particles [see Eq. (11–2) in Table 11–8] (Fair et al., 1968). Computation of the clean-water headloss through a filter is illustrated in Example 11–1.

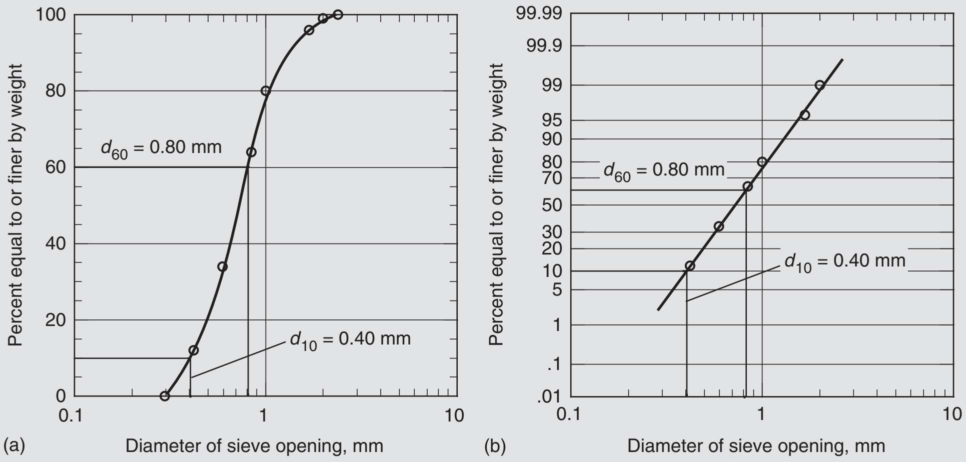
EXAMPLE 11–1 **Determination of Clean-water Headloss in a Granular Medium Filter** Determine the effective size, the uniformity coefficient, and the clean-water headloss in a filter bed composed of 0.75 m of uniform sand with the size distribution given below for a filtration rate of 160 L/m^2·min. Assume that the operating temperature is 20°C. Use the Rose equation [Eq. (11–6)] given in Table 11–8 for computing the headloss. Assume the porosity of the sand in the various layers is 0.40 and use a value of 0.85 for the sphericity factor for sand.

Sieve size or number	Percent of sand retained	Cumulative percent passing	Geometric mean size^a, mm
6–8	0	100	
8–10	1	99	2.18
10–12	3	96	1.83
12–18	16	80	1.30
18–20	16	64	0.92
20–30	30	34	0.71
30–40	22	12	0.50
40–50	12		0.35

^{a} Using sieve size data from Table 11–6, the geometric mean size $= \sqrt{d_1 d_2}$

Solution

1. Determine the effective size and the uniformity coefficient of the sand. Plot the cumulative percent passing versus the corresponding sieve size. Two different methods of plotting the data are presented below.



a. The effective size, d_{10}, read from the graphs is 0.40 mm
b. The uniformity coefficient is

$$\text{UC} = \frac{d_{60}}{d_{10}} = \frac{0.80\text{ mm}}{0.40\text{ mm}} = 2.0$$

2. Determine the clean-water headloss using Eq. (11–6).

$$h = \frac{1.067}{\psi}\frac{Lv_s^2}{\alpha^4 g}\sum C_d \frac{p}{d_g}$$

a. Set up computation table to determine the summation term in Eq. (11–6)

Sieve size or number	Fraction of sand retained	Geometric mean size, mm	Reynolds number	C_d	$C_d\left(\frac{p}{d}\right)$, m^{-1}
8–10	0.01	2.18	4.93	6.56	30
10–12	0.03	1.83	4.15	7.60	124
12–18	0.16	1.30	2.93	10.28	1268
18–20	0.16	0.92	2.08	13.99	2441
20–30	0.30	0.71	1.60	17.71	7509
30–40	0.22	0.50	1.13	24.38	10,729
40–50	0.12	0.35	0.80	33.73	11,459
Sum					33,560

b. Determine the Reynolds number for each geometric mean as illustrated below.

$$N_R = \frac{\psi d v_s \rho}{\mu} = \frac{\psi d v_s}{\nu}$$

$d = 2.18$ mm

$$v_s = \left(\frac{160\,\text{L}}{\text{m}^2\cdot\text{min}}\right)\left(\frac{1\ \text{m}^3}{1000\,\text{L}}\right)\left(\frac{1\ \text{min}}{60\,\text{s}}\right) = 0.00267\ \text{m/s}$$

$\nu = 1.003 \times 10^{-6}\ \text{m}^2/\text{s}$ (see Appendix C)

$$N_R = \frac{(0.85)(0.00218\,\text{m})(0.00267\,\text{m/s})}{(1.003 \times 10^{-6}\,\text{m}^2/\text{s})}$$

$N_R = 4.93$

c. Determine C_d using Eq. (11–7)

$$C_d = \frac{24}{N_R} + \frac{3}{\sqrt{N_R}} + 0.34$$

$$C_d = \frac{24}{4.93} + \frac{3}{\sqrt{4.93}} + 0.34 = 6.56$$

d. Determine the headloss through the stratified filter bed using Eq. (11–6).

$L = 0.75$ m
$v_s = 0.00267$ m/s
$\psi = 0.85$
$\alpha = 0.40$
$g = 9.81\ \text{m/s}^2$

$$h = \frac{1.067(0.75\,\text{m})(0.00267\,\text{m/s})^2}{(0.85)(0.4)^4(9.81\,\text{m/s}^2)}(33{,}560/\text{m})$$

$h = 0.90$ m

Comment Given that the Reynolds numbers are less than 6 (i.e., 4.93 or less), most of the headloss in this example is due to viscous forces operative in the laminar flow region, which is reflected by the first term in the C_d relationship [Eq. (11–7)]. As larger media are used and the flowrate increases, the second and third terms of the C_d relationship will have a greater impact. Although many equations have been proposed over the years, the Rose equation has proven to be quite satisfactory for estimating the clear-water headloss in granular medium filter beds for a variety of flow regimes.

Backwash Hydraulics. To understand what happens during the backwash operation it will be helpful to refer to Fig. 11–7 in which the pressure drop across a packed bed is illustrated as the upward backwash velocity through it increases. Between points *A* and *B*, the bed is stable, and the pressure drop and Reynolds number N_R are related linearly. At point *B*, the pressure drop essentially balances the weight of the filter. Between points *B* and *C* the bed is unstable, and the particles adjust their position to present as little resistance to flow as possible. At point *C*, the loosest possible arrangement is obtained in which the particles are still in contact. Beyond point *C*, the particles begin to move freely but collide frequently so that the motion is similar to that of particles in hindered settling. Point *C* is referred to as the "point of fluidization." By the time point *D* is reached, the particles are all in motion, and, beyond this point, increases in N_R result in very small increases in ΔP as the bed continues to expand and the particles move in more rapid and more independent motion. Ultimately, the particles will stream with the fluid, and the bed will cease to exist at point *E*.

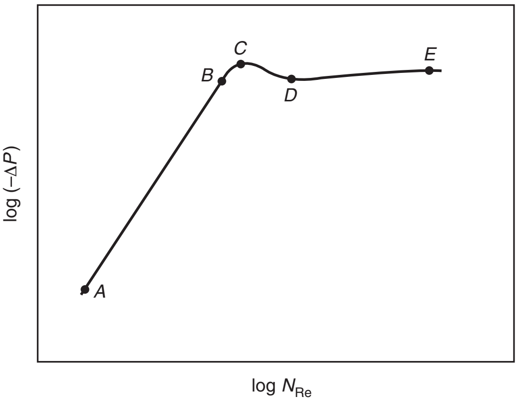
To expand a filter bed comprised of a uniform filter medium hydraulically, the headloss must equal the buoyant mass of the granular medium in the fluid. Mathematically this relationship can be expressed as

$$h = L_e(1 - \alpha_e)\left(\frac{\rho_m - \rho_w}{\rho_w}\right) \tag{11–13}$$

where h = headloss required to expand the bed
L_e = the depth of the expanded bed
α_e = the expanded porosity
ρ_m = density of the medium
ρ_w = density of water

Figure 11–7

Schematic diagram illustrating the fluidization of a filter bed. (Adapted from Foust et al., 1960.)



Because the individual particles are kept in suspension by the drag force exerted by the rising fluid it can be shown from settling theory (see Sec. 5–5 in Chap. 5) that

$$C_D A_p \rho_w \frac{v^2}{2} \phi(\alpha_e) = (\rho_m - \rho_w) g v_p \tag{11–14}$$

where v = face velocity of backwash water, m/s
$\phi(\alpha_e)$ = correction factor to account for the fact that v is the velocity of the backwash water and not the particle-settling velocity v_p

other terms are as defined previously.

From experimental studies (Fair, 1951; Richardson and Zaki, 1954) it has been found that the expanded bed porosity can be approximated using the following relationships, assuming the Reynolds number is approximately one.

$$\phi(\alpha_e) = \left(\frac{v_s}{v}\right)^2 = \left(\frac{1}{\alpha_e}\right)^9 \tag{11–15}$$

Thus

$$\alpha_e = \left(\frac{v}{v_s}\right)^{0.22} \tag{11–16}$$

or

$$v = v_s \alpha_e^{4.5} \tag{11–17}$$

where v_s = settling velocity of particle

However, because the volume of the filtering medium per unit area remains constant, $(1 - \alpha)L$ must be equal to $(1 - \alpha e)L_e$ so that

$$\frac{L_e}{L} = \frac{1 - \alpha}{1 - \alpha_e} = \frac{1 - \alpha}{1 - (v/v_s)^{0.22}} \tag{11–18}$$

Where the filter medium is stratified, the smaller and lighter particles in the upper layers expand first. To expand the entire bed, the backwash velocity must be sufficient to lift the largest and heaviest particle. To account for filter bed stratification, Eq. (11–18) is modified assuming that particles retained between sieve sizes are substantially uniform (Fair and Hatch, 1933).

$$\frac{L_e}{L} = (1 - \alpha) \sum \frac{p}{(1 - \alpha_e)} \tag{11–19}$$

Where p = fraction of filter medium retained between sieve sizes

Thus, the required backwash velocity and expanded depth can be estimated using Eqs. 11–18 and 11–19, respectively, as illustrated in Example 11–2. Additional details on filter bed expansion may be found in Amirtharajah (1978), Cleasby and Fan (1982), Dharmarajah and Cleasby (1986), Kawamura (2000), Leva (1959), and Richardson and Zaki (1954).

EXAMPLE 11–2 **Determination of Required Backwash Velocities for Filter Cleaning** A stratified sand bed with the size distribution given below is to be backwashed at a rate of 0.75 $m^3/m^2 \cdot min$. Determine the degree of expansion and whether the proposed backwash rate will expand all of the bed. Assume the following data are applicable:

Sieve size or number	Percent of sand retained	Geometric mean size[a], mm
8–10	1	2.18[b]
10–12	3	1.83
12–18	16	1.30
18–20	16	0.92
20–30	30	0.71
30–40	22	0.50
40–50	12	0.35

[a] Based on sieve sizes given in Table 11–6.

[b] $2.18 = \sqrt{2.38 \times 2.0}$.

1. Granular medium = sand
2. Specific gravity of sand = 2.65
3. Depth of filter bed = 0.90 m
4. Temperature = 20°C

Solution

1. Set up computation table to determine the summation term in Eq. (11–19).

$$\frac{L_e}{L} = (1 - \alpha)\sum \frac{p}{(1 - \alpha_e)}$$

Sieve size or number	Percent of sand retained[a]	Geometric mean size, mm	v_s, m/s	v/v_s	α_e	$p/(1 - \alpha_e)$
8–10	1	2.18	0.304	0.041	0.496	1.98
10–12	3	1.83	0.270	0.046	0.509	6.11
12–18	16	1.30	0.210	0.060	0.538	34.62
18–20	16	0.92	0.157	0.080	0.573	37.51
20–30	30	0.71	0.123	0.102	0.605	75.97
30–40	22	0.50	0.085	0.146	0.655	63.81
40–50	12	0.35	0.055	0.227	0.722	43.15
Summation						263.15

[a] For ease of computation, the percentage value is used instead of the decimal fractional value.

a. Determine the particle settling velocity using Fig. 5–20 in Chap. 5. Alternatively the particle settling velocity can be computed as illustrated in Example 5–5. The settling velocity values from Fig. 5–20 are entered in the computation table.

b. Determine the values of v/v_s and enter the computed values in the computation table.

The backwash velocity is

$v = 0.75 \text{ m/min} = 0.0125 \text{ m/s}$

c. Determine the values of α_e and enter the computed values in the computation table.

$$\alpha_e = \left(\frac{v}{v_s}\right)^{0.22} = \left(\frac{0.0125}{0.304}\right)^{0.22} = 0.496$$

d. Determine the values for column 7 and enter the computed values in the computation table.

$$\frac{p}{1 - \alpha_e} = \frac{0.01}{1 - 0.496} = 0.02$$

2. Determine the expanded bed depth using Eq. (11–19).

$$\frac{L_e}{L} = (1 - \alpha)\sum\frac{p}{(1 - \alpha_e)}\left(\frac{1}{100}\right)$$

$$L_e = (0.9 \text{ m})\ (1 - 0.4)(263.15)(1/100) = 1.42 \text{ m}$$

3. Because the expanded porosity of the largest size fraction (0.496) is greater than the normal porosity of the filter material, the entire filter bed will be expanded.

Comment The expanded depth needs to be known to establish the minimum height of the washwater troughs above the surface of the filter bed. In practice, the bottom of the backwash water troughs is set from 50 to 150 mm (2 to 6 in) above the expanded filter bed and filter expansion of 30 to 50 percent is used commonly. The width and depth of the troughs should be sufficient to handle the volume of backwash water used to clean the bed, with a minimum freeboard of 600 mm (24 in) above the top of the trough.

Modeling the Filtration Process

The modeling of the filtration process involves the development of equations to describe the (1) removal of suspended solids with time and distance within the filter bed and (2) buildup of headloss as suspended solids are removed from the liquid passing through the filter.

Removal of Suspended Solids. In general, the mathematical modeling of the time-space removal of particulate matter within the filter is based on a consideration of the equation of continuity, together with an auxiliary rate equation. The equation of continuity for the filtration operation may be developed by considering a suspended solids mass balance for a section of filter of cross-sectional area A, and of thickness Δz, measured in the direction of flow as illustrated on Fig. 11–8. Following the approach outlined in Chap. 1, the resulting equation is:

$$-v\frac{\partial C}{\partial z} = \frac{\partial q}{\partial t} + \alpha(t)\frac{\partial \overline{C}}{\partial t} \qquad (11\text{–}20)$$

where v = filtration velocity, L/m²·min

$\partial C/\partial z$ = change in concentration of suspended solids in fluid stream with distance, g/m³·m

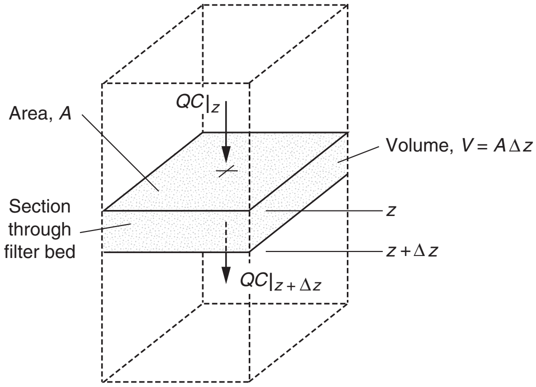
$\partial q/\partial t$ = change in quantity of solids deposited within the filter with time, g/m³·min

$\alpha(t)$ = average porosity as a function of time

$\partial \overline{C}/\partial t$ = change in average concentration of solids in pore space with time, g/m³·min

Figure 11–8

Definition sketch for the analysis of the filtration process.



In Eq. (11–20), the first term represents the difference between the mass of suspended solids entering and leaving the section, the second term represents the time rate of change in the mass of suspended solids accumulated within the interstices of the filter medium, and the third term represents the time rate of change in the suspended solids concentration in the pore space within the filter volume.

Because the quantity of fluid contained within the bed in a flowing process is usually small compared with the volume of liquid passing through the bed, the materials balance equation can be written as:

$$-v\frac{\partial C}{\partial z} = \frac{\partial q}{\partial t} \tag{11–21}$$

This equation is the one most commonly found in the literature dealing with filtration theory.

To solve Eq. (11–21), an additional independent equation is required. The most direct approach is to derive a relationship that can be used to describe the change in concentration of suspended matter with distance, such as

$$\frac{\partial C}{\partial z} = \phi(V_1, V_2, V_3 \ldots) \tag{11–22}$$

in which V_1, V_2, and V_3 are the variables governing the removal of suspended matter from solution. An alternative approach is to develop a complementary equation in which the pertinent process variables are related to the amount of material retained (accumulated) within the filter at various depths. In equation form, this may be written as

$$\frac{\partial q}{\partial t} = \phi(V_1, V_2, V_3 \ldots) \tag{11–23}$$

Using one or the other of the above expressions, [Eq. (11–21) or (11–22)], a number of solutions have been proposed for the continuity equation [Eq. (11–21)] (Caliskaner and Tchobanoglous, 2000).

Headloss Development. In the past, the most commonly used approach to determine headloss in a clogged filter was to compute it with a modified form of the equations used to evaluate the clear-water headloss (see Table 11–8). In all cases, the difficulty encountered in using these equations is that the porosity must be estimated for various degrees of clogging. Unfortunately, the complexity of this approach renders most of these formulations useless or, at best, extremely difficult to use. An alternative approach is to relate the development of headloss to the amount of material removed by the filter. The headloss would then be computed using the expression

$$H_t = H_o + \sum_{i=i}^{n} (h_i)_t \tag{11–24}$$

where H_t = total headloss at time t, m (ft)
H_o = total initial clean-water headloss, m (ft)
$(h_i)_t$ = headloss in the ith layer of the filter at time t, m (ft)

From an evaluation of the incremental headloss curves for uniform sand and anthracite, the buildup of headloss in an individual layer of the filter was found to be related to the amount of material contained within the layer. The form of the resulting equation for headloss in the ith layer is

$$(h_i)_t = a(q_i)_t^b \tag{11–25}$$

where $(q_i)_t$ = amount of material deposited in the ith layer at time t, mg/cm^3
a, b = constants

In this equation, it is assumed that the buildup of headloss is only a function of the amount of material removed. The application of these modeling equations may be found in the 3rd and 4th editions of this textbook.

11–5 DEPTH FILTRATION: SELECTION AND DESIGN CONSIDERATIONS

The ability to select and design filter technologies must be based on (1) knowledge of the types of filters that are available, (2) a general understanding of their performance characteristics, and (3) an appreciation of the process variables controlling depth filtration. Important design considerations for effluent filtration systems include (1) filter influent wastewater characteristics, (2) design and operation of the biological treatment process, (3) type of filtration technology to be used, (4) available flow control options, (5) type of filter backwashing system to be employed, (6) necessary filter appurtenances, and (7) filter control systems and instrumentation (not considered in this textbook). An understanding of issues related to effluent filtration with chemical addition, the type of filter problems encountered in the field, and the importance of pilot plant studies is also necessary. These subjects are presented and discussed in this section.

Available Filtration Technologies

The principal types of depth filters that have been used for the filtration of wastewater are described in Table 11–9. As shown in Table 11–9, the filters can be classified in terms of their operation as semi-continuous or continuous. Filters that must be taken offline periodically to be backwashed are classified operationally as semi-continuous. Filters in which the filtration and backwash operation occurs simultaneously are classified as continuous. Within each of these two classifications there are a number of different types of filters depending on bed depth (e.g., shallow, conventional, and deep bed), the type of filtering medium used (mono-medium, dual-, and multi-media), whether the

Table 11–9

Comparison of principal types of granular and synthetic medium filters

Type of filter	Type of filter operation	Filter bed details[a]		Typical direction of flow	Backwash operation	Flowrate through filter	Solids storage location	Type of design	Remarks
		Type	Filtering medium						
Conventional	Semi-continuous	Mono-medium (stratified or unstratified)	Sand or anthracite	Downward	Batch	Constant/ variable	Surface and upper bed	Individual	Rapid headloss buildup
Conventional	Semi-continuous	Dual-media (stratified	Sand and anthracite	Downward	Batch	Constant/ variable	Internal	Individual	Dual-media design used to extend length of filter run
Conventional	Semi-continuous	Multi-media (stratified)	Sand, anthracite, and garnet	Downward	Batch	Constant/ variable	Internal	Individual	Multi-media design used for particle depth penetration
Deep bed	Semi-continuous	Mono-medium (stratified or unstratified)	Sand or anthracite	Downward	Batch	Constant/ variable	Internal	Individual	Deep bed used to store solids and extend length of filter run
Deep bed	Semi-continuous	Mono-medium (stratified)	Sand	Upward	Batch	Constant	Internal	Proprietary	Deep bed used to store solids and extend length of filter run
Deep bed	Semi-continuous	Mono-medium (unstratified)	Sand	Upward	Continuous	Constant	Internal	Proprietary	Sand bed moves in countercurrent direction to fluid flow
Pulsed bed	Semi-continuous	Mono-medium (stratified)	Sand	Downward	Batch	Constant	Surface and upper bed	Proprietary	Air pulses used to break up surface mat and increase run length
Fuzzy filter	Semi-continuous	Mono-medium (unstratified)	Synthetic fiber	Upward	Batch	Constant	Internal	Proprietary	Perferorated plate is used to retain the filter medium during backwash
Traveling bridge	Continuous	Mono-medium (stratified)	Sand	Downward	Semi-continuous	Constant	Surface and upper bed	Proprietary	Individual filter cells backwashed sequentially
Traveling bridge	Continuous	Dual-media (stratified)	Sand and anthracite	Downward	Semi-continuous	Constant	Surface and upper bed	Proprietary	Individual filter cells backwashed sequentially
Pressure filters	Semi-continuous	Mono medium or dual media	Sand and/or anthracite	Downward	Batch	Constant/ variable	Surface and upper bed	Individual and proprietary	Used for small plants

[a] For filter bed depths, see Tables 11–15 and 11–16.

filtering medium is stratified or unstratified, the type of operation (downflow or upflow), and the method used for the management of solids (i.e., surface or internal storage). For the mono-medium and dual-media semi-continuous filters, a further classification can be made based on the driving force (e.g., gravity or pressure) although most of the filters used commonly in wastewater applications are gravity flow. Another important distinction that must be noted for the filters identified in Table 11–9 is whether they are proprietary or individually designed.

The five types of depth filters used most commonly for wastewater filtration at larger treatment plants [greater than 1000 m^3/d (0.25 Mgal/d)] are (1) conventional downflow filters (mono-medium, dual-, and multi-media), (2) deep-bed downflow filters, (3) deep-bed upflow continuous-backwash filters, (4) synthetic medium filters, (5) the pulsed bed filter, and (6) traveling bridge filters. A two-stage deep-bed filtration system which incorporates phosphorus removal is also used. Pressure filters, which operate in the same manner as gravity filters, are used at smaller plants. Many of the filters are proprietary and are supplied by the manufacturer as a complete unit. Each of these eight filter types is described in greater detail in Table 11–10. Views of several different types of filter installations are shown on Fig. 11–9.

Performance of Different Types of Depth Filters

The critical question associated with the selection of any depth filter is whether it will perform as anticipated. Performance of depth filters can be assessed from a review of the (1) hydraulic loading rate, (2) removal of turbidity and total suspended solids, (3) variability of turbidity and TSS removal, (4) removal of different particle sizes, (5) removal of microorganisms, and (6) backwash water requirements.

Hydraulic Loading Rate. The principal operational considerations for a depth filter are the volume of water produced in a given time period at a specified quality and the volume of washwater used to clean the filter. The volume of water produced is related to the development of headloss and filter performance, typically measured in terms of turbidity (see Fig. 11–4). The objective of a balanced filter design is to have the limiting headloss and turbidity breakthrough occur at or near the same time. In small plants, the water filtered during the ripening period is wasted during the filter-to-waste step (usually returned to the plant inflow). In large plants with many filters, the filter to waste cycle is often omitted. Chemical addition has also been used to extend the time to turbidity breakthrough and to achieve a variety of other treatment objectives including the removal of specific contaminants such as phosphorus, metal ions, and humic substances. Chemicals used commonly in effluent filtration include a variety of organic polymers, alum, and ferric chloride. It should be noted that the use of filter aid chemicals will normally result in more rapid headloss development and overuse of these chemicals can result in mudball formation.

Both the volume of water filtered and the rate at which headloss increases are related to the hydraulic loading rate (HLR). Typical operating characteristics, including hydraulic loading rates, for depth filters are reported in Table 11–11. Also reported in Table 11–11 are the filtration rates allowed by the California Department of Public Health for various filters in reuse applications. Because of the wide variation in the allowable rates, pilot plant studies are recommended.

Removal of Turbidity and Total Suspended Solids. The results of long-term testing of seven different types of pilot-scale filters on the effluent from the same activated sludge process ($SRT > 8$ d), without chemical addition, are shown on Fig. 11–10.

Table 11–10

Description of commonly used depth filters for reclaimed water applications[a]

Filter type	Description
(a) Conventional downflow  	Wastewater containing suspended matter is applied to the top of the filter bed. Mono-medium, dual-, or multi-media filter materials are used. Typically sand or anthracite is used as the filtering material in single-medium filters. Dual-media filters usually consist of a layer of anthracite over a layer of sand. Other combinations include (1) activated carbon and sand, (2) resin beads and sand, and (3) resin beads and anthracite. Multi-media filters typically consist of a layer of anthracite over a layer of sand over a layer of garnet or ilmenite. Other combinations include (1) activated carbon, anthracite, and sand, (2) weighted, spherical resin beads, anthracite, and sand, and (3) activated carbon, sand, and garnet.
(b) Deep-bed downflow  	The deep-bed downflow filter is similar to the conventional downflow filter with the exception that the depth of the filter bed and the size of the filtering medium (usually anthracite) are greater than the corresponding values in a conventional filter. Because of the greater depth and larger medium size (i.e., sand or anthracite), more solids can be stored within the filter bed and the run length can be extended. The maximum size of the filter medium used in these filters depends on the ability to backwash the filter. In general, deep-bed filters are not fluidized completely during backwashing. To achieve effective cleaning, air scour plus water is used in the backwash operation.
(c) Deep-bed upflow continuous backwash  	Wastewater to be filtered is introduced into the bottom of the filter where it flows upwards through a series of riser tubes and is distributed evenly into the sand bed through the open bottom of an inlet distribution hood. The water then flows upward through the downward moving sand. Clean filtrate exits from the sand bed, overflows a weir, and is discharged from the filter. At the same time sand particles, along with trapped solids, are drawn downward into the suction of an airlift pipe which is positioned in the center of the filter. A small volume of compressed air, introduced into the bottom of the airlift, draws sand, solids, and water upward through the pipe by creating a fluid with a density less than one. Impurities are scoured (abraded) from the sand particles during the turbulent upward flow. Upon reaching the top of the airlift, the dirty slurry spills over into the central reject compartment. A steady stream of clean filtrate flows upward, countercurrent to the movement of sand, through the washer section. The upflow liquid carries away the solids and reject water. Because the sand has a higher settling velocity than the removed solids, the sand is not carried out of the filter. The sand is cleaned further as it moves down through the washer. The cleaned sand is redistributed onto the top of the sand bed, allowing for a continuous uninterrupted flow of filtrate and reject water.

Table 11–10 (*Continued*)

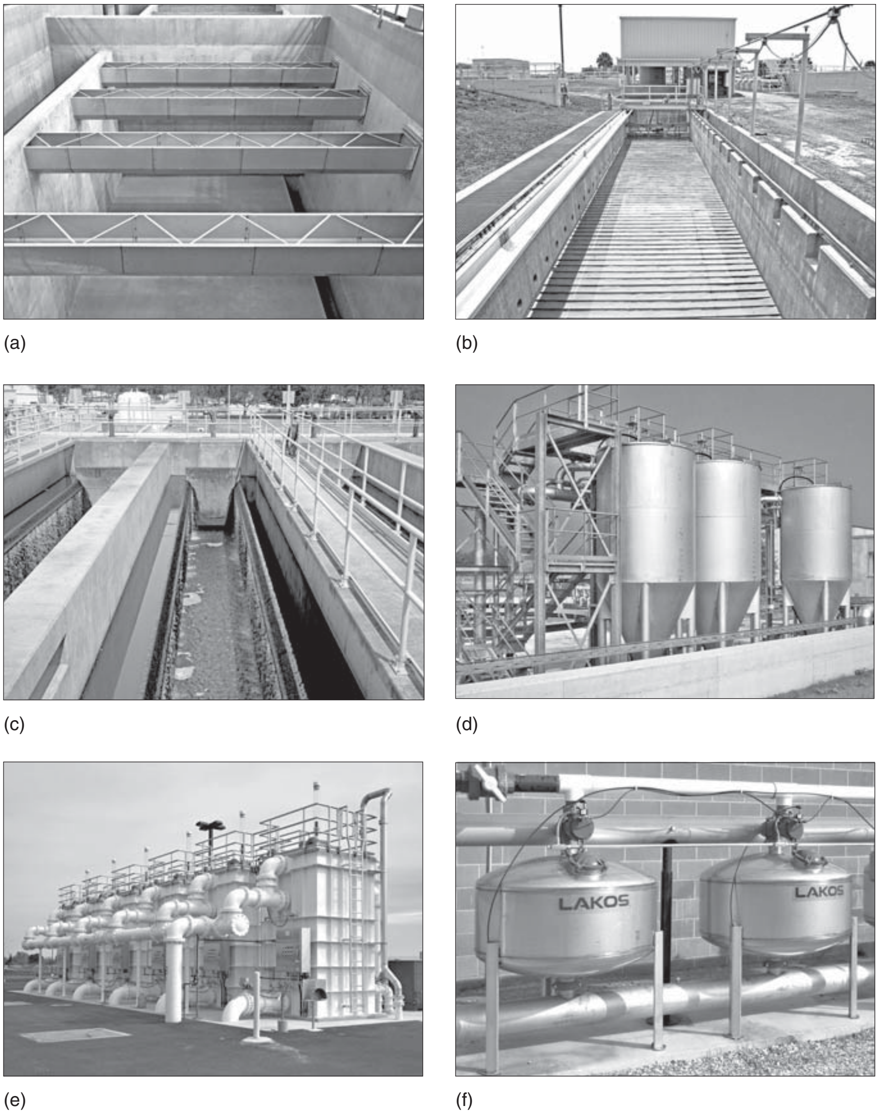
Filter type	Description
(d) Synthetic medium (Fuzzy filter)  	A synthetic medium filter, developed originally in Japan, is used for reclaimed water filtration. Unusual features of the filter are: (1) the porosity of the filter bed can be modified by compressing the filter medium and (2) the size of the filter bed is increased mechanically to backwash the filter. The filter medium, a highly porous synthetic material made of polyvaniladene, allows the influent to flow through the medium as opposed to flowing around the filtering medium, as in sand and anthracite filters. The porosity of the uncompacted quasi-spherical filter medium itself is estimated to be about 88 to 90 percent, and the porosity of the filter bed is approximately 94 percent. In the filtering mode, secondary effluent is introduced in the bottom of the filter. The influent wastewater flows upward through the filter medium, retained by two porous plates, and is discharged from the top of the filter. To backwash the filter, the upper porous plate is raised mechanically. While flow to the filter continues, air is introduced sequentially from the left and right sides of the filter below the lower porous plate, causing the filter medium to move in a rolling motion. The filter medium is cleaned by the shearing forces as the backwash water moves past the filter and by abrasion as the filter medium rubs against itself. Backwash water containing the solids removed from the filter is diverted for subsequent processing. To put the filter back into operation after the backwash cycle has been completed, the raised porous plate is returned to its original position. After a short flushing cycle, the filtered effluent valve is opened, and filtered effluent is discharged.
(e) Pulsed-bed (PBF)  	The pulsed bed filter is a proprietary downflow gravity filter with an unstratified shallow layer of fine sand as the filtering medium. The shallow bed is used for solids storage, as opposed to other shallow-bed filters where solids are principally stored on the sand surface. An unusual feature of this filter is the use of an air pulse to disrupt the sand surface and thus allow penetration of suspended solids into the bed. The air pulse process involves forcing a volume of air, trapped in the underdrain system, up through the shallow filter bed to break up the surface mat of solids and renew the sand surface. When the solids mat is disturbed, some of the trapped material is suspended but the most of solids are entrapped within the filter bed. The intermittent air pulse causes a folding over the sand surface, burying solids within the medium and regenerating the filter bed surface. The filter continues to operate with intermittent pulsing until a terminal headloss limit is reached. The filter then operates in a conventional backwash cycle to remove solids from the sand. During normal operation the filter underdrain is not flooded as it is in a conventional filter.

(*continued*)

Table 11–10 (*Continued*)

Filter type	Description
(f) Traveling bridge  	The traveling bridge filter is a proprietary continuous downflow, automatic backwash, low-head, granular medium depth filter. The bed of the filter is divided horizontally into long independent filter cells. Each filter cell contains approximately 280 mm (11 in.) of medium. Treated wastewater flows through the medium by gravity and exits to the clearwell plenum via a porous plate, polyethylene underdrain. Each cell is backwashed individually by an overhead, traveling bridge assembly, while all other cells remain in service. Water used for backwashing is pumped directly from the clearwell plenum up through the medium and deposited in a backwash trough. During the backwash cycle, wastewater is filtered continuously through the cells that are not being backwashed. The backwash mechanism includes a surface wash pump to assist in breaking up of the surface matting and "mudballing" in the medium. Because the backwashing operation is performed on an "as needed" basis, the backwash cycle is termed semi-continuous.
(g) Two-stage  	A proprietary two-stage filtration process is used for the removal of turbidity, total suspended solids, and phosphorus. Two deep-bed upflow continuous backwash filters are used in series to produce a high quality effluent. A large size sand diameter is used in the first filter to increase the contact time and to minimize clogging. A smaller sand size is used in the second filter to remove residual particles from the first stage filter. The waste washwater from the second filter which contains small particles and residual coagulant is recycled to the first filter to improve floc formation within the first stage filter and the influent to waste ratio. Based on full scale installations the reject rate has been found to be less than 5 percent. Phosphorus levels equal to or less than 0.02 mg/L have been achieved in the final filter effluent.
(h) Pressure filters  	Pressure filters operate in the same manner as gravity filters and are used at smaller plants. The only difference is that, in pressure filters, the filtration operation is carried out in a closed vessel under pressurized conditions achieved by pumping. Pressure filters normally are operated at higher terminal headlosses, resulting in longer filter runs and reduced backwash requirements. If however, they are not backwashed on a regular basis, problems have been experienced with the formation of mudballs.

Long-term data from other water reclamation plants are also shown. The principal conclusions to be reached from an analysis of the data presented on Fig. 11–10 are that (1) given a high quality filter influent (turbidity less than 5 to 7 NTU) all of the filters tested are capable of producing an effluent with an average turbidity of 2 NTU or less without chemical addition; (2) when the influent turbidity is greater than about 7 to 10 NTU,



(a) (b) (c) (d) (e) (f)

Figure 11–9

Views of typical filtration installations: (a) view of empty conventional gravity filter without underdrain system (see Fig. 11–20), but with washwater troughs in place; (b) typical traveling bridge filter (empty) with individual cells exposed; (c) deep-bed denitrifying filter; (d) continuous backwash upflow filters (courtesy Austep, Italy); (e) Fuzzy filter installation comprised of six filters; and (f) bank of small pressure filters used at small wastewater treatment plants. Additional information on these filters is presented in Tables 11–9 and 11–10.

chemical addition is required with all of the filters to achieve an effluent turbidity of 2 NTU or less; and (3) effluent quality is directly related to influent quality if chemical addition is not used. Typical values of effluent quality for turbidity and total suspended solids for depth filtration using granular media are presented in Table 11–12. For comparison, comparable data for other advanced filtration processes (e.g. membranes) used for the removal of particulate matter are presented in Table 11–31 in Sec 11–7.

Keeping in mind the limitations associated with turbidity measurements, the following two relationships can be used to approximate TSS values from measured turbidity values.

Settled secondary effluent

$$\text{TSS, mg/L} = (2.0 \text{ to } 2.4) \times (\text{turbidity, NTU}) \qquad (11\text{–}26)$$

Table 11–11

Comparison of operational characteristics for selected depth filters when filtering settled activated sludge effluent

	Filter bed details[a]		Typical operational filtration rate		Maximum filtration rate approved by CDPH[c,d]		
Type of filter	Type	Filtering medium[b]	gal/ft^2·min	m^3/m^2·min	gal/ft^2·min	m^3/m^2·min	Backwash percentage
Conventional shallow	Mono-medium	S	2–6	0.08–0.24	5	0.20	4–8
Conventional	Dual-media	S and A	2–6	0.08–0.24	5	0.20	4–8
Conventional	Multi-media	S, A, and G	2–6	0.08–0.24	5	0.20	4–8
Deep bed	Mono-medium	S	5–8	0.20–0.33	5	0.20	4–8
Deep bed	Mono-medium	A	5–8	0.20–0.33	5	0.20	4–8
Deep bed, upflow	Mono-medium	S	4–6	0.16–0.15	5	0.20	8–15
Fuzzy filter	Mono-medium	SM	15–40	0.60–1.60	40	1.60	2–5
Pulsed bed	Mono-medium	S	2–6	0.08–0.24	5	0.08	4–8

[d] For Title 22 wastewater reuse applications.

Figure 11–10

Performance data for seven different types of depth filters used for wastewater applications tested using the effluent from the same activated sludge plant at filtration rate 160 L/m^2·min (4 gal/ft^2·min) with the exception of the Fuzzy Filter which was operated at 800 L/m^2·min (20 gal/ft^2·min).

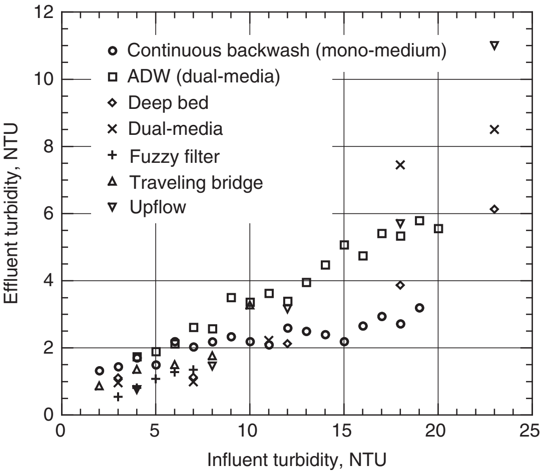

Table 11–12

Typical range of effluent quality variability observed from particulate removal processes

Particulate removal process	Unit	Typical range of effluent values	Geometric standard deviation, s_g[a] Range	Typical
Depth filtration following activated sludge process				
Turbidity	NTU	0.5–4	1.2–1.4	1.25
TSS	mg/L	2–8	1.3–1.5	1.4
Depth filtration following activated sludge with BNR				
Turbidity	NTU	0.3–2	1.2–1.4	1.25
TSS	mg/L	1–4	1.3–1.5	1.35
Surface filtration following activated sludge process				
Turbidity	NTU	0.5–2	1.2–1.4	1.25
TSS	mg/L	1–4	1.3–1.5	1.25

[a] s_g = geometric standard deviation; $s_g = P_{84.1}/P_{50}$.

Filter effluent

$$\text{TSS, mg/L} = (1.3 \text{ to } 1.6) \times (\text{turbidity, NTU}) \tag{11–27}$$

Using the above approximations, turbidity values of 5 to 7 NTU in the settled secondary effluent, which is the influent to the filter, correspond to TSS concentrations varying from about 10 to 17 mg/L, and an effluent turbidity of 2 NTU corresponds to TSS concentrations varying from 2.8 to 3.2 mg/L.

Variability in Turbidity and Total Suspended Solids Removal. In water reuse applications the variability of filter performance is of critical importance because there are specific effluent turbidity limits that must be met consistently. For example, the turbidity standard for reclaimed water for unrestricted use in California is equal to or less than 2 NTU. Because the required turbidity value is written without a decimal point, a turbidity value of 2.49 NTU is reported as 2 NTU. The variability observed in the operating data from a large water reclamation facility is illustrated on Fig. 11–11, for the years 2010 and 2011.

Comparing the mean turbidity and TSS values for the two different years, the TSS/turbidity ratios are 1.51 and 1.32, respectively, which is consistent with the range given in Eq. (11–27). The corresponding geometric standard deviations, s_g, for turbidity for the two years are 1.26 and 1.23, respectively. Similarly, the geometric standard deviations for TSS are 1.37 and 1.42, respectively. Both sets of values are consistent with the range of s_g values reported in the literature, as given in Table 11–12. Characterization of the variability in effluent constituents using the geometric standard deviation, s_g, is discussed in Appendix D. The greater the numerical value of s_g, the greater the observed range in the measured values. Use of the data in Table 11–12 is illustrated in Example 11–3.

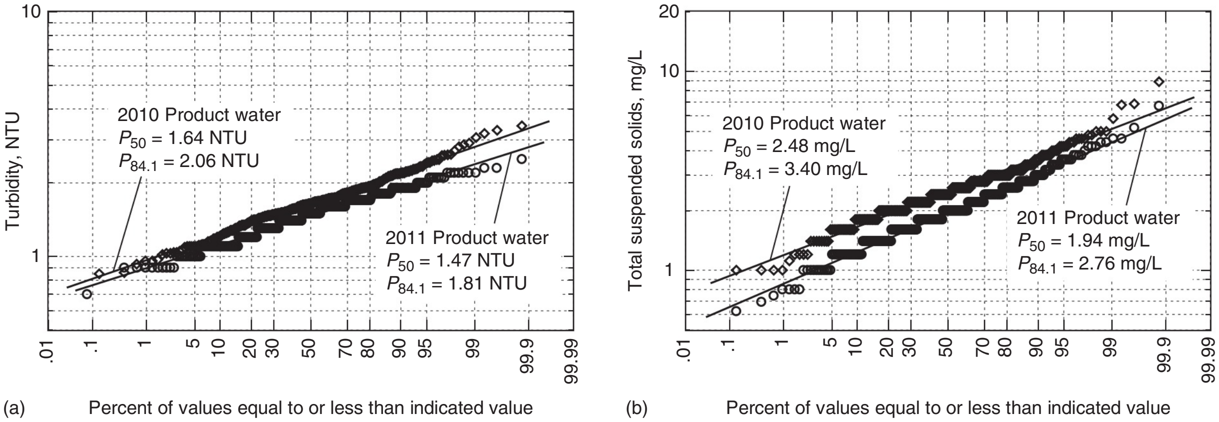

Figure 11–11

Probability distributions for filter performance for the filtration of settled activated sludge effluent from a large water reclamation facility: (a) turbidity and (b) total suspended solids.

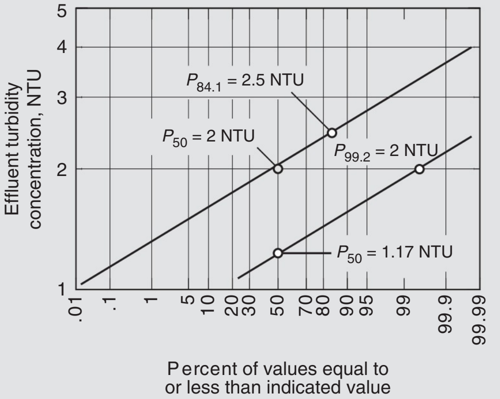
EXAMPLE 11–3 **Evaluation of the Effluent Variability of an Activated Sludge Process with Mono-medium Filtration** An activated sludge process with mono-medium filtration has been designed to have a mean effluent turbidity value of 2 NTU. Determine the maximum turbidity value that is expected to occur with a frequency of (a) once per year and (b) once every three years. If the effluent turbidity standard is 2.49 NTU, estimate how often the process will exceed the turbidity limit.

Solution

1. Select an s_g value from Table 11–12 that corresponds to the effluent turbidity for an activated sludge with filtration process. From Table 11–12, use the typical s_g value of 1.25.
2. Determine the probability distribution of the effluent turbidity values.
   a. Using the s_g value, compute the turbidity value corresponding to the plotting position on $P_{84.1}$ (see Appendix D).

   $$P_{84.1} = s_g \times P_{50} = 1.25 \times 2 \text{ NTU} = 2.5 \text{ NTU}$$

   b. Estimate the distribution of effluent turbidity values by plotting the $P_{84.1}$ and P_{50} values. As the effluent turbidity values are expected to follow a log normal distribution, a straight line can be drawn through the $P_{84.1}$ and P_{50} values, as shown on the following plot.



3. Compute the effluent turbidity value expected to occur with the frequency of interest.
   a. The probability of occurrence of a given event with a frequency of once per year is (1 / 365) x 100 = 0.3 percent. Using the plot developed in step 2, an effluent turbidity value equal to or greater than 3.5 NTU will occur 0.3 percent of the time.
   b. Similarly, turbidity values equal to greater than 3.7 NTU will occur with a frequency of once in three years (i.e., 99.9 percent).
4. Estimate how often the combined treatment process will exceed the turbidity standard of 2.49 NTU. From the plot presented in step 2, the effluent turbidity will exceed 2.49 NTU approximately 16 (100–84) percent of the time.

Comment Recognition of the variability in performance is of importance in the design of filtration systems, especially where more stringent mean effluent turbidity values must be met. For example, it the turbidity standard had been 2.0 NTU at a reliability of at least 99.2 percent (three exceedances per year), the mean design value, as illustrated in the above figure, would have to be about 1.17 NTU, assuming that the geometric standard deviation remained constant and was equal to 1.25. To reach a mean turbidity value of 1.17 NTU would, in most cases, require the addition of chemicals, although many plants with deep secondary clarifiers reach these values consistently without chemical addition.

Removal of Different Particle Sizes. Although all of the filters shown on Fig. 11–10 can produce an effluent with an average turbidity of two or less with a suitable secondary effluent, the filtered effluent particle size distribution is different for each of the filters. Typical data on the removal of particle sizes from activated sludge effluent using depth filtration are shown on Fig. 11–12. As shown, the particle removal rate is essentially independent of the filtration rate in the range from 100 to about 260 L/m^2·min. It is significant to note that most depth filters will pass some particles with diameters greater than 15 to 20 μm.

Depending on the quality of the settled secondary effluent, chemical addition has been used to improve the performance of effluent filters, with respect to turbidity. An example of the change in the distribution of particle sizes in the effluent from an activated sludge process following depth filtration without and with chemical coagulation is illustrated on

Figure 11–12

Particle size removal efficiency for a depth filter for effluent from an activated sludge plant at two different filtration rates.

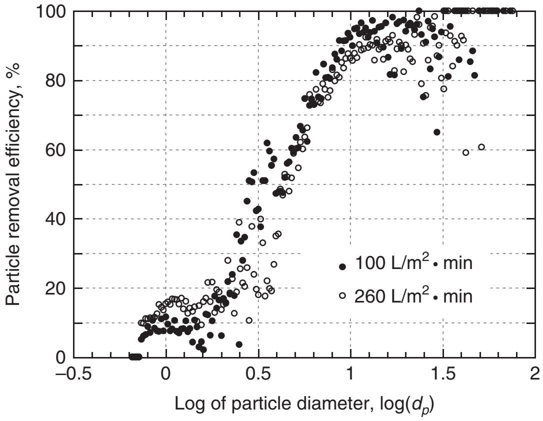


Figure 11–13

Effect of the use of chemicals on filter particle size removal performance (courtesy of K. Bourgeous, 2005): (a) original data as collected and, (b) the original data, plotted functionally according to the power law (see Example 2–4 in Chap. 2).

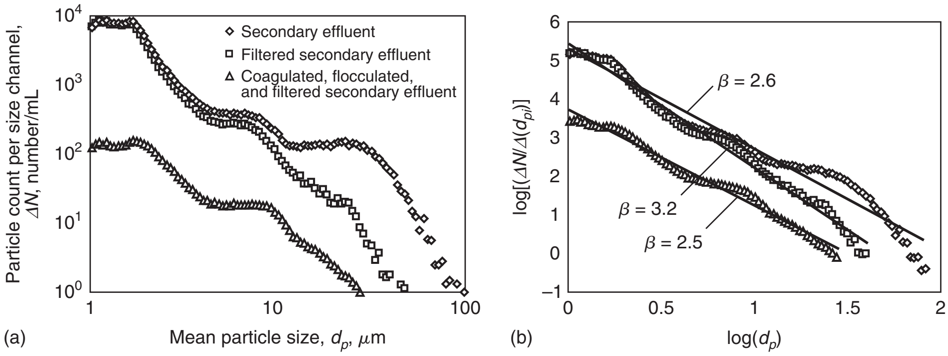

Fig. 11–13. The original data, as collected, are shown on Fig. 11–13(a). The original data, plotted functionally according to the power law (see Example 2–4 in Chap. 2), are presented on Fig. 11–13(b). As shown on Fig. 11–13(a), filtration alone only affected the larger particles, whereas with chemical coagulation all of the particles were affected more-or-less uniformly. As shown on Fig. 11–13(b), even though the number of particles in each size range was reduced by an order of magnitude, a significant number of particles remains in each size range.

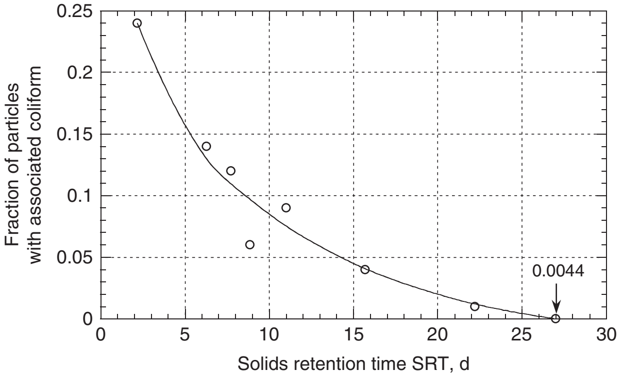
Removal of Microorganisms. Where chemicals are not used, the removal of coliform bacteria and viruses from biologically treated secondary effluent is on the order of 0 to 1.0 and 0 to 0.5 logs, respectively. The degree of removal depends on the solids retention time (SRT) at which the biological process is operated. For example, as shown on Fig. 11–14, as the SRT is increased, fewer of the particles have one or more associated coliform bacteria. Typical data on the removal of the bacteriophage MS2 are illustrated on Fig. 11–15. As shown, the mean removal of MS2 across the effluent filters is about 0.3 logs. However, what is of more interest is the distribution of the removal data. Based on the distribution shown on Fig. 11–15, which is also typical for the removal of coliform organisms, allowing a disinfection credit of one log of removal for filtration in water reuse applications may not be protective of public health. Where chemicals are used, the data on the removal for microorganisms is confounded statistically. In general, it is not possible to separate the effect of chemical addition from the performance of the filter.

Backwash Water Requirements. The amount of backwash water needed to clean the filter bed, expressed as a percentage of plant flow, will depend on the characteristics of filter influent and the design of the filter bed. Typical backwash water percentages for

Figure 11–14

Number of particles with one or more associated coliform organisms as a function of the solids retention time for the activated sludge process. (Adapted from Darby, et al., 1999.)



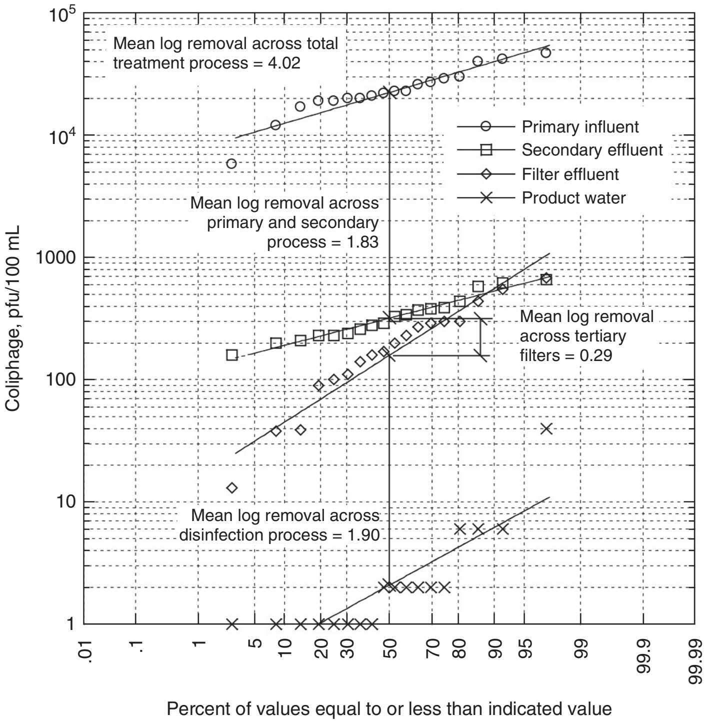


Figure 11–15

Removal of MS2 coliphage through a treatment process comprised of an activated sludge process, depth filtration, and chlorine disinfection.

depth filters shown in Table 11–11 will vary from 4 to 15 percent. By comparison, the backwash percentages for surface filters, discussed in the following section, will typically vary from 1 to 4 percent. When adding effluent filtration to an existing plant, the impact of the return backwash water on plant hydraulics must be evaluated carefully. In many locations, the percentage of backwash water will control filter selection. The volume of backwash water required to wash a filter is related to filter area and desired degree of backwash bed expansion, the size of the media, and water temperature.

Considerations Related to Design and Operation of Treatment Facilities

The design and operation of the treatment facilities can have a significant impact on the performance of depth filters. Issues related to the design and operation of wastewater treatment facilities will depend on whether filtration is being considered for an existing or new facility. Both existing and new facilities are considered in the following discussion.

Existing Treatment Plants. Where effluent filtration must be added to or retrofitted to an existing treatment plant it will be important to consider the factors that can impact the effluent quality including (1) the design and operation of the secondary sedimentation facilities, (2) the type and operation of biological treatment process, (3) the operation of the treatment plant with respect to return flows, and (4) the potential use of flow equalization.

Design and Operation of Secondary Sedimentation Facilities. The concentration and variability of the suspended solids and colloidal material in the effluent from sedimentation facilities will vary depending on the characteristics of the biological solids to be settled; the depth of the sedimentation basins; the use of energy dissipation inlets (see Fig. 8–54); the presence of sludge density currents, as described in Chap. 5; short circuiting caused by a variety of factors and the placement of the effluent weirs. Typically, the TSS concentration in the effluent from activated sludge and trickling filter plants varies between 6 and 30 mg/L. Corresponding turbidity values, as discussed previously, can vary from 3 to 15 NTU. It should be noted that properly designed deep secondary sedimentation tanks 6 to 7 m (19.5 to 23 ft) can produce an average settled effluent with turbidity of 2 NTU or less consistently, and in some cases less than 1 NTU. Depending on the concentration and variability of the suspended solids in the effluent from the secondary sedimentation it may be appropriate to consider a filter that can continue to function even when heavily loaded. Both downflow and upflow deep-bed coarse medium filters, the fuzzy filter, and the pulsed-bed filter have been used in such applications.

Type and Operation of Biological Treatment Process. The three principal types of biological treatment processes used for secondary treatment are suspended growth, as exemplified by the activated sludge process; attached growth processes, as exemplified by the trickling filter process; and pond processes. The floc strength and filterability of the effluents from each of these processes will vary with the mode of operation. For example, the strength of the biological floc from the activated sludge process will vary with the mean cell-residence time, increasing with longer mean cell residence time. The increased strength derives in part from the production of extracellular polymers as the mean cell residence time is lengthened. At extremely long mean cell residence times (15 d and longer), it has been observed that the floc strength will decrease due to floc breakup. It has also been observed that the residual suspended solids remaining after secondary clarification from treatment processes with extremely long mean cell residence times are far more difficult to filter and as a result can impact the performance of disinfection systems (Emerick, 2012). Further, the residual floc from the chemical precipitation of biologically processed wastewater may be considerably weaker than the residual biological floc before precipitation. If there is uncertainty about the characteristics of the effluent from the secondary sedimentation facilities, pilot plant studies should be conducted, as discussed subsequently.

Management of Return Flows. Currently, in most treatment plants, return flows from sludge thickeners, sludge dewatering (e.g., centrifuges, and belt presses), sludge stabilization (e.g., digester supernatant), and sludge drying facilities are returned to the wastewater treatment plant headworks for reprocessing. In many instances, these return flows contain constituents that deteriorate overall plant performance (e.g., nitrogenous compounds, colloidal material and total dissolved solids). Unfortunately, these return flows can impact the overall performance of the biological treatment process especially with respect to the removal of nitrogen and colloidal material. Flow equalization facilities and or separate systems for the treatment of return flows, as discussed in Chap. 15, are now being installed at a number of treatment plants that need to meet more stringent discharge requirements. (Tchobanoglous et al., 2011).

Flow Equalization. Flow equalization is a method used to improve the performance and variability of the downstream treatment processes and to reduce the size and cost of treatment facilities (see extended discussion in Sec. 3–7 in Chap. 3). In advanced wastewater treatment, the principal benefits include (1) reduced variability of incoming water quality; (2) enhanced performance at constant flow operation, especially for membrane processes; and (3) reduced wear and tear on membranes due to fluctuating flows and loads (Tchobanoglous et al., 2003). If full plant flow equalization is not feasible, consideration should be given to flow equalization of the return flows.

New Treatment Plants. For new wastewater treatment plants all of the factors discussed above should be considered. However, extra care should be devoted to the design of the secondary settling facilities. With properly designed settling facilities resulting in an effluent with low TSS (typically 3 to 4 mg/L or less) and turbidity (less than 1 to 2 NTU), the decision on what type of filtration system is to be used is often based on plant-related variables, such as the space available, duration of filtration period (seasonal versus year-round), the time available for construction, and costs. The most important influent characteristics in the filtration of treated secondary effluents are the suspended-solids concentration, particle size and distribution, and floc strength.

Selection of Filtration Technology

In selecting a filter technology, important factors that must be considered include (1) the required effluent quality, (2) the influent wastewater characteristics, (3) type of filter to be used: proprietary or individually designed, (4) the filtration rate, (5) filtration driving force, (6) number and size of filter units, (7) the backwash water requirements, (8) the need for pilot-plant studies, and (9) system redundancy. Each of these issues is described in Table 11–13. The importance of the influent characteristics has been discussed previously. The backwash requirements, the need for chemical addition, and the need to conduct pilot plant studies are considered in the following discussion because of the impact these factors can have on the selection of a depth filtration process.

Table 11–13

Important factors in selecting filter technology for effluent filtration applications[a]

Factor	Remarks
Required effluent quality	Usually fixed regulatory requirement, depending on the final use of the effluent.
Influent wastewater characteristics	The required effluent quality will impact the selection process, as some filters are more able to withstand periodic shock loadings. For example, wider variations in effluent quality would be expected where shallow clarifiers are used. More predictable effluent quality can be expected from deep clarifiers. In recent designs employing deep clarifiers (5 to 6 m side water depths), effluent turbidity values of less than 2 NTU are achieved consistently.
Type of filter: proprietary vs. individually designed	Currently available filter technologies are either proprietary or individually designed. With proprietary filters, the manufacturer is responsible for providing the complete filter unit and its controls, based on basic design criteria and performance specifications. In individually designed filters, the design engineer is responsible for working with several suppliers in developing the design of the system components. Contractors and suppliers then furnish the materials and equipment in accordance with the engineer's design.
Filtration rate	The filtration rate affects the areal size of the filters that will be required. For a given filter application, the rate of filtration depends primarily on floc strength and the size of the filtering medium. For example, if the strength of the floc is weak, high filtration rates tend to shear the floc particles and carry much of the material through the filter. Filtration rates generally in the range of 80 to 330 $L/m^2 \cdot min$ will not affect the effluent quality when filtering settled activated sludge effluent (see Table 11–11).
Filtration driving force	Either the force of gravity or an applied pressure force can be used to overcome the frictional resistance to flow offered by the filter bed. Gravity filters of the type discussed in Table 8-5 are used most commonly for the filtration of treated effluent at large plants. Pressure filters operate in the same manner as gravity filters and are used at smaller plants. In pressure filters, the filtration operation is carried out in a closed vessel under pressurized conditions achieved by pumping.

(*continued*)

Table 11–13 (*Continued*)

Factor	Remarks
Number and size of filtration units	The number of filter units generally should be kept to a minimum to reduce the cost of piping and construction, but it should be sufficient to assure that (1) backwash flowrates do not become excessively large and (2) that when one filter unit is taken out of service for backwashing, the transient loading on the remaining units is not excessive. Transient loadings due to backwashing are not an issue with filters that backwash continuously. To meet redundancy requirements, a minimum of two filters should be used. The sizes of the individual filter units should be consistent with the sizes of equipment available for use as underdrains, washwater troughs, and surface washers. Typically, width-to-length ratios for individually designed gravity filters vary from 1:1 to 1:4. A practical limit for the surface area on an individual depth filter (or filter cell) is about 100 m^2 (1075 ft^2), although larger filters units have been built. For proprietary filters, use standard sizes that are available from manufacturers. The surface area of a depth filter is based on the peak filtration and peak plant flowrates. The allowable peak filtration rate is usually established on the basis of regulatory requirements. Operating ranges for a given filter type are based on past experience, the results of pilot-plant studies, manufacturers recommendations, and regulatory constraints.
Backwash water requirements	As noted in Table 8–4, depth filters operate in either a semi-continuous or continuous mode. In semi-continuous operation, the filter is operated until the effluent quality starts to deteriorate or the headloss becomes excessive at which point the filter is taken out of service and backwashed to remove the accumulated solids. With filters operated in the semi-continuous mode, provision must be made for the backwash water needed to clean the filters. Typically, the backwash water is pumped from a filtered water clearwell or obtained by gravity from an elevated storage tank. The backwash storage volume should be sufficient to backwash each filter every 12 h. For filters that operate continuously such as the upflow filter and the traveling bridge filter, the filtering and backwashing phases take place simultaneously. In the traveling bridge filter, the backwash operation can either be continuous or semi- continuous as required. For filters that operate continuously, there is no turbidity breakthrough or terminal headloss.
Chemical addition	Need for chemical addition is site specific. Depending on the final use of the effluent, provision of chemical dosing facilities may be mandated by local and/or state regulations.
Pilot-plant studies	Because of the many variables involved, pilot-plant studies are often conducted when filtration facilities are to be added to an existing facility. For new plants, pilot-plant studies can be conducted at treatment plants of similar design.
System redundancy	System redundancy is related to uninterruptible power and the need to provide standby capacity for routine maintenance. Most water reclamation plants in continuous service have emergency storage and onsite power generation to operate process equipment. In general, one standby filter, as a minimum, is recommended for standby service. Where the provision of standby facilities is not possible due to space or other limitations, the filters and related piping should be sized to handle periodic overloads during maintenance periods.

[a] Adapted, in part, from Tchobanoglous et al. (2003).

Filter Backwash Water Requirements. Methods commonly used for backwashing granular medium filter beds are considered subsequently. In general, depth filters require more backwash water as compared to surface filters. For existing plants with limited hydraulic capacity, the percentage of backwash water that can be processed may be the limiting factor in the selection of a filter technology. Because it is impossible to predict a priori what percentage backwash water will be needed, pilot-plant studies must be conducted to resolve the issue.

Effluent Filtration with Chemical Addition. Depending on the quality of the settled secondary effluent, chemical addition has been used to improve the performance of effluent filters. Chemical addition has also been used to achieve specific treatment objectives including the removal of specific contaminants such as phosphorus, metal ions, and humic substances. The removal of phosphorus by chemical addition is considered in Chap. 6. To control eutrophication, the contact filtration process is used in many parts of the country to remove phosphorus from wastewater treatment plant effluents which are discharged to sensitive water bodies. The two-stage filtration process, described in Table 11–10, has proven to be very effective, achieving phosphorus levels of 0.2 mg/L or less in the filtered effluent. Chemicals commonly used in effluent filtration include a variety of organic polymers, alum, and ferric chloride. Use of organic polymers and the effects of the chemical characteristics of the wastewater on alum addition are considered in the following discussion.

Use of Organic Polymers. Organic polymers are typically classified as long chain organic molecules with molecular weights varying from 10^4 to 10^6. With respect to charge, organic polymers can be cationic (positively charged), anionic (negatively charged), or nonionic (no charge). Polymers are added to settled effluent to bring about the formation of larger particles by bridging as described in Chap. 6. Because the chemistry of the wastewater has a significant effect on the performance of a polymer, the selection of a given type of polymer for use as a filter aid generally requires experimental testing (e.g., jar testing).

Common test procedures for polymers involve adding an initial dosage (usually 1.0 mg/L) of a given polymer and observing the effects. Depending upon the effects observed, the dosage should be increased by 0.5 mg/L increments or decreased by 0.25 mg/L increments (with accompanying observation of effects) to obtain an operating range. After the operating range is established, additional testing can be done to establish the optimum dosage. Great care must be taken to insure that the polymer is well dispersed before reaching the filter to avoid the formation of mudballs.

A recent development is the use of lower molecular weight polymers that are intended to serve as alum substitutes. When these polymers are used, the dosage is considerably higher ($\geq$10 mg/L) than with higher molecular weight polymers (0.25 to 1.25 mg/L). As with the mixing of alum, the initial mixing step is critical in achieving maximum effectiveness of a given polymer. In general, mixing times of less than 1 second with G values of $>2500\ \text{s}^{-1}$ are recommended (see Table 5–9 in Chap. 5). It should be noted that, as a practical matter, as treatment plants get larger it is difficult to achieve mixing times less than one second unless multiple mixing devices are used.

Effects of Chemical Characteristics of Wastewater on Alum Addition. As with polymers, the chemical characteristics of the treated wastewater effluent can have a significant impact on the effectiveness of aluminum sulfate (alum) when it is used as an aid to filtration. For example, the effectiveness of alum is dependent on pH (see Fig. 6–9 in Chap. 6). Although Fig. 6–9 was developed for water treatment applications, it has been found to apply to most wastewater effluent filtration uses with minor variations. As shown on Fig. 6–9, the approximate regions in which the different phenomena associated with particle removal in conventional sedimentation and filtration processes are operative are plotted as a function of the alum dose and the pH of the treated effluent after alum has been added. For example, optimum particle removal by sweep floc occurs in the pH range of 7 to 8 with an alum dose of 20 to 60 mg/L. Generally, for many wastewater effluents that have high pH values (e.g. 7.3 to 8.5), low alum dosages in the range of 5 to 10 mg/L will not be effective. To operate with low alum dosages, pH control will generally be required.

Need for Bench-Scale and Pilot-Plant Studies. Although the information presented earlier in this section and previously in Sec. 11–3 will help the reader understand the nature of the filtration operation as it is applied to the filtration of treated wastewater, it must be stressed that there is no generalized approach to the design of full-scale filters. The principal reason is the inherent variability in the characteristics of the influent suspended solids to be filtered. For example, changes in the degree of flocculation of the suspended solids in the secondary settling facilities will significantly affect the particle sizes and their distribution in the effluent, which in turn will affect the performance of the filter. Further, because the characteristics of the effluent suspended solids will also vary with the organic loading on the process as well as with the time of day, filters must be designed to function under a rather wide range of operating conditions. The best way to ensure that the filter configuration selected for a given application will function properly is to conduct pilot-plant studies (see Fig. 11–16).

Because of the many variables that can be analyzed, care must be taken not to change more than one variable at a time so as to confound the results in a statistical sense. Bench-scale and pilot-plant testing should be carried out at several intervals, ideally throughout a full year, to assess seasonal variations in the characteristics of the effluent to be filtered. All test results should be summarized and evaluated in different ways to ensure their proper analysis. Because the specific details of each test program will be different, no generalization on the best method of analysis can be given.

Design Considerations for Granular Medium Filters

As noted in Table 11–9, the currently available filter technologies are either proprietary or individually designed. With proprietary filters, the manufacturer is responsible for providing the complete filter unit and its controls, based on basic design criteria and performance specifications. In individually designed filters, the designer is responsible for working with several suppliers in developing the design of the system components. Contractors and suppliers then furnish the materials and equipment in accordance with the engineer's design.

Because granular medium filters are still designed individually, important design considerations for depth filters are summarized in Table 11–14. Although some of the factors listed in Table 11–14 have been discussed previously and other design details are beyond the scope of this textbook, it is nevertheless important to consider the selection of the type of filter bed and filter medium(s) used in depth filters, the backwashing operation, and filter appurtenances.

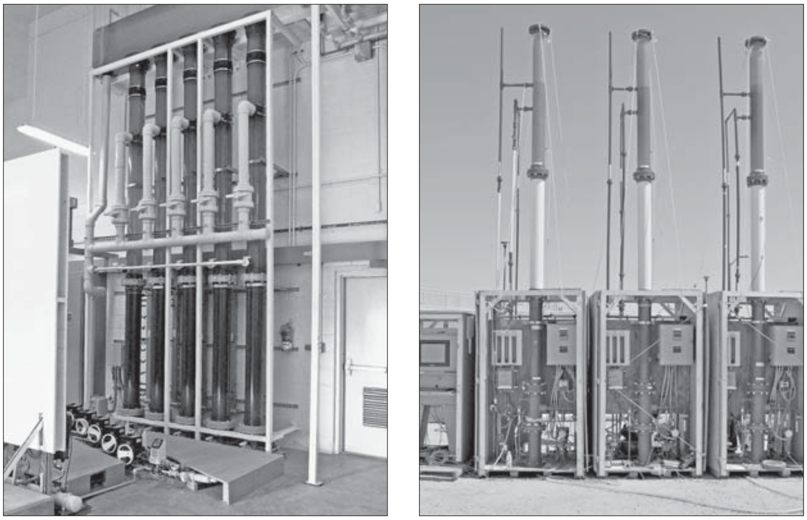

Figure 11–16

Views of filtration pilot plant: (a) filter columns fed from the source and (b) instrumentation used to monitor filter performance including turbidity and particle size counting.

Table 11–14

Design considerations for granular medium filters for effluent for filtration

Variable	Significance
1. Required effluent quality	Usually fixed regulatory requirement, depending on the final use of the effluent.
2. Influent wastewater characteristics	Considered in previous section.
3. Filter medium characteristics a. Effective size, d_{10} b. Uniformity coefficient, UC c. Type, grain shape, density, and composition	Affects clean-water headloss, particulate matter removal efficiency, and headloss buildup.
4. Filter-bed characteristics a. Bed depth b. Porosity c. Stratification d. Degree of medium intermixing	Porosity affects the amount of solids that can be stored within the filter. Bed depth affects initial headloss, length of run. Degree of intermixing will affect performance of filter bed.
5. Filtration rate	Used in conjunction with variables 2, 3, and 4 to compute clean-water headloss. Maximum rate typically specified by regulatory agency (see Table 11–11).
6. Flowrate control	The principal methods now used to control the rate of flow through downflow gravity filters may be classified as (1) constant-rate filtration with fixed head, (2) constant-rate filtration with variable head, and (3) variable-declining-rate filtration. Other control methods are also in use.
7. Allowable headloss	Design variable, depends on whether driving force will be gravity or applied pressure.
8. Backwashing system	Methods commonly used for backwashing granular medium filter beds operated in the semi-continuous mode include (1) water backwash with auxiliary surface washwater agitation, (2) water backwash with auxiliary air scour, and (3) combined air-water backwashing. With the first two methods, fluidization of the granular medium is necessary to achieve effective cleaning of the filter bed at the end of the run. With the third method, fluidization is not necessary. Typical backwash flowrates required to fluidize various filter beds are reported in Table 11–11.
9. Backwash requirements	Affects size of filter piping and pipe gallery.
10. Filter appurtenances	Filter appurtenances include: (1) the underdrain system used to support the filtering materials, collect the filtered effluent, and distribute the backwash water and air (where used); (2) the washwater troughs used to remove the spent backwash water from the filter; and (3) the surface washing systems used to help remove attached material from the filter medium.

Filter Bed Configuration and Filter Medium. Important considerations in individually designed depth filters are the selection of the type of filter bed and the corresponding media characteristics.

Selection of Filter Bed Configuration. The principal types of non-proprietary filter bed configurations now used for wastewater filtration may be classified according to the number of filtering media that are used as mono-medium, dual-media, or multi-media beds (see Fig. 11–6). In conventional downflow filters, the distribution of grain sizes for each medium after backwashing is from small to large. Typical design data for mono-medium, and dual- and multi-media filters are presented in Tables 11–15 and 11–16, respectively.

Table 11–15

Typical design data for depth filters with mono-medium[a]

Characteristic	Value		
	Unit	Range	Typical
Shallow bed (stratified)			
Anthracite			
Depth	mm	300–500	400
Effective size	mm	0.8–1.5	1.3
Uniformity coefficient	unitless	1.3–1.8	≤1.5
Filtration rate	$m^3/m^2 \cdot min$	0.08–0.24	
Sand			
Depth	mm	300–360	330
Effective size	mm	0.45–0.65	0.45
Uniformity coefficient	unitless	1.2–1.6	≤1.5
Filtration rate	$m^3/m^2 \cdot min$	0.08–0.24	
Conventional (stratified)			
Anthracite			
Depth	mm	600–900	750
Effective size	mm	0.8–2.0	1.3
Uniformity coefficient	unitless	1.3–1.8	≤1.5
Filtration rate	$m^3/m^2 \cdot min$	0.08–0.40	
Sand			
Depth	mm	500–750	600
Effective size	mm	0.4–0.8	0.65
Uniformity coefficient	unitless	1.2–1.6	≤1.5
Filtration rate	$m^3/m^2 \cdot min$	0.08–0.24	
Deep-bed (unstratified)			
Anthracite			
Depth	mm	900–2100	1500
Effective size	mm	2–4	2.7
Uniformity coefficient	unitless	1.3–1.8	≤1.5
Filtration rate	$m^3/m^2 \cdot min$	0.08–0.40	
Sand			
Depth	mm	900–1800	1200
Effective size	mm	2–3	2.5
Uniformity coefficient	unitless	1.2–1.6	≤1.5
Filtration rate	$m^3/m^2 \cdot min$	0.08–0.40	
Fuzzy filter			
Depth	mm	600–1080	800
Effective size	mm	25–30	28
Uniformity coefficient	unitless	1.1–1.2	1.1
Filtration rate	$m^3/m^2 \cdot min$	0.60–1.60	

[a] Adapted in part from Tchobanoglous (1988) and Tchobanoglous et al. (2003).

Note: $m^3/m^2 \cdot min \times 24.5424 = gal/ft^2 \cdot min$.

Table 11–16

Typical design data for dual- and multi-media depth filters[a]

Characteristic	Value[b]		
	Unit	Range	Typical
Dual-media			
Anthracite ($\rho = 1.60$)			
Depth	mm	360–900	720
Effective size	mm	0.8–2.0	1.5
Uniformity coefficient	unitless	1.3–1.6	≤1.5
Sand ($\rho = 2.65$)			
Depth	mm	180–360	360
Effective size	mm	0.4–0.8	0.65
Uniformity coefficient	unitless	1.2–1.6	≤1.5
Filtration rate	$m^3/m^2 \cdot min$	0.08–0.40	0.20
Multi-media			
Anthracite (top layer of quad-media filter, $\rho = 1.60$)			
Depth	mm	240–600	480
Effective size	mm	1.3–2.0	1.6
Uniformity coefficient	unitless	1.3–1.6	≤1.5
Anthracite (second layer of quad-media filter, $\rho = 1.60$)			
Depth	mm	120–480	240
Effective size	mm	1.0–1.6	1.1
Uniformity coefficient	unitless	1.5–1.8	1.5
Anthracite (top layer of tri-media filter, $\rho = 1.60$)			
Depth	mm	240–600	480
Effective size	mm	1.0–2.0	1.4
Uniformity coefficient	unitless	1.4–1.8	≤1.5
Sand ($\rho = 2.65$)			
Depth	mm	240–480	300
Effective size	mm	0.4–0.8	0.5
Uniformity coefficient	unitless	1.3–1.8	≤1.5
Garnet ($\rho = 4.2$)			
Depth	mm	50–150	100
Effective size	mm	0.2–0.6	0.35
Uniformity coefficient	unitless	1.5–1.8	≤1.5
Filtration rate	$m^3/m^2 \cdot min$	0.08–0.40	0.20

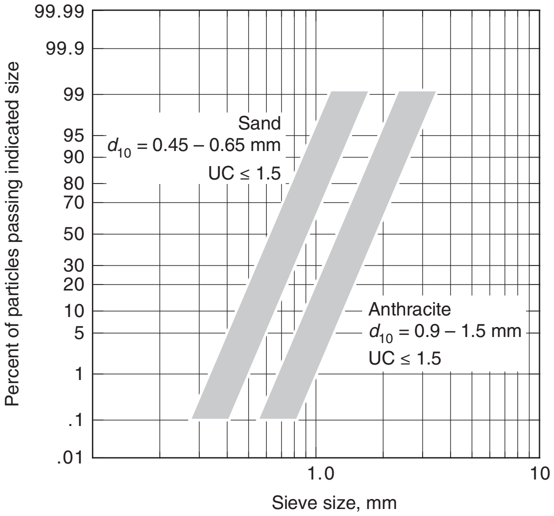
[b] Anthracite, sand, and garnet sizes selected to limit the degree of intermixing. Use Eq. (11–28) for other values of density, ρ.

Note: $m^3/m^2 \cdot min \times 24.5424 = gal/ft^2 \cdot min$.

Figure 11–17

Typical particle size distribution ranges for sand and anthracite used in dual medium depth filters. Note that for sand the 10 percent size by weight corresponds approximately to the 50 percent size by count.



Selection of Filter Medium. Once the type of filter to be used has been selected, the next step is to specify the characteristics of the filter medium, or media, if more than one is used. Typically, this process involves the selection of the grain size as specified by the effective size, d_{10}, uniformity coefficient, UC, the 90 percent size, the specific gravity, solubility, hardness, and depth of the various materials used in the filter bed. Typical particle size distribution ranges for sand and anthracite filtering material are shown on Fig. 11–17. The 90 percent size designated, d_{90}, as read from a grain size analysis is used commonly to determine the required backwash rate for depth filters. The physical properties of filter materials used in depth filters are summarized in Table 11–17.

To avoid extensive intermixing of the individual mediums in multi-media filter beds, the settling rate of the filter media comprising the dual- and multi-media filters must have essentially the same settling velocity. Some intermixing is unavoidable, and the degree of intermixing in the dual- and multi-media beds depends on the density and size differences of the various media. The following relationship can be used to establish the appropriate sizes (Kawamura, 2000).

$$\frac{d_1}{d_2} = \left(\frac{\rho_2 - \rho_w}{\rho_1 - \rho_w}\right)^{0.667} \tag{11–28}$$

where d_1, d_2 = effective size of filter medium
ρ_1, ρ_2 = density of filter medium
ρ_w = density of water

The application of Eq. (11–28) is illustrated in Example 11–4.

Table 11–17

Typical properties of filter materials used in depth filtration[a]

Filter material	Specific gravity	Porosity, α	Sphericity
Anthracite	1.4–1.75	0.56–0.60	
Sand	2.55–2.65	0.40–0.46	0.75–0.85
Garnet	3.8–4.3	0.42–0.55	0.75–0.85
Ilmenite	4.5	0.40–0.5	
Fuzzy filter medium		0.87–0.89	

[a] Adapted in part from Cleasby and Logsdon (1999).

EXAMPLE 11–4 **Determination of Filter Medium Sizes** A dual media filter bed comprised of sand and anthracite is to be used for the filtration of settled secondary effluent. If the effective size of the sand in the dual medium filter is to be 0.55 mm, determine the effective size of the anthracite to avoid significant intermixing.

Solution

1. Summarize the properties of the filter media
    a. For sand
        i. Effective size = 0.55 mm
        ii. Specific gravity = 2.65 (see Table 11–17)
    b. For anthracite
        i. Effective size = to be determined, mm
        ii. Specific gravity = 1.7 (see Table 11–17)
2. Compute the effective size of the anthracite using Eq. (11–28)

$$d_1 = d_2\left(\frac{\rho_2 - \rho_w}{\rho_1 - \rho_w}\right)^{0.667}$$

$$d_1 = 0.55\text{ mm}\left(\frac{2.65 - 1}{1.7 - 1}\right)^{0.667}$$

$$d_1 = 0.97\text{ mm}$$

Comment Another approach that can be used to assess whether intermixing will occur is to compare the fluidized bulk densities of the two adjacent layers (e.g., upper 450 mm sand and lower 100 mm of anthracite).

Filter Flowrate Control. The principal methods now used to control the rate of flow through downflow gravity filters may be classified as (1) constant-rate filtration with fixed head, (2) constant rate filtration with variable head, and (3) variable-declining-rate filtration. A variety of other control methods are also in use (Cleasby and Logsdon, 1999; Kawumura, 2000).

Constant Rate Filtration with Fixed Head. In constant-rate filtration with fixed head [see Fig. 11–18(a)], the flow through the filter is maintained at a constant rate. Constant-rate filtration systems are either influent controlled or effluent controlled. Pumps or weirs are used for influent control whereas an effluent modulating valve that can be operated manually or mechanically is used for effluent control. In effluent control systems, at the beginning of the run, a large portion of the available driving force is dissipated at the valve, which is almost closed. The valve is opened as the headloss builds up within the filter during the run. Because the required control valves are expensive and because they have malfunctioned on a number of occasions, alternative methods of flowrate control involving pumps and weirs have been developed and are coming into wider use.

Constant Rate Filtration with Variable Head. In constant-rate variable head filtration head [see Fig. 11–18(b)], the flow through the filter is maintained at a constant rate. Pumps or weirs are used for influent control. When the head or effluent turbidity reaches a preset value, the filter is backwashed.

Variable Rate Filtration with Fixed or Variable Head. In variable-declining-rate filtration [see Fig. 11–18(c)], the rate of flow through the filter is allowed to decline as the

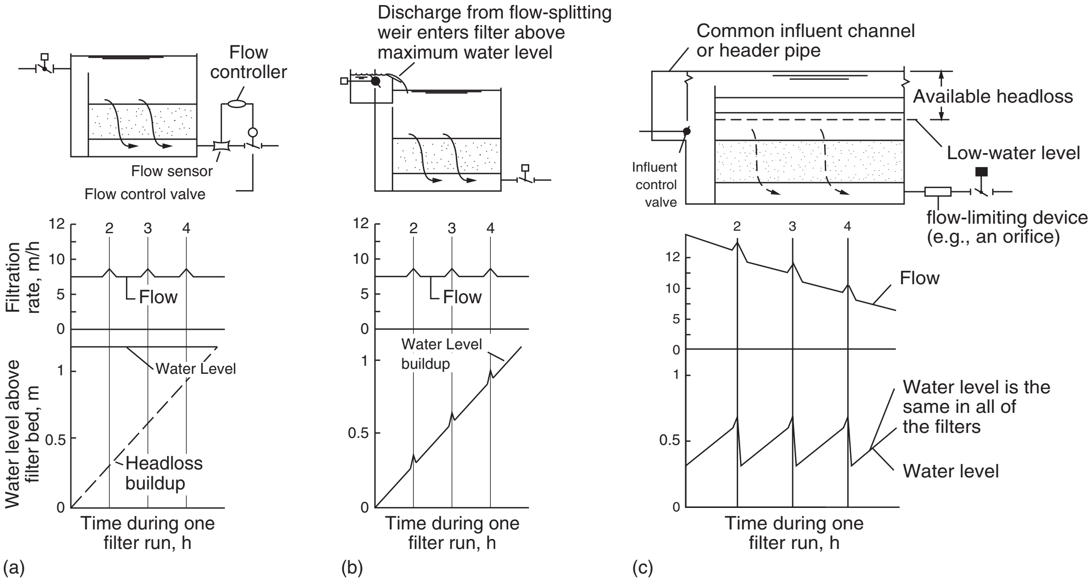


Figure 11–18

Definition sketch for filter operation: (a) fixed head, (b) variable head, and (c) variable-flow variable-head. Curves for filters in (a), (b), and (c) are for the operation of one filter in a bank of four filters. The numbers represent the filter that is backwashing during the filter run. In practice, the time before backwashing will not be the same for all of the filters. (Adapted from Tchobanoglous and Schroeder, 1985.)

rate of headloss builds up with time. Declining-rate filtration systems are either influent controlled or effluent controlled. When the rate of flow is reduced to the minimum design rate, the filter is removed from service and backwashed.

Filter Backwashing Systems. Methods commonly used for backwashing granular-medium filter beds operated in the semi-continuous mode include (1) water backwash only, (2) water backwash with auxiliary surface water-wash agitation, (3) water backwash with auxiliary air scour, and (4) combined air-water backwashing. With the first three methods, fluidization of the granular medium is necessary to achieve effective cleaning of the filter bed at the end of the run. With the fourth method, fluidization is not necessary.

Water Backwash Only. In the past, the most common method used to clean a filter of accumulated material was to backwash it with filtered water. Based on experimental studies, it has been found that the optimum cleaning of a conventional filter bed occurs when the expanded porosity of the bed is in the range of 0.65 to 0.70 (Amirtharajah, 1978). At this degree of expansion, it has been found that the shearing action of the rising backwash water and particle abrasion is most effective in removing the accumulated material from the filtering medium. Approximate backwash water flowrates required to fluidize various filter beds are reported in Table 11–18. To reduce the potential for the formation of mud balls and to enhance the removal of accumulated material either surface washers or air scour, as described below, are now used in conjunction with the water backwash.

Water Backwash with Auxiliary Surface Wash. Surface washers (see Fig. 11–19) are often used to provide the shearing force required to clean the grains of the filtering medium

Table 11–18

Approximate backwash water flowrates required to fluidize various filter beds at 20°C

Filter media	Effective size, mm	Minimum backwash velocity needed to fluidize bed[a] gal/ft²·min	Minimum backwash velocity needed to fluidize bed[a] m³/m²·min
Sand	1	24–27	1.0–1.2
Sand	2	44–50	1.8–2.0
Anthracite	1.7	22–24	0.9–1.0
Anthracite and sand	1.5 (A) and 0.65 (S)	15–30	0.8–1.2
Anthracite, sand, and garnet	1.4 (A), 0.5 (S), and 0.35 (G)	15–30	0.6–1.2
Fuzzy filter	28–30	10–15	0.4–0.6

[a] Varies with size, shape, and specific gravity of the medium and the temperature of the backwash water.

Note: $m^3/m^2 \cdot min \times 24.5424 = gal/ft^2 \cdot min$.

used for wastewater filtration. Surface washers for filters can be fixed or mounted on rotary sweeps. According to data on a number of systems, rotary sweep washers appear to be the most effective. Operationally, the surface washing cycle is started about 1 or 2 min before the water backwashing cycle is started. Both cycles are continued for about 2 min, at which time the surface wash is terminated. Water usage for a single-sweep surface backwashing system varies from 0.02 to 0.04 $m^3/m^2 \cdot min$ (0.5 to 1.0 $gal/ft^2 \cdot min$) and from 0.06 to 0.08 $m^3/m^2 \cdot min$ (1.5 to 2.0 $gal/ft^2 \cdot min$) for a dual-sweep surface backwashing system.

Water Backwash with Auxiliary Air Scour. The use of air to scour the filter provides a more vigorous washing action than water alone. Operationally, the water level above the filter bed is lowered to within 150 mm (6 in.) of the top of the media and air is usually applied for 3 to 4 min before the low-rate water backwashing cycle begins. In some

[b] Dual medium filter bed is fluidized.

Note: $m^3/m^2·min \times 24.5424 = gal/ft^2·min$

$m^3/m^2·min \times 3.2808 = ft^3/ft^2·min$.

systems, air is also injected during the first part of the low-rate water-washing cycle, referred to as combined or concurrent air scour (see below). Typical air flowrates range from 0.9 to 1.6 $m^3/ m^2·min$ (3 to 5 $ft^3/ft^2·min$). A typical operating sequence for a dual media filter is given in Table 11–19. Also, as noted in Table 11–19, a water wash at the end of the air/water backwash cycle is used at the end to purge the filter of any residual air which could cause air binding. The reduced washwater requirements for the air-water backwash system can be appreciated by comparing the values given in Table 11–18 with those given in Table 11–19.

Combined Air-Water Backwash. The combined air-water backwash system is used in conjunction with the single-medium unstratified filter bed. Operationally, air and water are applied simultaneously for several minutes. The specific duration of the combined backwash varies with the design of the filter bed. Ideally, during the backwash operation, the filter bed should be agitated sufficiently so that the grains of the filter medium move in a circular pattern from the top to the bottom of the filter as the air and water rise up through the bed. Some typical data on the quantity of water and air required are reported in Table 11–19. At the end of the combined air-water backwash, a 2- to 3-min water a low-rate backwash at sub-fluidization velocities [typically 0.2 $m^3/ m^2·min$ (5 $gal/ft^2·min$)] is used to remove any air bubbles that may remain in the filter bed. This step is required to eliminate the possibility of air binding within the filter. Normally, a high-rate washing step follows the low-rate washing. High-rate washing is typically conducted at [$0.6 - 0.8$ $m^3/m^2·min$ ($15-20$ $gal/ft^2·min$)]. Air scour combined with high-rate washing is not conducted because of the possibility of excessive expansion of media resulting in media loss into the washwater troughs.

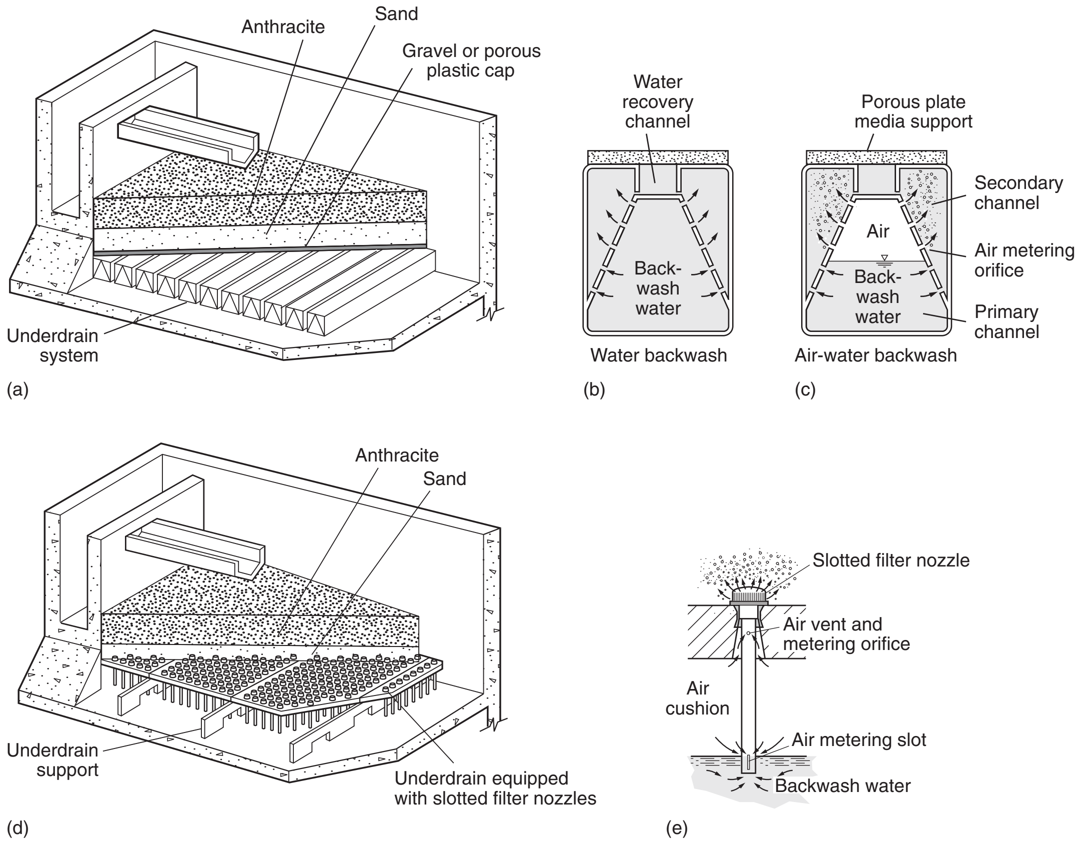

Figure 11–20

Typical underdrain systems used for granular media filters: (a) underdrain system used with gravel or porous plastic cap support for filter media, (b) underdrain system shown in (a) during water backwash, (c) underdrain system shown in (a) during air-water backwash, (d) underdrain system equipped with slotted air-water nozzles used without gravel support layer, and (e) air-water nozzle used in underdrain system shown in (d) without gravel support layer [(b) and (c) adapted from Leopold; (e) adapted from Infilco-Degremont, Inc.].

Filter Appurtenances. The principal filter appurtenances are as follows: (1) the underdrain system used to support the filtering materials, collect the filtered effluent, and distribute the backwash water and air (where used); (2) the washwater troughs used to remove the spent backwash water from the filter; and (3) the surface washing systems or air scour blower used to help remove attached material from the filter medium.

Underdrain Systems. The type of underdrain system to be used depends on the type of backwash system. In conventional water backwashed filters without air scour, it is common practice to place the filtering medium on a support consisting of several layers of graded gravel. The design of a gravel support for a granular medium is delineated in the AWWA Standard for Filtering Material B100–96 (AWWA, 1996). Typical underdrain systems are shown on Fig. 11–20. The gravel is not intended to aid in filtration. Rather, the purpose of the gravel is to prevent media from entering the underdrain. Air scour for filters with a gravel support system can be challenging, and would normally be comprised of the air scour piping grid laid on top of the gravel itself. Disruption of gravel support will

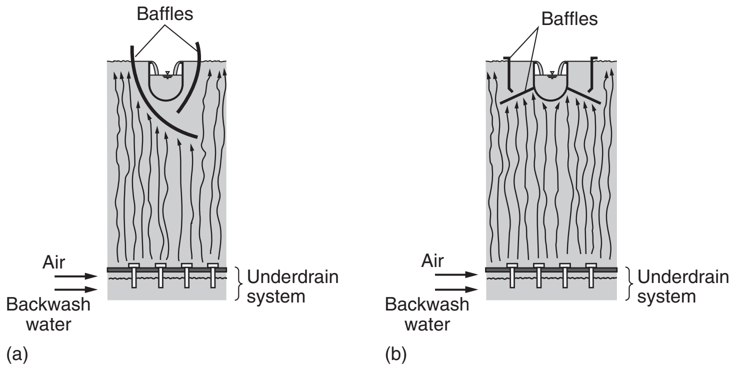

Figure 11–21

Details of baffle systems developed to minimize loss of filtering medium during backwash operation: (a) section through dual-baffle system and . (b) more elaborate baffle with two wings and side baffles.

lead to potential media passage to the underdrain or media plugging the underdrain apertures. As an alternative to gravel, newer filter underdrains are often equipped with a porous, HDPE direct media retention plate, typically 25mm (1 in.) thick and fastened to the top of each underdrain block. This arrangement precludes the need for gravel and therefore can allow for a deeper filter bed.

Washwater Troughs. Washwater troughs are constructed of fiberglass, plastic, or sheet metal or of concrete with adjustable weir plates. The particular design of the trough will depend to some extent on the other equipment to be used in the design and construction of the filter. Loss of filter material during backwashing is a common operating problem. To reduce this problem, baffles can be placed on the under side of the washwater troughs as shown on Fig. 11–21.

Operational Problems with Depth Filters. The principal operational problems encountered in wastewater filtration with depth filters are (1) turbidity breakthrough; (2) mudball formation; (3) buildup of emulsified grease; (4) development of cracks and contraction of the filter bed; (5) loss of filter medium or media, by mechanical and operational means; and (6) gravel mounding. Because these problems can affect both the performance and operation of a filter system, care should be taken in the design phase to provide the necessary facilities to minimize their impact. These issues are considered further in Table 11–20. Because of the inherent variability in the wastewater characteristics and their potential impact upon filter design and operation, the best way to ensure the filter configuration selected for a given application will function properly is to conduct pilot plant studies representative of the range of operating conditions.

11–6 SURFACE FILTRATION

Surface filtration, as shown in Table 11–4, involves the removal of particulate material suspended in a liquid by mechanical sieving by passing the liquid through a thin septum (i.e., filter material). The mechanical sieving action is similar to a kitchen colander. Membrane filters, microfiltration, and ultrafiltration, discussed in Sec. 11–6, are also surface filtration devices but are differentiated on the basis of the sizes of the pores in the filter medium. Surface filter mediums typically have openings in the size range from 5 to 30 μm or larger; in microfiltration and ultrafiltration, the pore size can vary from 0.05 to 2.0 μm for MF and 0.005 to 0.1 μm for UF.

Surface filtration has been used in several applications including (1) as a replacement for depth filtration to remove residual suspended solids from secondary effluents, (2) for the

Table 11–20

Summary of commonly encountered problems in depth filtration of wastewater and control measures for those problems

Problem	Description/control
Turbidity breakthrough[a]	Unacceptable levels of turbidity are recorded in the effluent from the filter, even though the terminal headloss has not been reached. To control the buildup of effluent turbidity levels, chemicals and polymers have been added to the filter. The point of chemical or polymer addition must be determined by testing.
Mudball formation	Mudballs are an agglomeration of biological floc, dirt, and the filtering medium or media. If the mudballs are not removed, they will grow into large masses that often sink into the filter bed and ultimately reduce the effectiveness of the filtering and backwashing operations. The formation of mudballs can be controlled by auxiliary washing processes such as air scour or water surface wash concurrent with, or followed by, water wash.
Buildup of emulsified grease	The buildup of emulsified grease within the filter bed increases the headloss and thus reduces the length of filter run. Both air scour and water surface wash systems help control the buildup of grease. In extreme cases, it may be necessary to steam clean the bed or to install a special washing system.
Development of cracks and contraction of filter bed	If the filter bed is not cleaned properly, the grains of the filter bed filtering medium become coated. As the filter compresses cracks develop, especially at the sidewalls of the filter. Ultimately, mudballs may develop. This problem can be controlled by adequately backwashing and scouring.
Loss of filter medium or media (mechanical)	In time, some of the filter material may be lost during backwashing and through the underdrain system (where the gravel support has been upset and the underdrain system has been installed improperly). The loss of the filter material can be minimized through the proper placement of washwater troughs and underdrain system. Special baffles have also proved effective.
Loss of filter medium or media (operational)	Depending on the characteristics of the biological floc, grains of the filter material can become attached to it, forming aggregates light enough to be floated away during the backwashing operations. The problem can be minimized by the addition of an auxiliary air and/or water scouring system.
Gravel mounding	Gravel mounding occurs when the various layers of the support gravel are disrupted by the application of excessive rates of flow during the backwashing operation. A gravel support with an additional 60 to 75 mm (2 to 3 in.) layer of high density material, such as ilmenite or garnet, can be used to overcome this problem.

[a] Turbidity breakthrough does not occur with filters that operate continuously.

removal of suspended solids and algae from stabilization pond effluents, and (3) as a pretreatment operation before microfiltration or UV disinfection. Surface filtration is gaining in popularity because of the high quality effluent produced, smaller footprint, low backwash rates, and reduced maintenance requirements. Information on surface filtration technologies, their performance, and design considerations is presented and discussed in this section.

Available Filtration Technologies

The principal types of surface filtration devices are identified and described in Table 11–21. With the exception of the inclined surface and cartridge filters, all of the other surface filters have been used for the filtration of secondary effluent. Some of the surface filters have also been used for the filtration of algae for lagoon effluents. The inclined surface

Table 11–21

Description of some surface filters used in effluent filtration applications

Type	Description
(a) Cloth Media Filter (CMF)  	The CMF, marketed under the trademark AquaDisk® by Aqua-Aerobic Systems, also consists of several disks mounted vertically in a tank. Each disk is comprised of six equal segments. Operationally, water flows by gravity from the exterior of the disks through the filter medium to an internal collection system. Typically, two types of filter cloth are used: (1) a needle felt cloth made of polyester or (2) synthetic pile fabric cloth. A vacuum system is. Vacuum suction heads, located on either side of the disk, are used to remove the accumulated solids by drawing filtrate water from the filtrate header back through the cloth media while the disk is rotating. Solids are removed when a predetermined increase in headloss has occurred.
(b) Diamond Cloth Media Filter (DCMF)  	The DCMF, marketed under the trademark AquaDisk® by Aqua-Aerobic Systems, consists of cloth filter elements, which have a diamond shaped cross section. The filter elements are cleaned by a vacuum sweep which moves back and forth along the length of the filter, when a predetermined increase in headloss has occurred. Solids that settle to the bottom of the reactor below the filter element are removed periodically by a vacuum header. Using a diamond shape for the filter, it is possible to increase the cloth filter surface area per unit of aerial surface area. Because higher volumes for filtered water can be produced per unit area, the DCFM is used in new installations and as a replacement for existing sand filters.
(c) Discfilter® (DF)  	The DF, developed by Hydrotech and marketed in the U.S. by Veolia Water Systems, consists of a series of disks comprised of two vertically mounted parallel disks that are used to support the filter cloth Each disk is connected to a central feed tube. The cloth screen material used can be of either polyester or Type 304 or 316 stainless steel. Accumulated solids are removed from the screen by high-pressure water jets. The filter mechanism can be furnished with a self-contained tank or for installation in a concrete tank. In cold climates or where odor control is a consideration, an enclosure can be provided for the disks.

Table 11–21 (*Continued*)

Type	Description
(d) Ultrascreen®  	The Ultrascreen® developed by Nova Water technologies that consists of two continuously rotating circular screens of woven stainless steel mesh. The liquid to be filtered is introduced between the two screens at right angles to the screens. The filtered effluent that flows through the screen flows out and is directed to a collection chamber below the screen. Unlike other disk type screens, the discharge from the screen is by gravity as there is no water on the discharge side of the screen. High- pressure water jets are used to clean the accumulated solids from the screens.
(e) Drum Filter (DF)[a]  	As the name implies the drum filter is in the shape of a drum. The liquid to be filtered is introduced on the inside of the drum and flows out thought the periphery of the drum, through a filter cloth of polyester or polypropylene or stainless steel, as the drum rotates slowly. When the water level within the drum rises to specified level, a backwash cycle is initiated to remove the accumulated solids. A high pressure water spray is used to dislodge and remove the accumulated solids as the drum rotates. The solids removed from the drum are collected in a collection trough on the inside of the drum. Drum filter can be installed in concrete, stainless steel, or fiberglass tankage. The range of pore openings for the filter cloth range from 10 μm to 1 mm, depending on the application.
(f) Inclined Cloth Media Screen  	Developed by M2 Renewables, the inclined screen is used for the filtration of untreated wastewater. As the moving screen rotates, solids are accumulated on the screen. When the screen exits the water pool, the accumulated solids are partially dewatered by the force of gravity. The accumulated solids are removed from the screen as it passes over the upper roller. High-pressure water jets can also be used. As noted in Chap. 5, the fact that the screen alters the particle size distribution of the solids to be treated and has a relatively small footprint is significant relative to conventional primary clarification.

Type	Description
(g) Cartridge Filter  	Most cartridge filters are usually polypropylene wound cartridges from 800 to 1000 mm in length housed inside a vertical or horizontal stainless steel or fiberglass vessel. They are employed in a number of different applications, typically to protect downstream applications. In advanced water treatment, they are employed to remove contaminates found in the chemicals added to control scaling in reverse osmosis membranes. Cartridge filters are not considered further in the discussion of surface filtration, but are included because they are used as a pretreatment step for reverse osmosis. Pleated cartridge filters are used almost exclusively to concentrate virus from treated wastewater for analysis.

[a] Courtesy of Xylem.

filter [see Table 11–21(f)], discussed in Sec. 5–9 in Chap. 5, is used for the filtration of untreated wastewater following coarse and intermediate screening. Cartridge filters [see Table 11–21(g)], are used for pretreatment prior to membrane filtration, particularly where reverse osmosis (RO) is used.

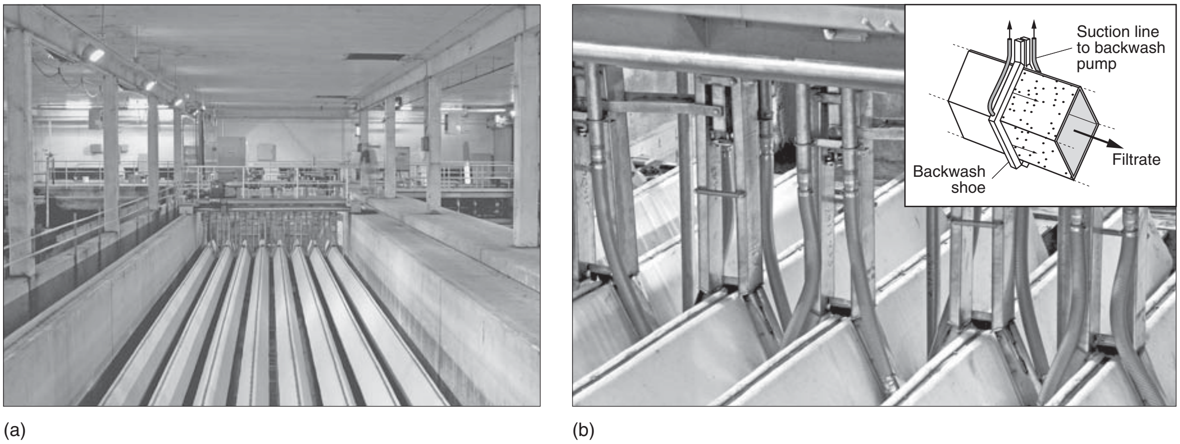
Description of the Surface Filtration Process

The key features of surface filters are (1) the filter configuration, (2) the filter medium, (3) the method used to introduce the liquid to be filtered, (4) the method used to clean the filtering medium, and (5) the impact of the accumulation of solids has on process performance.

Filter Configurations. Surface filters are available in a variety of configurations. The most common type of surface filter is comprised of a series of disks attached to a central shaft. The individual disks are made up of two filtering surfaces attached to a metal support frame as shown in Table 11–21 (a) and (c). The diamond cloth-media filter (DCMF), a relatively recent development, is shown schematically in Table 11–21(b) and pictorially on Fig. 11–22. The drum filter for effluent filtration [see Table 11–21(e)] is a relatively recent development, although drum filters are used in a number of filtering applications. Operation of the different surface filters depends on how the liquid to be filtered is applied to the filtering medium and how the filtering material is cleaned of accumulated material.

Filter Materials. The filter material used in surface filters can be categorized as two dimensional and three dimensional. Two dimensional mediums are typically made of synthetic fabrics of different weaves and woven metal fabrics (most commonly stainless steel). The most common weave for synthetic materials is known as a plain weave, which is similar to broadcloth. Stainless steel weaves can include plain weave, twilled weave, and Dutch weave wire meshes. Three dimensional filtering mediums include polyester needle felt cloth and synthetic pile fabric cloth.

Flow Path for Liquid to be Filtered. The flow path can also be used to classify surface filters. Basically, two methods are used to apply the liquid to be filtered to the



(a) (b)

Figure 11–22

Views of Diamond Cloth Media Filter: (a) view of filters installed in an existing sand filter basin and (b) view of backwash shoe.

filtering medium. In the first, the liquid enters the feed tank and flows from the outside through the filter cloth into a receiving area (out-in) [see Table 11–21(a), (b) and (f)]. In the second method, the liquid to be filtered is introduced into the annular volume between the two filtering surfaces and flows outward through the filtering medium into the collection vessel (in-out) [see Table 11–21 (c), (d), and (e)]. In either case, solids accumulate on the surface in the direction of flow. The direction of flow affects the method to be used for the removal of the accumulated material, the submergence (i.e. the active filter area), and the overall depth of the unit.

Cleaning the Filter Medium. Two types of methods are used to remove the accumulated material removed from the fluid: (1) vacuum removal and (2) intermittent and/or continuous high-pressure spray washing. The vacuum removal system is used for surface filters where the flow is from the outside in whereas the high-pressure water spray nozzles are used where the flow is from the inside to the outside.

Vacuum Removal. When the headloss through the CMF reaches a predetermined set point, the disks are cleaned. As the disks rotate, solids are removed from both sides of the disk by liquid vacuum suction heads, located on either side of each disk, which draws filtered water from the filtrate header back through the cloth media while the disk is rotating. This reversal of flow removes particles that have become entrapped on the surface and within the cloth medium. The diamond cloth filter is also cleaned by a vacuum sweep which moves back and forth along the length of the filter. Solids that settle to the bottom of the reactor below the filter element are removed periodically by a vacuum header.

Over time, particles will accumulate in the cloth medium that can not be removed by a typical backwash. This accumulation of particles leads to increased headloss across the filter, an increase in the backwash suction pressure, and shorter run times between backwashes. When the backwash suction pressure or operating time reaches predetermined setpoints, a high pressure spray wash is initiated automatically. The high pressure spray wash flushes the particles that have become lodged inside the cloth filter media in 2 rev of the disk. The time interval between high pressure spray washes is a function of the feed water quality.

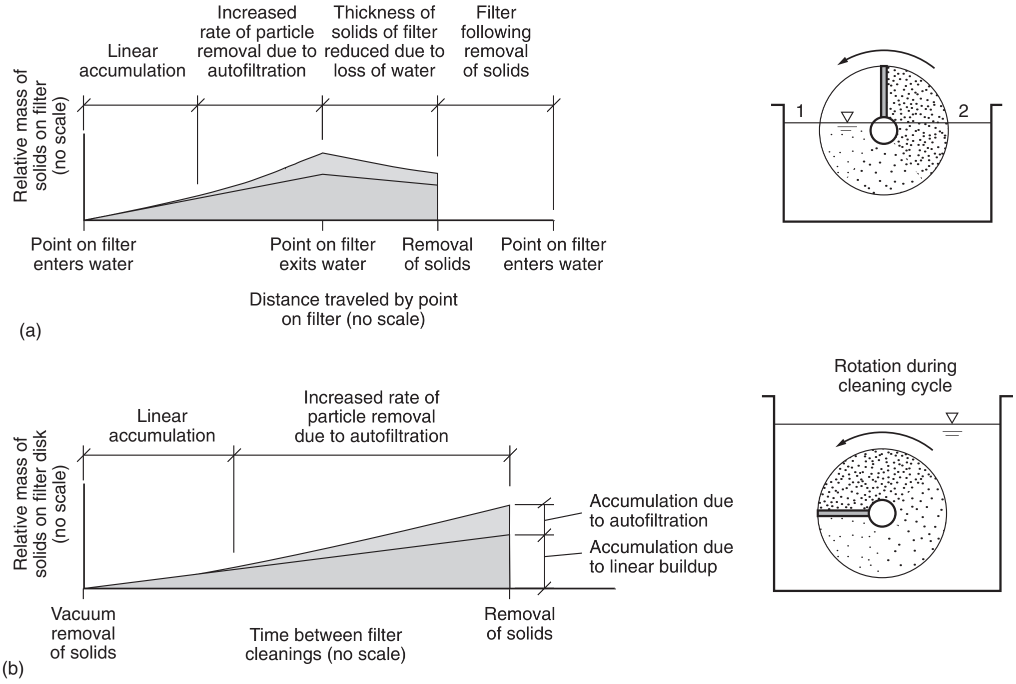


Figure 11–23

Generalized schematic of the operation of disc type surface filters based on following a point with time on the filter cloth between cleaning events, including the removal of particles by size exclusion and finer particles due to autofiltration: (a) for surface filters that are partially submerged and (b) for submerged filter with vacuum removal of accumulated solids.

High-Pressure Water Sprays. In surface filters where the flow is from inside to outside, high-pressure water sprays are used to remove the material that accumulates on the inside of the disk. Most high-pressure water spray wash systems can operate in either an intermittent or continuous backwash mode. In the intermittent mode, high-pressure backwash spray jets are activated only when headloss through the filter reaches a preset level or time. Once activated, washwater is sprayed through the filter material from the outside as the disk rotates. The accumulated solids that are dislodged fall into a collection trough. When operating in a continuous backwash mode, the production of filtered water and backwashed occur simultaneously. The location and configuration of the high-pressure spray nozzles and solids collection trough are manufacturer specific.

Impact of the Accumulation of Solids on Process Performance. The removal of particulate matter with surface filters is illustrated schematically on Fig. 11–23 for partially and completely submerged surface filters. For partially submerged filters [see Fig. 11–23(a)], the accumulation of solids on the filter medium occurs between point 1, where the clean filter comes in contact with the fluid to be filtered, and point 2, where the filter leaves the fluid. For the completely submerged filter [see Fig. 11–23(b)], the accumulation of solids occurs with time until the backwash headloss is reached, at which time the filter is cleaned. In both cases, the accumulated material on the surface of the filter begins to act as a filter. The filtering action of the accumulated material is known as *autofiltration*. Autofiltration can be used to explain why material of a smaller size than the pore size of the filter medium can be removed by surface filtration. For both types of surface filters, the onset of autofiltration, and the degree of additional removal that can be achieved, will depend on the mesh size of the filtering medium, the characteristics of the wastewater, and the filtration rate.

Performance of Surface Filters

In investigations of surface filters in comparison to granular medium filters in filtering secondary effluent (Riess et al., 2001 and Olivier et al., 2003), it has been observed that surface filters performed as well or better than granular medium filters in removing turbidity and the number and size of particles, with increased surface loading and reduced backwash water requirements. As with depth filters, insight into the operation of surface filters can be gained from a review of performance data with respect to the (1) hydraulic loading rate, (2) removal of turbidity and total suspended solids, (3) variability of turbidity and TSS removal, (4) removal of different particle sizes, (5) removal of microorganism, and (6) backwash water requirements.

Hydraulic Loading Rate. As with depth filters, there is a considerable difference in the HLRs over which surface filters operate. Typical HLRs for surface filters are reported in Table 11–22. For example, while two surface filters can produce a

Table 11–22

Comparison of operational characteristics for selected surface filters

Parameter	Unit	Cloth media filter®	Diamond cloth media filter®	Diskfilter®	Ultrascreen®	Drumfilter®
Typical hydraulic loading rate	$m^3/m^2 \cdot min$	0.08–0.20	0.08–0.20	0.08–0.20	0.20–0.65	0.08–0.26

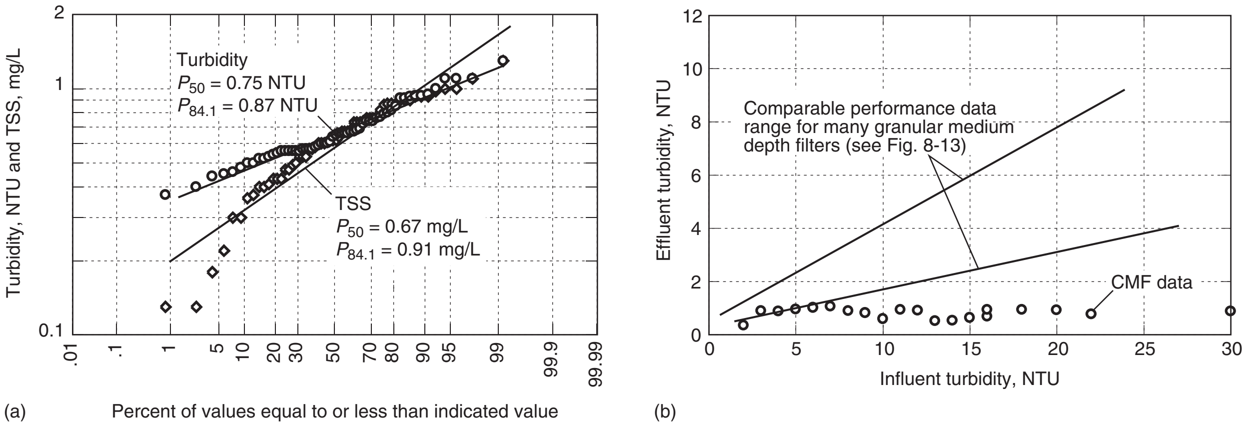

Figure 11–24

Performance data for cloth-media filter for secondary effluent: (a) effluent turbidity as a function of influent turbidity at a filtration rated of 176 L/min·m^2 and (b) effluent probability distributions for turbidity and TSS.

filtered effluent with turbidity of 2 NTU or less filtering the same effluent, the HLRs can vary by more that a factor of four or five. As with depth filters, the HLR and the backwash water requirements for surface filters will impact cost and the carbon footprint significantly.

Removal of Turbidity and Total Suspended Solids. To evaluate performance capabilities of surface filtration, a CMF pilot plant was tested using secondary effluent from an extended aeration activated sludge process with a solids retention time greater than 15 d. Effluent TSS and turbidity values from the activated sludge process ranged from 3.9 to 30 mg/L and 2 to 30 NTU, respectively. Based on a long-term study, it was found, as shown on Fig. 11–24(a), that both TSS and turbidity values of the filtered effluent were less than 1, 92 percent of the time (Riess et al., 2001). The performance of the CMF as compared to depth filters, all tested with the same activated sludge effluent, is shown on Fig. 11–24(b). As shown, the effluent turbidity from the CMF remained constant over a range of influent turbidity values that tested up to 30 NTU. The degree of removal of TSS from settled activated sludge effluent with surface filters, as with depth filters, will depend on the SRT at which the activated sludge process is operated. Similar results have been reported for other surface filtration technologies.

Variability in Turbidity and Total Suspended Solids Removal. The performance variability of surface filters is of critical importance where specific effluent turbidity limits must be met consistently. The variability observed in the operating data for surface filters as reported in Table 11–12, presented previously, is similar to that observed for depth filters. However it should be noted that average turbidity and TSS values tend to be lower.

Removal of Different Particle Sizes. In comparative testing with a granular medium filter, the surface filter consistently out-performed the granular medium filter in respect to particle removal (see Fig. 11–25). The particle size reduction also had a

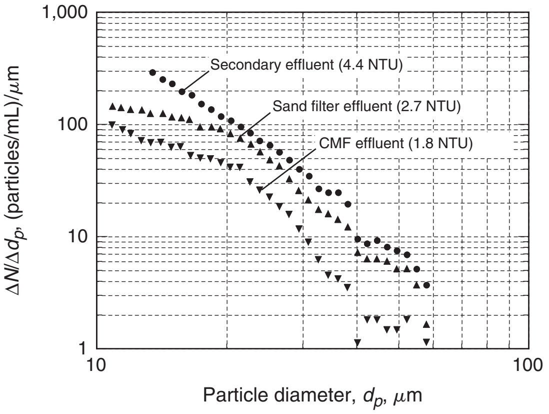

Figure 11–25

Comparison of particle sizes in effluent from secondary treatment, granular medium filter, and cloth media filter (Olivier et al., 2003).

significant impact on the inactivation of total coliform bacteria when used with UV disinfection (Olivier et al., 2002, 2003).

Removal of Microorganisms. Where chemicals are not used, the removal of coliform bacteria and viruses from biologically treated secondary effluent is on the order of 0 to 1.0 and 0 to 0.5 logs, respectively, similar to the values observed for depth filters.

Backwash Water Requirements. The amount of backwash water needed to clean surface filters, expressed as a percentage of plant flow, will depend on the characteristics of filter influent and the design of the surface filter. Typical backwash water percentages for surface filters as shown in Table 11–22 will vary, from 1 to 4 percent.

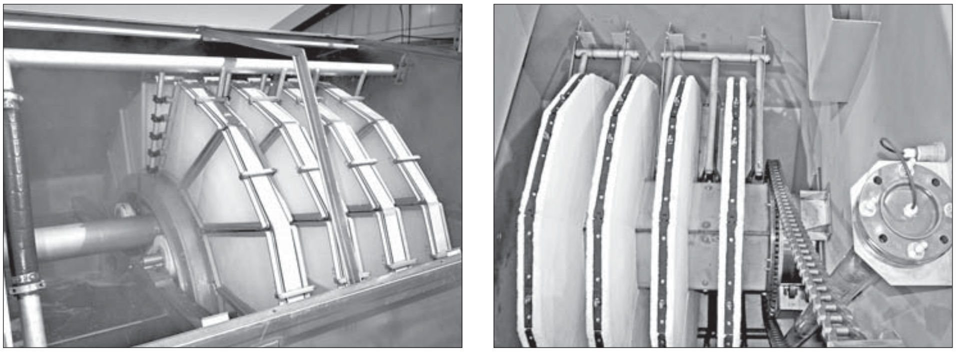
Design Considerations

Pilot studies are recommended in developing design and operating parameters for new installations. Useful data for design includes (1) the variability of the characteristics of the feed water to be treated and (2) the amount of backwash water required for normal operation. The backwash water requirements are a function of the TSS in the feed water and the solids loading on the filters. If the secondary treatment system is effective in TSS removal, the volume of backwash water can be reduced substantially.

Because cloth-media surface filtration is a relatively new technology, little long-term data are available on the life of the filter cloth. Where surface filtration is being considered, performance should be evaluated from operating installations using a similar type of cloth medium. One operating advantage cited for cloth-media filters is that the filter cloth can be removed and washed in a heavy-duty washing machine.

Pilot Plant Studies

As with granular media filtration, discussed above, there is no generalized approach to the design of full-scale filters for the treatment of wastewater. The discussion presented in the previous section on pilot plant testing also applies to the cloth filter. Typical cloth filter test facilities are illustrated on Fig. 11–26. It should be noted that the single disk shown on Fig. 11–26(b) is full sized. In a larger installation, a number of disks would be arranged on the center shaft.



(a) (b)

Figure 11–26

View of cloth filter pilot test filters. It should be noted that the cloth filters shown are full size.

11–7 MEMBRANE FILTRATION PROCESSES

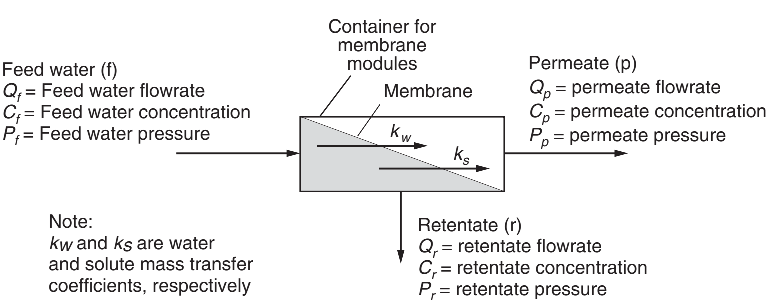
Filtration, as defined in Sections 11–3 and 11–5, involves the separation (removal) of particulate and colloidal matter from a liquid. In membrane filtration the range of particle sizes is extended to include dissolved constituents (typically from 0.0001 to 1.0 μm). The role of the membrane, as shown in Table 11–4, is to serve as a selective barrier that will allow the passage of certain constituents and will retain other constituents found in the liquid. To introduce membrane technologies and their application, the following subjects are considered in this section: (1) membrane process terminology, (2) membrane classification, (3) membrane configurations, (4) application of membrane technologies, and (5) the need for pilot-plant studies. The disposal of concentrated waste streams is considered at the end of this section. Electrodialysis, also a membrane process, used typically for the removal of dissolved constituents, is considered separately in Sec 11–7 following the discussion of the application of pressure driven membranes.

Membrane Process Terminology

Terms used commonly in the membrane technology field include: *feed water*, *permeate*, and *retentate*. These terms are illustrated on Fig. 11–27. The influent water to supplied to the membrane system for treatment is known as the *feed water*. The liquid that has passed through the membrane is known as the *permeate*. The portion of the feed water that does not pass through the membrane is known as the *retentate* (also referred to as concentrate, reject, or waste stream). Flux, the rate at which permeate flows through the membrane expressed as L/m^2·h or L/m^2·d, is the principal measure of membrane performance. Flux is synonymous with the concept of filter hydraulic loading rate presented in the discussion of depth and surface filtration.

Figure 11–27

Definition sketch for operation of a membrane process.



Membrane Process Classification

Membrane processes include microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), reverse osmosis (RO), and electrodialysis (ED). Membrane processes can be classified in a number of different ways including (1) membrane configuration, (2) the type of material from which the membrane is made, (3) the nature of the driving force, (4) the separation mechanism, and (5) the nominal size of the separation achieved. Each of these methods of classifying membrane processes is considered in the following discussion. The general characteristics of membrane processes including typical operating ranges are reported in Table 11–23. The focus of the following discussion is on pressure driven membrane processes used for the removal of residual TSS, colloidal matter and dissolved solids. Pressure driven membranes are further defined as "low pressure," which includes MF and UF, and "high pressure," which includes NF and RO.

Membrane Configurations. In the membrane field, the term *module* is used to describe a complete unit comprised of the membrane elements (or modules), the pressure support structure for the membranes, the feed inlet and outlet permeate and retentate ports, and an overall support structure. The principal types of membrane modules used for wastewater treatment are (1) tubular, (2) hollow fine-fiber, and (3) spiral wound. Plate and frame and pleated cartridge filters are also available, but are used more commonly in industrial applications.

Definition sketches for the various membranes and detailed descriptions are presented in Table 11–24. There are two basic flow patterns with membranes: (1) outside-in [see Fig. 11–28(a)] and (2) inside-out [see Fig. 11–28(b)]. In most wastewater treatment applications where hollow fiber and membrane sheets are used, the flow is pattern is outside-in. With an outside-in flow pattern, the membrane can be backwashed with air, water, or a combination of both. The outside-in flow pattern is also used for feed water solutions with higher TSS and turbidities.

Membrane Materials. Most commercial membranes are produced as tubular, fine hollow fibers, or flat sheets. In general, three types of membranes are produced: symmetric, asymmetric and thin film composite (TFC) (see Fig. 11–29). As shown on Fig. 11–29(a) and (b), symmetric membranes are the same throughout. Symmetric membranes can vary from microporous to nonporous (so called dense). Asymmetric membranes [see Fig. 11–29(c)] are cast in one process and consist of a very thin (less than 1 μm) layer and a thicker (up to 100 μm) porous layer that adds support and is capable of high water flux.

Thin-film composite membranes [see Fig. 11–29(d)] are made by bonding a thin cellulose acetate, polyamide, or other active layer (typically 0.15 to 0.25 μm thick) to a thicker porous substrate, which provides stability. As reported in Table 11–23 membranes can be made from a number of different organic and inorganic materials. The membranes used for wastewater treatment are typically organic, although some ceramic membranes have been used. The choice of membrane and system configuration is based on minimizing membrane clogging and deterioration, typically based on pilot plant studies.

Driving Force. The distinguishing characteristic of the first four membrane processes considered in Table 11–23 (MF, UF, NF, and RO) is the application of hydraulic pressure, or vacuum, to bring about the desired separation. Electrodialysis involves the use of an electromotive force and ion selective membranes to accomplish the separation of charged ionic species.

Table 11–23

General characteristics of membrane processes

Membrane process	Membrane driving force	Typical separation mechanism	Typical pore size, μm	Typical operating range, μm	Membrane details	
					Materials (arranged alphabetically)	**Configuration**
Microfiltration	Hydrostatic pressure difference or vacuum in open vessels	Sieve	Macropores (> 50 nm)	0.07–2.0	Acrylonitrile, ceramic (various materials), polypropylene (PP), polysulfone (PS), polytetrafluorethylene (PTFE), polyvinylidene fluoride (PVDF), nylon	Spiral wound, hollow fiber, plate and frame
Ultrafiltration	Hydrostatic pressure difference or vacuum in open vessels	Sieve	Mesopores (2–50 nm)	0.008–0.2	Aromatic polyamides, ceramic (various materials) cellulose acetate (CA), polypropylene (PP), polysulfone (PS), polyvinylidene fluoride (PVDF), Teflon	Spiral wound, hollow fiber, plate and frame
Nanofiltration	Hydrostatic pressure difference in closed vessels	Sieve + solution/diffusion + exclusion	Micropores (< 2 nm)	0.0009–0.01	Cellulosic, aromatic polyamide, polysulfone (PS), polyvinylidene fluoride (PVDF), thin-film composite (TFC)	Spiral wound, hollow fiber, thin film composit
Reverse osmosis	Hydrostatic pressure difference in closed vessels	Solution/diffusion + exclusion	Dense (< 2 nm)	0.0001–0.002	Cellulosic, aromatic polyamide, thin-film composite (TFC)	Spiral wound, hollow fiber, thin film composite
Electrodialysis	Electromotive force	Ion exchange	Ion exchange	0.0003–0.002	Ion exchange resin cast as a sheet	Plate and frame

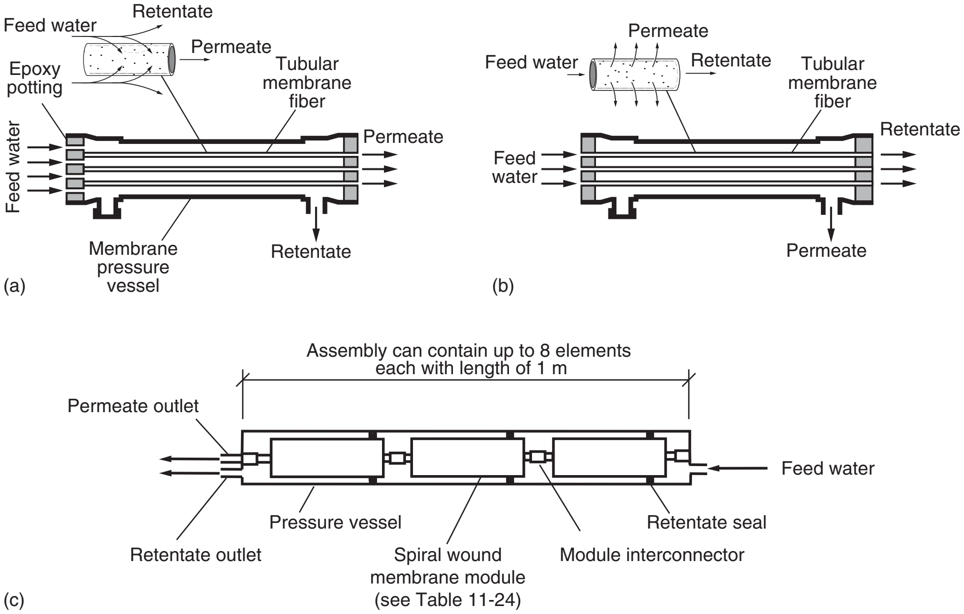
Table 11–24

Description of commonly used membrane types

Type	Description
(a) Tubular 	In the tubular configuration the membrane is cast on the inside of a support tube. A number of tubes (either singly or in a bundle) is then placed in an appropriate pressure vessel. The feed water is pumped through the feed tube and product water is collected on the outside of the tubes. The retentate continues to flow through the feed tube. These units are used generally for water with high suspended solids or plugging potential. Tubular units are the easiest to clean, which is accomplished by circulating chemicals and pumping a "foamball" or "spongeball" through to mechanically wipe the membrane. Tubular units produce at a low product rate relative to their volume, and the membranes are generally expensive. The internal diameter of the Tubes will vary from 6 to 40 mm in diameter with lengths as long as 3.66 m (12 ft).
(b) Hollow fiber 	The hollow fiber membrane module consists of a bundle of hundreds to thousands of hollow fibers. The entire assembly is inserted into a pressure vessel. The feed can be applied to the inside of the fiber (inside-out flow) or the outside of the fiber (outside-in flow). Hollow fiber membrane modules are commonly used in membrane bioreactors (MBRs) as described in Chap. 7. Typical inside and outside diameters of the individual hollow fine fibers are about 35 to 45 and 90 to 100 μm, respectively. The typical length of a bundle of fibers is about 1.2 m (4 ft) long. A 100 mm (4 in.) diameter bundle may contain up to 650,000 individual fibers, although most contain fewer fibers per bundle. Fiber bundles can vary from 100 to 200 mm (4 to 8 in.) in diameter. Depending on the size of the bundle up to 7 bundles can be placed in a single pressure vessel [see Fig. 11–28(b)].
(c) Spiral wound 	In the spiral wound membrane, a flexible permeate spacer is placed between two flat membrane sheets. The membranes are sealed on three sides. The open side is attached to a perforated pipe. A flexible feed spacer is added and the flat sheets are rolled into a tight circular configuration. Thin film composites are used most commonly in spiral wound membrane modules. The term spiral derives from the fact that the flow in the rolled-up arrangement of membranes and support sheets follows a spiral flow pattern. The diameter of spiral wound elements will typically vary from 100 to 200 mm (4 to 8 in.), however, up to 300 mm (12 in.) diameter elements have been used. The active length of the membrane element is typically about 0.9 m (3 ft) between glue lines, although element lengths varying from 150 mm (6 in.) up to 1.5 m (5 ft) have been used. Operationally, from 2 to 6 membrane elements are included in a single pressure vessel [see Fig. 11–28(c)]. Six membrane elements are normally used for reverse osmosis. As an example, the membrane surface area in a pressure vessel containing four 100 mm (4 in.) diameter by 0.9 m (3 ft) long membrane elements is about 8.33 m^2 (90 ft^2).
(d) Plate and frame 	Plate and frame membrane modules are comprised of a series of flat membrane sheets and support plates. The water to be treated passes between the membranes of two adjacent membrane assemblies. The plate supports the membranes and provides a channel for the permeate to flow out of the unit. Typically, the dimensions of individual plates that comprise the plate and frame filter are about 20 by 40 mm (7.5 × 15 in.). The packing density of plate and frame units will vary between 100 to 400 m^2/m^3.

Figure 11–28

Definition sketch for types of membrane operation: (a) definition sketch for hollow fine-fiber membranes with flow from the outside to the inside of the fiber, (b) definition sketch for hollow fine fiber membranes with flow from the inside to the outside, and (c) spiral wound membranes in a containment vessel.



Removal Mechanisms. The separation of particles in MF and UF is accomplished primarily by straining (sieving, i.e., physical size exclusion), as shown on Fig. 11–30(a). In NF and RO, in addition to straining, small particles are rejected by the water layer adsorbed on the surface of the membrane which is known as a *dense* membrane [see Fig. 11–30(b)]. Some ionic species such as sodium (Na^+) and chloride (Cl^-) can be transported across the membrane by diffusion through the pores of the macromolecule comprising the membrane. Typically NF can be used to reject constituents as small as 0.001 μm whereas RO can reject particles as small as 0.0001 μm.

Size of Separation. The pore sizes in membranes are identified as macropores (>50 nm), mesopores (2 to 50 nm), and micropores (<2 nm). Because the pore sizes in RO membranes are so small, the membranes are defined as dense. The classification of membrane processes on the basis of the size of separation is shown on Fig. 11–31 and in Table 11–23. Referring to Fig.11–31, it can be seen that there is considerable overlap in the sizes of particles removed, especially between NF and RO. Nanofiltration is used most commonly in water softening operations in place of chemical precipitation.

Membrane Containment Vessels

Two types of containment vessels are used with membrane modules: (1) pressurized and (2) submerged.

Figure 11–29

Types of membrane construction: (a) microporous symmetric membrane, (b) nonporous (dense) symmetric membrane, (c) asymmetric membrane, and (d) thin film composite (TFC), sometimes identified as an asymmetric membrane.

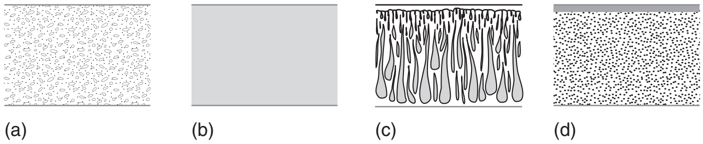


Figure 11–30

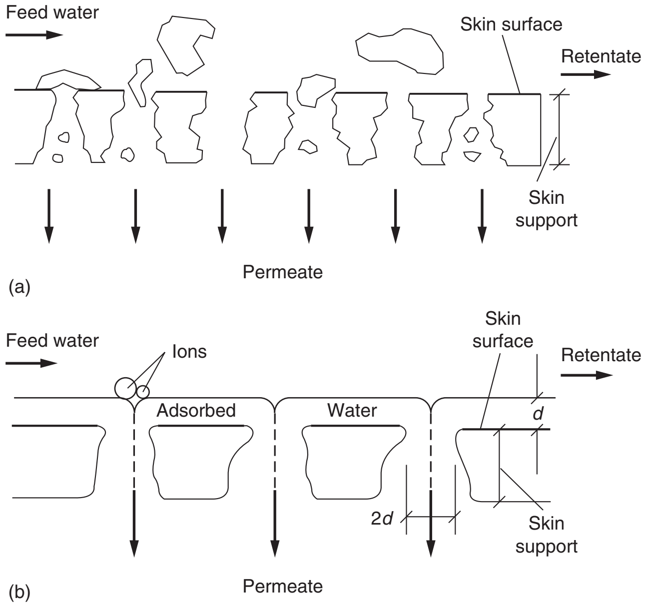
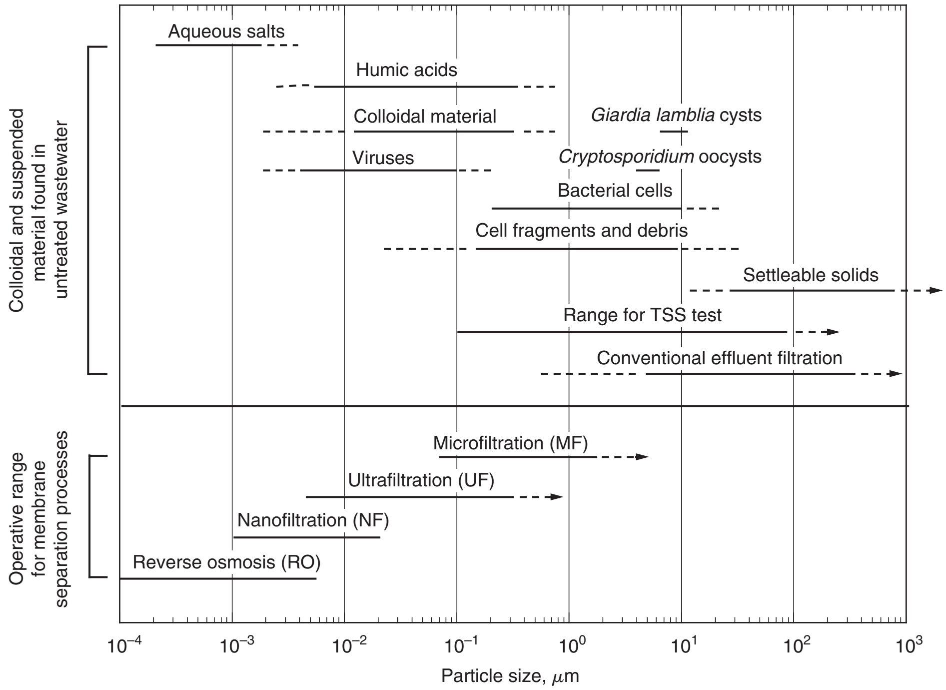
Definition sketch for the removal of wastewater constituents:
(a) removal of large molecules and particles by sieving (size exclusion) mechanism and
(b) rejection of ions by adsorbed water layer.



Pressurized. The primary purpose of the pressure vessel (or tube) is to support the membrane module or modules and keep the feed water and permeate (product water) isolated. The vessel must also be designed to prevent leaks and pressure losses to the outside, minimize the buildup of salt or fouling, and permit easy replacement of the membrane module. Microfiltration and ultrafiltration modules are generally 100 to 300 mm in

Figure 11–31

Comparison of the size of the constituents found in wastewater and the operating size ranges for membrane technologies. The operating size range for conventional depth filtration is also shown.



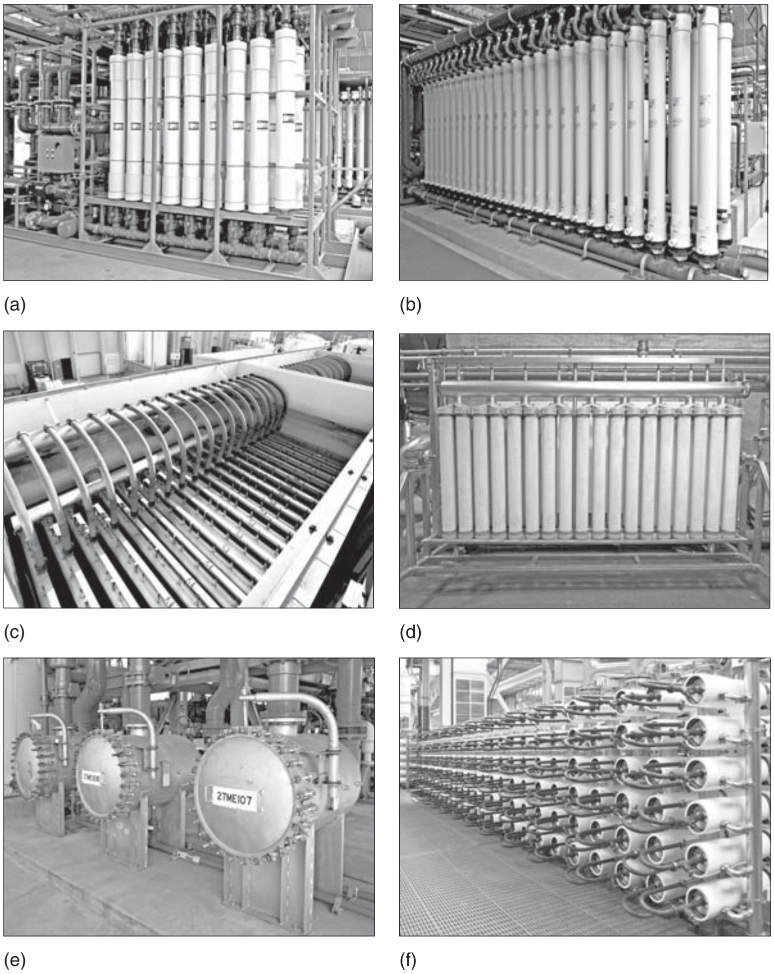


Figure 11–32

Views of various membrane installations: (a) pressurized microfiltration and (b) pressurized ultrafiltration membranes for the filtration of settled secondary effluent, (c) vacuum microfiltration membrane modules in open vessel, (d) membrane module used in open vessel shown in (c), (e) typical cartridge filter used before reverse osmosis, and (f) one bank of a large reverse osmosis installation used to treat activated sludge effluent following microfiltration, chemical addition, and cartridge filtration. Each bank of RO modules is designed to treat 19,000 m^3/d (5 Mgal/d). The capacity of the entire facility is 265,000 m^3/d (70 Mgal/d).

diameter, 0.9 to 5.5 m long, and a single module is placed in a pressurized vessel arranged in racks or skids. Each module must be piped individually for feed and permeate water. Typical pressurized MF membrane modules are shown on Figs. 11–32(a) and (b). The modules for NF and RO are 100 to 300 mm in diameter, 0.9 to 5.5 m long, and from two to eight modules are placed in a single pressurized vessel arranged in racks, either horizontally or vertically [see Figs. 11–32 (d) and (f)]. Vertical placement helps reduce the number of pipes and fittings and the total plant footprint.

In the pressurized configuration, pumps are used to pressurize the feed water and circulate it through the membrane [see Figs. 11–33(a) and (c)]. Centrifugal pumps can be used for MF, UF, and NF; positive displacement pumps or high-pressure turbine pumps are necessary for RO. Depending on the operating pressure and the characteristic of the feed water, a variety of materials have been used including plastic and fiberglass tubes and plumbing components. Steel pressure tubes are required for some reverse osmosis applications, and stainless steel is required for seawater and brackish water having high TDS.

Submerged (Vacuum) Type. In the submerged system, the membrane elements are immersed in a feed water tank as shown on Fig. 11–32(c). The permeate is withdrawn

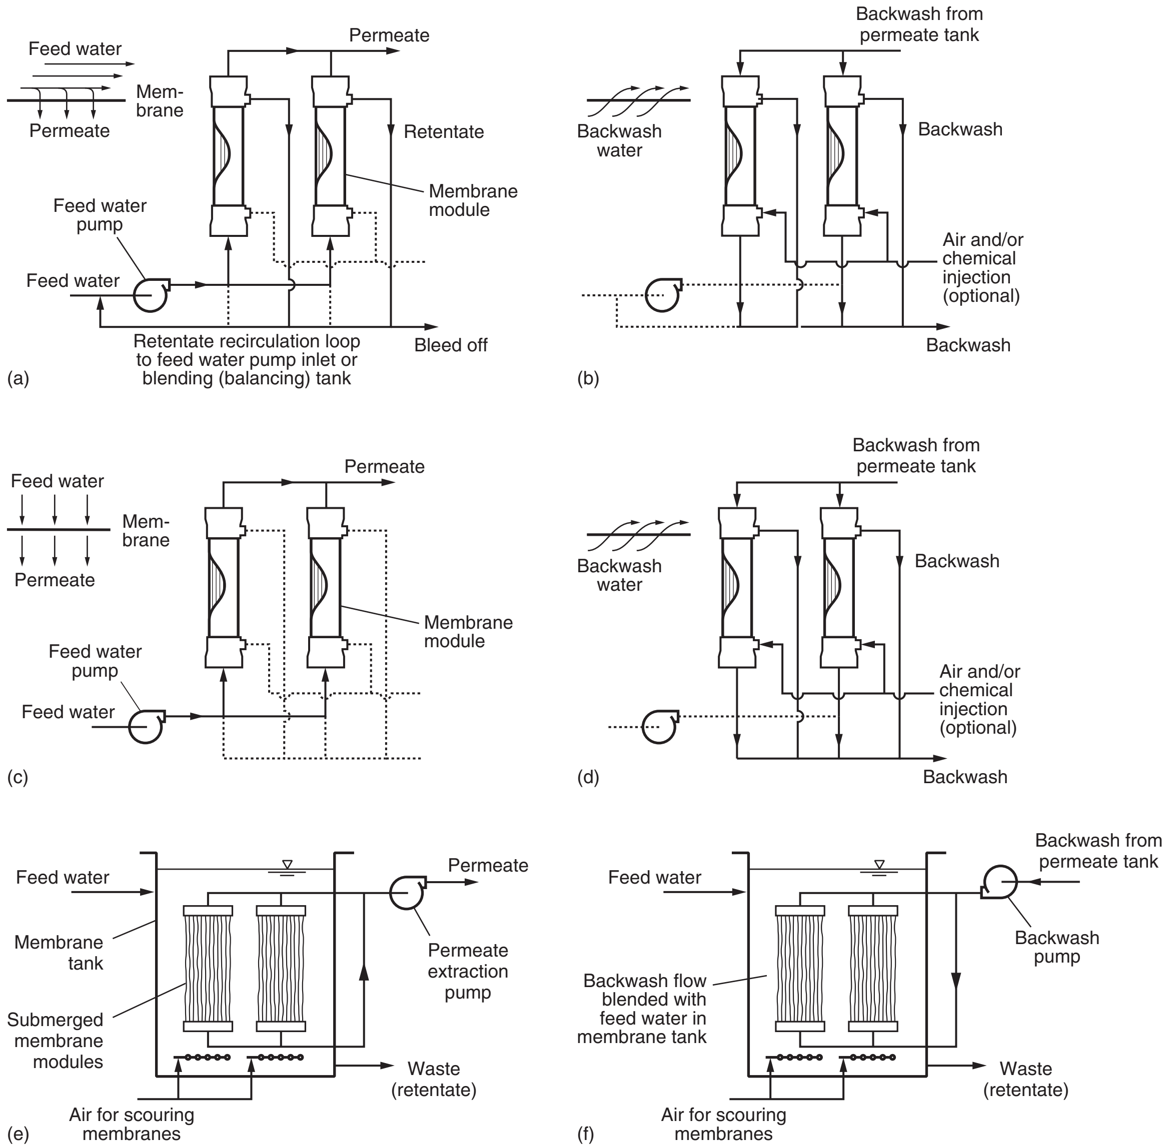

Figure 11–33

Definition sketch for membrane systems: (a) pressurized cross-flow membrane system (see insert), (b) backwashing pressurized cross-flow system, (c) pressurized dead-end flow [see insert, see also Fig. 8–32(a)] membrane system, (d) backwashing pressurized direct flow system, (e) submerged membrane with vacuum draw-off [see also Fig. 11-32(c)], and (f) backwashing submerged system.

through the membrane by applying a vacuum, usually from the suction of a centrifugal pump [see Fig. 11–33(e)]. Transmembrane pressure developed by the permeate pump causes clean water to be extracted through the membrane. Net positive suction head (NPSH) limitations of the permeate pump restrict the submerged membranes to a maximum transmembrane pressure of about 50 kPa, and they operate typically at a transmembrane pressure of 20 to 40 kPa (-28 to -100 kPa vacuum).

Operational Modes for Pressurized Configurations

Two different operational modes are used with pressurized microfiltration and ultrafiltration units: (1) cross-flow and (2) dead-end.

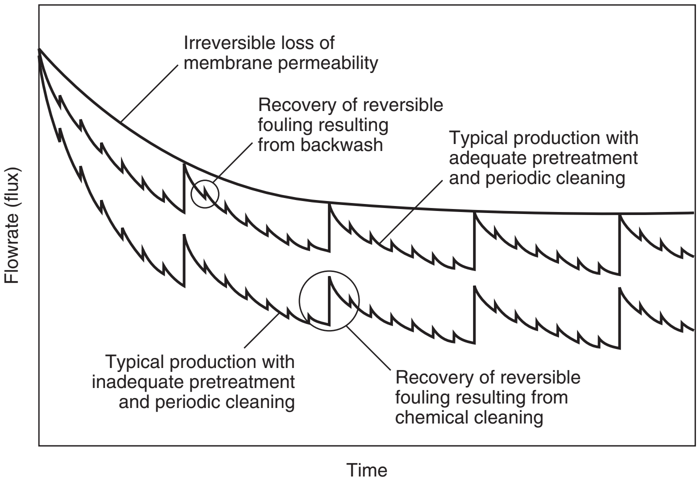
Cross-Flow Mode. In the *cross-flow* mode [see Fig. 11–33(a) and insert] the feed water is pumped more-or-less tangentially to the membrane. The accumulation of particulate matter on the surface of the membrane can be controlled by the shear force of the fluid velocity. The differential pressure across the membrane causes a portion of the feed water to pass through the membrane. Water that does not pass through the membrane is recirculated back to the membrane after blending with influent feed water or is recirculated to a blending (or balancing) tank. In addition, a portion of the water that did not pass through the membrane is bled off for separate processing and disposal [see Fig. 11–33(a)]. It should be noted that cross-flow is the flow pattern in spiral-wound membranes.

Dead-End Mode. In the second configuration, known as *dead-end* (also known as direct-feed or perpendicular feed) [see Fig. 11–33(c) and in the insert], there is no cross-flow (or liquid waste stream) during the permeate production mode. All of the water applied to the membrane passes through the membrane. Particulate matter that cannot pass through the membrane pores is retained on the membrane surface. Dead-end filtration is most effective when the concentration of particulate matter is low or where the accumulated material dose not cause a rapid headloss buildup. Dead-end filtration is used both for pretreatment and where the filtered water is to be used directly.

Membrane Cleaning. As constituents in the feed water accumulate on the membranes (often termed membrane fouling), the pressure builds up on the feed side, the membrane flux (i.e., flow through membrane) starts to decrease, and the percent rejection of certain water quality constituents [see Eq. (11–34)] may actually increase (see Fig. 11–34). When the flux has deteriorated to a given level, the membrane modules are taken out of service and backwashed and periodically cleaned chemically [see Figs. 11–33(b), (d), and (f)]. It should be noted that the quantity of waste washwater produced during membrane cleaning is typically less from pressurized as compared to submerged vacuum systems.

Figure 11–34

Definition sketch for the performance of a membrane filtration system as function of time with and without proper cleaning.



Chemical cleaning is used to restore the membrane performance to near its initial permeability. Two chemical cleaning methods are used typically: (1) clean-in-place (CIP) and (2) chemically enhanced backwash (CEB). In the CIP method, cleaning agents are used to soak and pass across the microfiber elements within the membrane module. In the CEB method, chemical cleaning agents are added to backwash water at selected backwash intervals (typically based on pressure buildup). Sometimes the CEB cleaning method is used for regular operation and when the membrane performance has deteriorated to a given level the CIP cleaning method is used.

A certain irreversible loss of membrane permeability will occur during process operation (see Fig. 11–34). The degree of irreversible permeability loss depends on the membrane material and operating conditions, including (1) long-term aging of the membrane material, (2) mechanical compaction and deformation from high operating pressures, (3) hydrolysis reactions related to solution pH, and (4) reactions with specific constituents in the feed water.

Process Analysis for MF and UF Membranes

Referring to Fig. 11–27, the process analysis for MF and UF membranes involves consideration of the operating pressure, permeate flow, the degree of recovery, and degree of rejection. Constituent and flowrate mass balances are used to assess the performance of the membranes.

Operating Pressure Cross-Flow Mode. For the cross-flow mode of operation, the transmembrane pressure is given by the following expression:

$$P_{tm} = \left(\frac{P_f + P_r}{2}\right) - P_p \tag{11–29}$$

where P_{tm} = transmembrane pressure gradient, bar (Note: 1 bar = 10^5 Pa)
P_f = inlet pressure of the feed water, bar
P_r = pressure of the retentate, bar
P_p = pressure of the permeate, bar

The overall pressure drop across the filter module for the cross-flow mode of operation is given by

$$P = P_f - P_p \tag{11–30}$$

where P = pressure drop across the module, bar
P_f and P_p as defined above

Operating Pressure Dead-End Mode. For the dead end pressurized and submerged modes of operation, the transmembrane pressure is given by the following expression:

$$P_{tm} = P_f - P_p \tag{11–31}$$

where P_{tm} = transmembrane pressure gradient, bar
P_f and P_p as defined above

Permeate Flowrate. The total permeate flowrate from a membrane system is given by

$$Q_p = F_w A \tag{11–32}$$

where Q_p = permeate flowrate, m^3/h
F_w = transmembrane water flux rate, m/h ($m^3/m^2 \cdot h$)
A = membrane area, m^2

As would be expected, the transmembrane water flux rate is a function of the quality and temperature of the feed water, the degree of pretreatment, the characteristics of the membrane, and the system operating parameters. Note that membrane area (A) is not the cross sectional area of the membrane module, but rather the active surface area of the membrane material. For example, a standard 200 mm diameter 1020 mm long (8-in. × 40-in.) RO module contains 37 m^2 (400 ft^2) of membrane surface area.

Recovery. Recovery, *r*, expressed as a percentage, is defined as the ratio of the net water produced to the total water applied during a filter run as follows:

$$r,\% = \frac{V_p}{V_f} \times 100 \tag{11–33}$$

where V_p = net volume of the permeate, m^3
V_f = volume of water fed to the membrane, m^3

In computing the net volume of permeate, the amount of backwash water used must also be taken into consideration.

Rejection. Rejection, *R*, expressed as a percentage or as a dimensionless fraction, is a measure of the amount of material removed from the feed water. It should be noted that there is a difference in the recovery, *r*, (which refers to the water) and rejection, *R*, (which refers to the solute). Rejection, *R*, is given by the following expression.

$$R,\% = \frac{C_f - C_p}{C_f} \times 100 = \left(1 - \frac{C_p}{C_f}\right) \times 100 \tag{11–34}$$

where C_f = feed water concentration, g/m^3, mg/L
C_p = permeate concentration, g/m^3, mg/L

Log Reduction. Another commonly used approach to express the rejection is as log rejection, *LR*, as given below.

$$LR = -\log(1 - R) = \log\left(\frac{C_f}{C_p}\right) \tag{11–35}$$

where *R* is the dimensionless form of Eq. (11–34).

Materials Mass Balance. The corresponding flowrate and constituent mass balance equations for the pressurized cross-flow membrane are:

Flowrate balance: $Q_f = Q_p + Q_r$ (11–36)

Constituent mass balance: $Q_f C_f = Q_p C_p + Q_r C_r$ (11–37)

where Q_f = feed water flowrate, m^3/h, m^3/s
Q_r = retentate flowrate, m^3/h, m^3/s
C_r = retentate concentration, g/m^3, mg/L

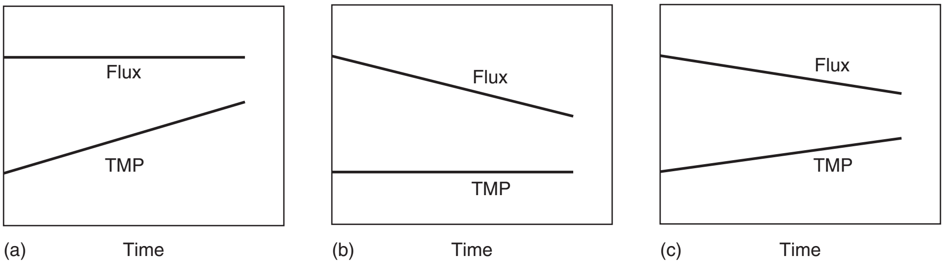


Figure 11–35

Three modes of membrane operation with respect to membrane flux and transmembrane pressure (TMP): (a) constant flux, (b) constant pressure, and (c) non restricted flux and pressure. (Adapted from Bourgeous et al., 1999.)

Operating Strategies for MF and UF Membranes

Operating strategies for membranes are developed based on a consideration of operating pressures and flux rates. Three different operating strategies can be used to control the operation of a membrane process with respect to flux and the transmembrane pressure (TMP). The three modes, illustrated on Fig. 11–35, are (a) constant flux in which the flux rate is fixed and the TMP is allowed to vary (increase) with time, (b) constant TMP in which the TMP is fixed and the flux rate is allowed to vary (decrease) with time, and (c) both the flux rate and the TMP are allowed to vary with time. Traditionally, the constant flux mode of operation has been used. However, based on the results of a study with various wastewater effluents (Bourgeous et al., 1999), the mode in which both the flux rate and the TMP are allowed to vary with time may be the most effective mode of operation. It should be noted that the diagrams on Fig. 11–35 do not reflect the irreversible permeability loss, as described previously. Regardless of the operating strategy an important issue with membranes systems is fiber breakage. The impact of fiber breakage is examined in Example 11–5.

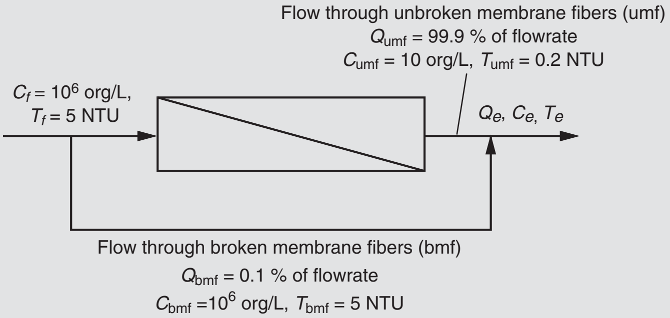
EXAMPLE 11–5 **Impact of Broken Fibers on Membrane Filter Effluent Quality** Membrane filtration is used to treat secondary effluent for reuse applications. The effluent from the wastewater treatment plant, which serves as the influent to the membrane filter installation, has an effluent turbidity of 5 NTU and contains a heterotrophic plate count (HPC) of 10^6 microorganisms/L. The effluent from the membrane filters typically contains less than 10 microorganisms/L and a turbidity of about 0.2 NTU. Using this information, what is the log rejection for microorganisms under normal operation with no broken fibers? If it is assumed that 6 out of 6000 (0.1 percent) membrane fibers have been broken during operation, determine the impact on the effluent microorganism count and turbidity. For the following analysis, neglect the water lost during the backwashing cycle.

Solution

1. Calculate the log rejection for microorganisms with no broken fibers using Eq. (11–35).

$$LR = \log\left(\frac{C_f}{C_p}\right) = \log\left[\frac{(10^6\ \text{org/L})}{(10\ \text{org/L})}\right] = 5.0$$

2. Determine the log rejection for microorganisms assuming that 6 fibers have been broken.
   a. Prepare a mass balance diagram for the condition with the broken fibers.



b. Write mass balance equation for microorganisms in the effluent from the membrane and solve for effluent microorganism concentration.

$$C_e = \frac{C_{\text{umf}}Q_{\text{umf}} + C_{\text{bmf}}Q_{\text{bmf}}}{Q_e}$$
$$= \frac{(10\text{ org/L})(0.999) + (10^6\text{ org/L})(0.001)}{1} = 1010\text{ org/L}$$

c. Calculate the log rejection for microorganisms for the condition with the broken fibers.

$$R_{\log} = \log\left(\frac{C_p}{C_f}\right) = \log\left[\frac{(10^6\text{ org/L})}{(1010\text{ org/L})}\right] = 3.0$$

3. Calculate the impact on turbidity assuming that 6 fibers have been broken. Use the mass balance equation developed in Step 2 and solve for the effluent turbidity.

$$T_e = \frac{T_{\text{umf}}Q_{\text{umf}} + T_{\text{bmf}}Q_{\text{bmf}}}{Q_e}$$
$$= \frac{(0.2\text{ NTU})(0.999) + (5\text{ NTU})(0.001)}{1} = 0.205\text{ NTU}$$

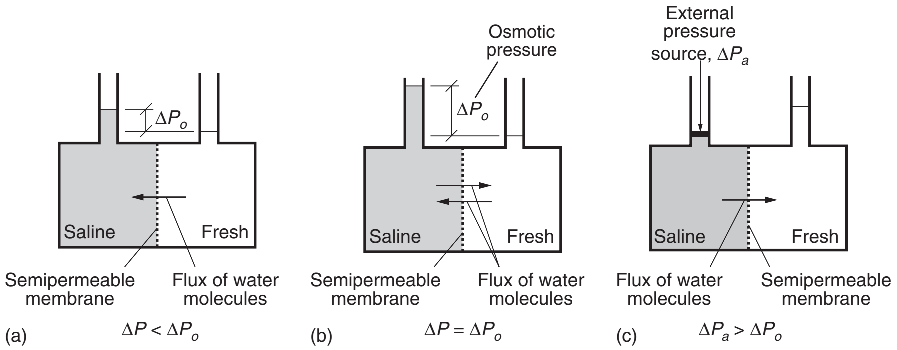
Comment This example is used to demonstrate that a few broken fibers can have a significant impact on the microorganism count in the effluent (1010 versus 10/L) and the log removal (5 versus 3.0 log) and essentially no impact on the effluent turbidity (0.2 versus 0.205 NTU, the difference is not measurable). For this reason, turbidity alone cannot be used as a surrogate measure for bacterial quality, and disinfection of microfiltration effluent will be required to protect public health in sensitive applications. The use of turbidity monitoring is often accompanied with the practice of pressure decay testing and particle counting for monitoring membrane integrity.

Process Analysis for Reverse Osmosis

Process analysis for reverse osmosis involves consideration of the membrane water and mass flux rate, permeate recovery ratio, rejection factor, and the corresponding mass balance analysis. To understand the details of the process analysis for reverse osmosis, it will be helpful to first review the fundamental basis for the reverse osmosis process.

Figure 11–36

Definition sketch for reverse osmosis: (a) osmosis (the differential pressure between solutions is less than the osmotic pressure), (b) osmotic equilibrium (the differential pressure between solutions is equal to the osmotic pressure), and (c) reverse osmosis (the applied pressure is greater than the osmotic pressure).



The fundamental basis is presented below followed by the expressions used for the analysis of the process.

Fundamental Basis for Reverse Osmosis Process. When two solutions having different solute concentrations are separated by a semipermeable membrane, a difference in chemical potential will exist across the membrane (see Fig. 11–36). Water will tend to diffuse through the membrane from the lower-concentration (higher-potential) side to the higher-concentration (lower-potential) side; this phenomenon is called forward osmosis [see Fig. 11–26(a)]. In a system having a finite volume, flow continues until the pressure difference balances the chemical potential difference. This balancing pressure difference is termed the osmotic pressure and is a function of the solute characteristics and concentration and temperature. If a pressure gradient, opposite in direction and greater than the osmotic pressure, is imposed across the membrane, flow from the more concentrated to the less concentrated region will occur; this phenomenon is termed *reverse osmosis* [see Fig. 11–36(c)].

Membrane Flux and Area Requirements. A number of different models have been developed to determine the membrane surface area and the number of stages (arrays) required (see Fig. 11–37). The basic equations used to develop the various models are as follows.

Feed Water Flux Rate. Referring to Fig. 11–27, the flux of water through the membrane is a function of the pressure gradient:

$$F_w = k_w(\Delta P_a - \Delta \Pi) = \frac{Q_p}{A} \tag{11–38}$$

where F_w = feed water flux rate, L/m^2·h

k_w = mass transfer coefficient for water flux (involving temperature, membrane characteristics, and solute characteristics), L/m^2·h·bar

ΔP_a = average applied pressure gradient, bar (Note: Number 1 bar = 10^5 Pa)

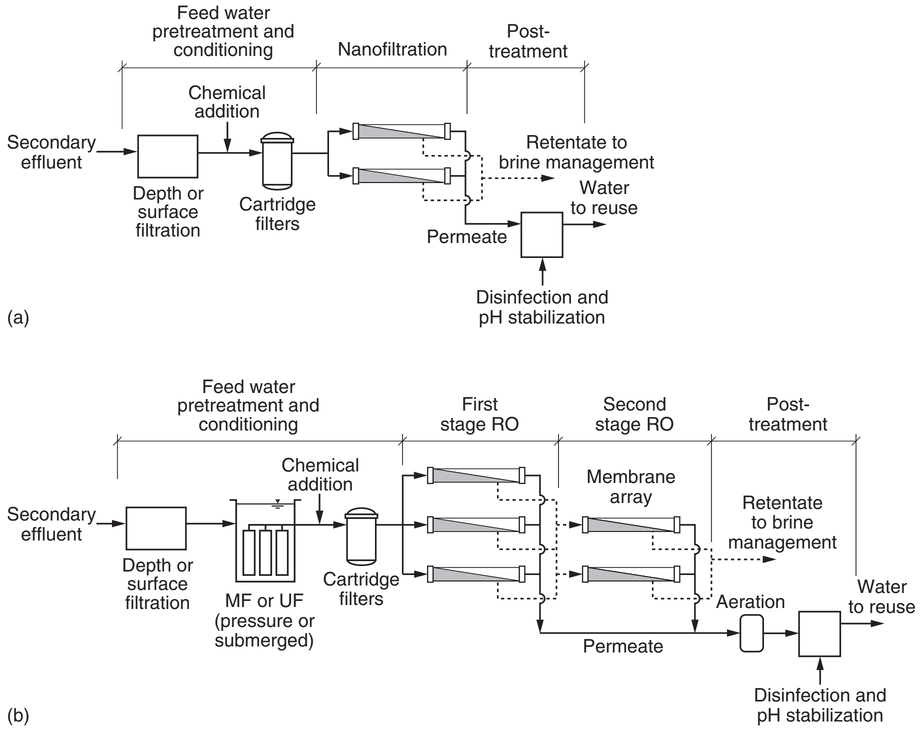
$$= \left(\frac{P_f + P_c}{2}\right) - P_p$$

$\Delta\Pi$ = osmotic pressure gradient, bar

$$= \left(\frac{\Pi_f - \Pi_c}{2}\right) - \Pi_p$$

Figure 11–37

Typical process flow diagrams: (a) depth or surface filtration with nanofiltration and (b) combined microfiltration or ultrafiltration with reverse osmosis.



P_f = inlet pressure of feed water, bar
P_r = pressure of retentate, bar
P_p = pressure of permeate, bar
Π_f = osmotic pressure of feed water, bar
Π_r = osmotic pressure of retentate, bar
Π_p = osmotic pressure of permeate, bar
Q_p = permeate flowrate, L/h
A = membrane area, m^2

Mass (Solute) Flux Rate. Some solute passes through the membrane in all cases. Solute flux can be described adequately by an expression of the form

$$F_s = k_s \, \Delta C_s = \frac{(Q_p)(10^{-3}\,\text{m}^3/\text{L})C_p}{A} \tag{11–39}$$

where F_s = mass flux of solute, $g/m^2 \cdot h$
k_s = mass transfer coefficient for solute, m/h
ΔC = solute concentration gradient across membrane, g/m^3
$= \left(\dfrac{C_f + C_r}{2}\right) - C_p$
C_f = solute concentration in feed water, g/m^3
C_r = solute concentration in retentate (concentrate), g/m^3
C_p = solute concentration in permeate, g/m^3
Q_p = permeate flowrate, L/h

Permeate Recovery Ratio. The permeate recovery ratio, *r*, expressed as a percentage, represents the conversion of feed water to permeate (product water), and is defined as

$$r, \% = \frac{Q_p}{Q_f} \times 100 \tag{11–40}$$

where Q_p = permeate flowrate, L/h, m^3/h, or m^3/s
Q_f = feed water flowrate, L/h, m^3/h, or m^3/s

The permeate recovery ratio affects the capital and operating cost of a membrane system. The volume of feed water required for a given permeate capacity is determined directly by the design recovery ratio. Also, the size of the feed water system, capacity of the pretreatment system, and size of the high pressure pumps and supply piping are also functions of the recovery ratio. With increased recovery, the feed water flowrate, is reduced, the pressure may increase somewhat, but the brine will be more concentrated which can make disposal more difficult.

An example of the effect of the permeate recovery ratio on feed pressure, power consumption and feed flow is shown on Fig. 11–38 for an RO system operating at recovery rates between 60 and 90 percent. The feed water flowrate depends only on the recovery ratio. The feed pressure is a complex function of recovery ratio, feed water salinity feed water temperature, and specific permeate flux of the membrane. The power requirement of the high pressure pump is proportional to the flowrate and pressure. In the usual range of operating parameters, for an increase in recovery ratio, the decrease in feed water flowrate will have a greater effect on power consumption than an increase in feed water pressure (Wilf, 1998). For RO, higher operating pressures are desirable because the degree of separation and the quality of the product are improved.

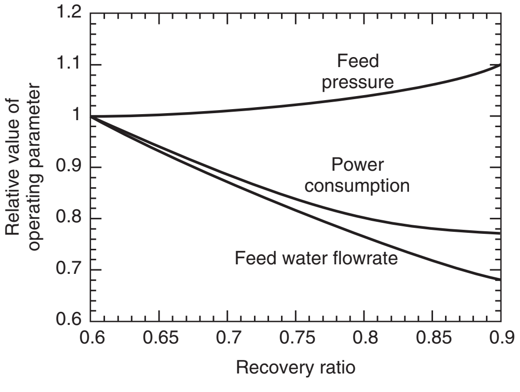
Rejection Factor. Rejection (or retention), R, expressed as percentage or as a dimensionless fraction, is a measure of the amount of solute or solid that is retained or does not pass through the membrane; it is calculated using the following expression.

$$R, \% = \left(\frac{C_f - C_p}{C_f}\right) \times 100 = \left(1 - \frac{C_p}{C_f}\right) \times 100 \tag{11–41}$$

where C_f = concentration in the feed water, g/m^3
C_p = concentration in the permeate, g/m^3

Figure 11–38

Effect of permeate recovery on feed pressure, feed flowrate, and power consumption.



The rejection efficiency of reverse osmosis membranes for specific species can range from 85 to 99.5 percent and is quoted by the manufacturer for a standard set of feed conditions. When the rejection of microorganisms is considered, it is more convenient to express the rejection as log rejection as given by Eq. (11–35), repeated here for convenience.

$$LR = -\log(1 - R) = \log\left(\frac{C_f}{C_p}\right) \qquad (11\text{–}42)$$

Materials Mass Balances. The flowrate and constituent mass balance equations given previously for microfiltration and ultrafiltrations also apply to NF and RO systems. The equations are

$$\text{Flowrate balance: } Q_f = Q_p + Q_r \qquad (11\text{–}43)$$

$$\text{Constituent mass balance: } Q_f\, C_f = Q_p\, C_p + Q_r\, C_r \qquad (11\text{–}44)$$

where Q_r = retentate flowrate, m^3/h, m^3/s
C_r = retentate concentration, g/m^3
Other terms are as defined previously

Use of the above equations to estimate the required surface area for TDS reduction is illustrated in Example 11–6.

EXAMPLE 11–6 **Determination of Membrane Area Required for Demineralization** A brackish water having a TDS concentration of 3000 g/m^3 is to be desalinized using a thin film composite membrane having a solvent (water) mass transfer coefficient k_w of 9×10^{-9} s/m (9×10^{-7} m/s·bar) and a solute (i.e., TDS) mass transfer coefficient k_i of 6×10^{-8} m/s. The product water is to have a TDS of no more than 200 g/m^3. The feed water flowrate is 0.010 m^3/s. The net operating pressure ($\Delta P_a - \Delta P$) will be 2500 kPa (2.5×10^6 kg/m·s^2). Assume the recovery rate, r, will be 90 percent and that all of the water is to be processed through the membrane unit to remove other constituents in addition to TDS. Estimate the rejection rate, R, and the concentration of the retentate.

Solution

1. The problem involves determination of the membrane area required to produce 0.009 m^3/s (0.9×0.010 m^3/s) of water with a TDS concentration equal to or less than 200 g/m^3. If the estimated permeate TDS concentration is well below 200 g/m^3 and TDS is the only constituent of concern, blending of feed water and permeate can be used to reduce the required membrane area.
2. Estimate the membrane area using Eq. (11–38) and the water mass transfer coefficient. The estimated area may need to be adjusted based on the solute mass transfer rate.

$$F_w = k_w(\Delta P_a - \Delta P)$$

$$= (9 \times 10^{-9}\ \text{s/m})(\,2.5 \times 10^6\ \text{kg/m·s}^2) = 2.25 \times 10^{-2}\ \text{kg/m}^2\text{·s}$$

$$Q_p = F_w \times A,\ Q_p = r\,Q_f,\ Q_p = 0.9\,Q_f$$

$$A = \frac{(0.9 \times 0.010\ \text{m}^3/\text{s})(10^3\ \text{kg/m}^3)}{(2.25 \times 10^2\,\text{kg/m}^2\text{·s})} = 400\ \text{m}^2$$

3. Estimate the permeate TDS concentration using Eq. (11–39) and the estimated area.

$$F_i = k_i\,\Delta C_i = \frac{Q_p C_p}{A}$$

Substituting for ΔC_i and solving for C_p yields

$$C_p = \frac{k_i[(C_f + C_r)/2]A}{Q_p + k_i A}$$

Assume $C_c \approx 10C_f$ (Note: If the estimated C_r value and the computed value of C_r, as determined below, are significantly different, the value of C_p must be recomputed)

$$C_p = \frac{(6 \times 10^{-8}\,\text{m/s})[(3\,\text{kg/m}^3 + 30\,\text{kg/m}^3)/2](400\,\text{m}^2)}{(0.01\,\text{m}^3/\text{s}) + (6 \times 10^{-8}\,\text{m/s})(400\,\text{m}^2)} = 0.044\,\text{kg/m}^3$$

4. Estimate the rejection rate using Eq. (11–41)

$$R,\% = \frac{C_f - C_p}{C_f} \times 100$$

$$R = \frac{(3.0\,\text{kg/m}^3) - (0.044\,\text{kg/m}^3)}{(3.0\,\text{kg/m}^3)} \times 100 = 98.5\%$$

5. Estimate the retentate TDS using Eq. (11–41).

$$C_r = \frac{Q_f C_f - Q_p C_p}{Q_r}$$

$$C_r = \frac{(1.0\,\text{L})(3.0\,\text{kg/m}^3) - (0.9\,\text{L})(0.044\,\text{kg/m}^3)}{(0.1\,\text{L})} = 29.6\,\text{kg/m}^3$$

The estimated value of C_r used in Step 3 (30 kg/m^3) is ok.

Comment If the permeate TDS concentration were significantly below 200 g/m^3, blending of feed and permeate could be used to reduce the required membrane area. In this example blending cannot be used.

Membrane Fouling

Membrane fouling is, perhaps, the most important consideration in the design and operation of membrane systems as it affects pretreatment needs, cleaning requirements, operating conditions, cost, and performance. Membrane fouling will occur depending on the site-specific physical, chemical, and biological characteristics of the feed water, the type of membrane, and operating conditions. As reported in Table 11–25, four general forms of fouling can occur: (1) particulate fouling, due to a buildup of the constituents in the feed water on the membrane surface, (2) precipitation of inorganic salts resulting in the formation of inorganic scales, (3) organic fouling due to the presence of organic matter, and (4) biological fouling due to the presence of microorganisms in the feed water. Any or all of these forms of fouling can occur simultaneously and over time. In addition, membranes can be damaged by the presence of chemical substances that can react with the membrane. Typical wastewater constituents in that can cause membrane fouling are also presented in Table 11–25.

Table 11–25

Typical constituents in wastewater that cause membrane fouling and other constituents that can cause damage to the membranes[a]

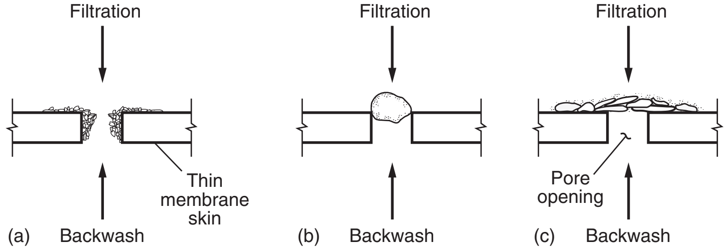
Type of fouling	Responsible wastewater constituents	Remarks
Particulate fouling	Organic and inorganic colloids Emulsified oils Clays and silts Silica Iron and manganese oxides Oxidized metals Metal salt coagulant products Powdered activated carbon	Particulate fouling can be reduced by cleaning the membrane at regular intervals
Scaling (precipitation of supersaturated salts)	Barium sulfate Calcium carbonate Calcium fluoride Calcium phosphate Strontium sulfate Silica	Scaling can be reduced by limiting salt content, by pH adjustment, and by other chemical treatments such as the addition of antiscalants
Organic fouling	Natural organic matter (NOM) including humic and fulvic acids, proteins and polysccharides Emulsified oils Polymers used in treatment process	Effective pretreatment can be used to limit organic fouling
Biofilm fouling	Dead microorganisms Living microorganisms Polymers produced by microorganisms	Biofilms are formed on membrane surface by colonizing bacteria
Damage to membrane	Acids Bases pH extremes Free chlorine Free oxygen	Membrane damage can be limited by controlling the amount of these substances in the feed water. The extent of the damage depends on the nature of the membrane selected

[a] In many cases all four types of fouling can occur simultaneously.

Particulate Fouling. Particulate fouling is caused by the presence of particulate matter in the feed water. To protect RO and NF membrane systems from large particulate fouling, cartridge filters [see Table 11–21(g)] are used ahead of the membrane feed pumps. These are normally 5 to 15 μm pore size woven filters designed to prevent fouling from relatively large particles. Nonetheless, much smaller particles can also damage and foul RO and NF modules. As noted in Table 11–25, particulate constituents can include organic and inorganic colloids, emulsified oils, clays and silts, silica, and metal oxides and salts. Of these constituents, silica has proven to be one of the more problematic in wastewater. Silica $(SiO_2)_n$ in wastewater can be found in a variety of different forms including reactive, colloidal, and particulate silica depending on the chemical characteristics of the feed water.

Figure 11–39

Modes of membrane fouling: (a) pore narrowing, (b) pore plugging, and (c) gel/cake formation caused by concentration polarization.



Three accepted mechanisms resulting in resistance to flow due to the accumulation of material (see Fig. 11–39) are (1) pore narrowing, (2) pore plugging, and (3) gel/cake formation caused by concentration polarization (Ahn et al., 1998). The mechanisms of pore plugging and pore narrowing will only occur when the particulate matter in the feed water is smaller than the pore size or the molecular weight cutoff. Pore plugging occurs when particles the size of the pores become stuck in the pores of the membrane. Pore narrowing consists of solid material attaching to the interior surface of the pores, which results in a narrowing of the pores. It has been hypothesized that once the pore size is reduced, concentration polarization is amplified further causing an increase in fouling (Crozes et al., 1997).

Gel/cake formation, caused by concentration polarization, occurs when the majority of the solid matter in the feed is larger than the pore sizes or molecular weight cutoff of the membrane. Concentration polarization can be described as the build up of matter close to or on the membrane surface that causes an increase in resistance to solvent transport across the membrane. Some degree of concentration polarization will always occur in the operation of a membrane system. The formation of a gel or cake layer, however, is an extreme case of concentration polarization where a large amount of matter has actually accumulated on the membrane surface forming a gel or cake layer.

Scaling. As chemical constituents in the feed water are removed at the surface of the membrane, their concentration increases locally. When the concentrations of the individual constituents increase beyond their solubility limits, a variety of different types of salts can be precipitated, depending on the chemical characteristics and temperature of the feed water. Chemical precipitation is especially critical in RO units used for desalination, because of the high initial salt concentration in seawater. The chemical scale that forms on the membrane surface is of importance because it can reduce the water permeability of the membrane and potentially cause irreversible damage to the membrane.

Organic Fouling. Most treated wastewater contains a variety of organic matter in varying concentrations. As noted in Table 11–25, organic foulants can include NOM that was present originally in the water supply, NOM produced during biological treatment, emulsified oils, and organic polymers that may have been used in the wastewater treatment process including polymers used as filter aids in tertiary treatment and polymers recycled to the treatment process from dewatering activities. Because these polymeric materials are sticky, they can accumulate on the membrane surface and accelerate fouling by forming stable organic/inorganic particulate matter, which can reduce the water permeability of the membrane.

Biological Fouling. Effluent from biological treatment systems presents a special problem, as the membranes are susceptible to fouling because of the biological activity that can occur. Because the concentration of organic matter and nutrients is elevated at the membrane surface, conditions are favorable for the growth of microorganisms. As microorganisms begin to colonize on the membrane surface, the water permeability of the membrane will be reduced. When a membrane process is operated intermittently, the water permeability of the membrane can be reduced further if the microorganisms start to grow into the membrane pores. The growth of microorganisms is also of concern because of the production of extracellular polymers which can interact with other foulants, as described previously.

Control of Membrane Fouling

Typically, three approaches are used to control membrane fouling: (1) pretreatment of the feed water, (2) membrane backflushing, and (3) chemical cleaning of the membranes. Pretreatment is used to reduce the TSS, colloidal material, and bacterial content of the feed water. Often the feed water will be conditioned chemically to limit chemical precipitation within the units. Many proprietary pretreatment chemicals such as anti-scalants, biocides, and scale inhibitors are available in the marketplace to control NF and RO fouling. In low pressure membrane operations (MF and UF), the method of eliminating the accumulated material from the membrane surface is backflushing with water and/or air. Chemical treatment is used to remove constituents that are not removed during conventional backwashing. Chemical precipitates can be removed by altering the chemistry of the feed water and by chemical treatment. Damage of the membrane due to deleterious constituents typically cannot be reversed. The need for pretreatment and pretreatment options for NF and RO are discussed below.

Assessing Need for Pretreatment for NF and RO. To assess the treatability of a given wastewater with NF and RO membranes, a variety of fouling indexes have been developed over the years. The three principal indices are the silt density index (SDI), the modified fouling index (MFI), and the mini plugging factor index (MPFI). Fouling indexes are determined from simple membrane tests. The sample must be passed through a 0.45 μm Millipore filter with a 47-mm internal diameter at 210 kPa (30 $\text{lb}_f/\text{in.}^2$) gauge to determine any of the indexes. The time to complete data collection for these tests varies from 15 min to 2 h, depending on the fouling nature of the water.

Silt Density Index. The most widely used index is the SDI (DuPont, 1977; ASTM, 2002). The SDI is defined as follows.

$$SDI = \frac{100[1 - (t_i/t_f)]}{t} \tag{11–45}$$

where t_i = time to collect the initial sample of 500 mL
t_f = time to collect final sample of 500 mL
t = total time for running the test

The silt density index is a static measurement of resistance which is determined by samples taken at the beginning and end of the test. The SDI does not measure the rate of change of resistance during the test. Recommended SDI values are reported in Table 11–26. The calculation of the SDI is demonstrated in Example 11–7.

Modified Fouling Index. The modified fouling index (MFI) is determined using the same equipment and procedure used for the SDI, but the volume is recorded every 30 s over a

Table 11–26

Recommended values for fouling indexes[a]

Membrane process	Fouling index		
	SDI	MFI, s/L^2	MPFI, L/s^2
Nanofiltration	0–2	0–10	0–1.5 × 10^{-4}
Reverse osmosis hollow fiber	0–2	0–2	0–3 × 10^{-5}
Reverse osmosis spiral wound	0–3[b]	0–2	0–3 × 10^{-5}

[a] Adapted in part from Taylor and Wiesner (1999) and AWWA (1996).

[b] Although a value of 3 is acceptable, the trend is to lower the upper limit to a value of 2 or less.

15-min filtration period (Schippers and Verdouw, 1980). Derived from a consideration of cake filtration, the MFI is defined as follows:

$$\frac{1}{Q} = a + \text{MFI} \times V \qquad (11\text{–}46)$$

where Q = average flowrate, L/s
a = constant (intercept of linear portion of curve)
MFI = modified fouling index, s/L^2
V = volume, L

The value of the MFI is obtained as the slope of the straight-line portion of the curve obtained by plotting the inverse of the flowrate versus the cumulative volume [see Fig. 11–40(a)].

Mini Plugging Factor Index. The mini-plugging factor index (MPFI) is a measure of the change in flowrate as a function of time, as illustrated on Fig. 11–40(b) (Taylor and Jacobs, 1996). The equipment used for the MPFI test is the same as that used for the SDI and MFI tests. The MPFI is defined as the slope of the linear portion of the flowrate versus time curve [see Fig. 11–40(b)], which is ascribed to cake fouling. In equation form, the MPFI is expressed as follows:

$$Q = (\text{MPFI})\,t + a \qquad (11\text{–}47)$$

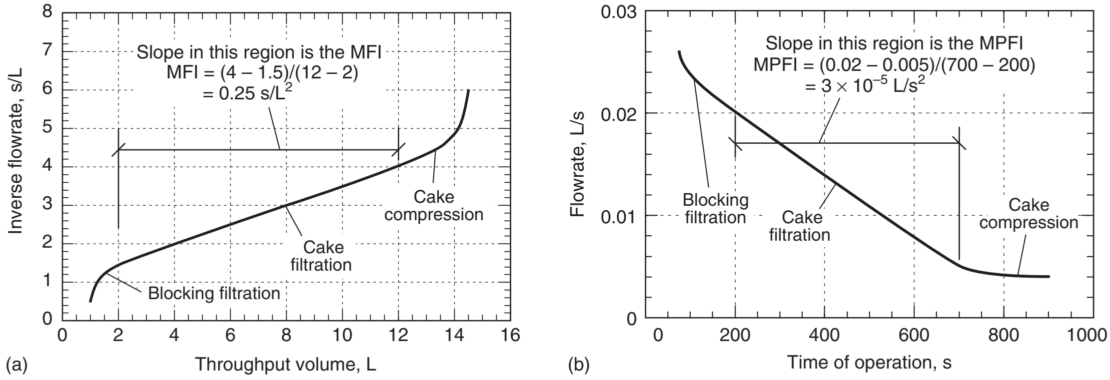


Figure 11–40

Typical plot to determine fouling indexes: (a) modified fouling factor (MFI) and (b) mini plugging factor index (MPFI).

where Q = average flowrate at 30 s intervals, L/s
MPFI = mini plugging factor index, L/s^2
t = time, s
a = constant (intercept of linear portion of curve)

Typical values for the MPFI are reported in Table 11–26. Because the MFI is based on throughput volume, it is thought to be a more sensitive index than the MPFI for characterization of fouling.

EXAMPLE 11–7 **Silt Density Index for Reverse Osmosis** Determine the silt density index for a proposed feed water from the following test data. If a spiral wound RO membrane is to be used, will pretreatment be required?

Test run time = 30 min
Initial 500 mL = 2 min
Final 500 mL = 10 min

Solution

1. Calculate the SDI using Eq. (11–45).

$$\text{SDI} = \frac{100[1 - (t_i/t_f)]}{t}$$

$$\text{SDI} = \frac{100[1 - (2/10)]}{30} = 2.67$$

2. Compare the SDI to the acceptable criteria.
   Calculated SDI value of 2.67 is less than 3 (see Table 11–26); therefore, further pretreatment would not be needed normally.

Comment As a practical matter, because the SDI value is close to 3.0 it may be prudent to consider some form of pretreatment to prolong the filtration cycle.

Limitations of Fouling Indexes. The SDI and MFI fouling indexes described above, and others currently in use, have serious limitations including (1) the fact that a dead-end test is used to gather data to predict the fouling performance of a cross-flow membrane, (2) the test is conducted with a 0.45 μm filter which does not capture the effect of smaller colloidal particles, (3) the test is not representative of cake filtration, which occurs in cross-flow, (4) the test does not measure the propensity for scale formation, and (5) the test is conducted under conditions of constant pressure with variable flux, where the opposite operational mode is normally used in practice. It should be noted that several other indexes, using MF or UF membranes in place of the Millipore filter, to reflect the effect of smaller colloidal material and large dissolved organic material on fouling, are currently under development.

Pretreatment for NF and RO. A very high quality feed is required for efficient operation of a nanofiltration or reverse osmosis unit. Membrane elements in the reverse osmosis unit can be fouled by colloidal matter and dissolved constituents in the feed water. The pretreatment options identified in Table 11–27 have been used singly and in combination. The effectiveness of the treatment options can be assessed with one or more of the indexes discussed previously. Regular chemical cleaning of the membrane elements (about once a month) is also necessary to restore and maintain the membrane flux.

Application and Performance of Membranes

With evolving health concerns and the development of new and lower cost membranes, the application of membrane technologies in the field of environmental engineering has increased dramatically within the past 5 years. The increased use of membranes is expected to continue well into the future. In fact, the use of conventional filtration technology, such as described in Sections 11–4 and 11–5, may be a thing of the past within 10 to 15 years, especially in light of the need to remove resistant organic constituents of concern. The principal applications of the various membrane technologies in wastewater treatment are reported in Table 11–28. Application of the membrane technologies for the removal of specific constituents from wastewater is given in Table 11–29. Each of the membrane technologies is considered further in the following discussion.

Microfiltration. Microfiltration membranes are the most numerous on the market and are the least expensive. The use of membranes for biological treatment is currently one of the most important uses of membranes in wastewater treatment. In advanced treatment applications, microfiltration has been used, most commonly as a replacement for depth filtration to reduce turbidity, remove residual suspended solids, and reduce microorganisms for effective disinfection and as a pretreatment step for reverse osmosis (see Fig. 11–41). Typical operating information for microfiltration including size range, operating pressures, and flux rate are presented in Table 11–30. Typical performance data are reported in Table 11–31. Corresponding variability data are presented in Table 11–32. Care should be used in applying the performance data reported in Table 11–30 as it has been found that the performance of MF is to a large extent site specific, especially with respect to fouling.

Ultrafiltration. Ultrafiltration (UF) membranes are used for many of the same applications as described above for microfiltration. Some UF membranes with small pore sizes have also been used to remove dissolved compounds with high molecular weight, such as colloids, proteins, and carbohydrates. The membranes do not remove sugar or salt. The major distinction between UF and MF is that UF can remove viruses whereas MF cannot.

Figure 11–41

Typical process flow diagram for the production of potable water employing filter screens, open vessel microfiltration, cartridge filters, revers osmosis, UV advanced oxidation, decarbonation, and lime stabilization. (Adapted from Orange County Water District, CA.)

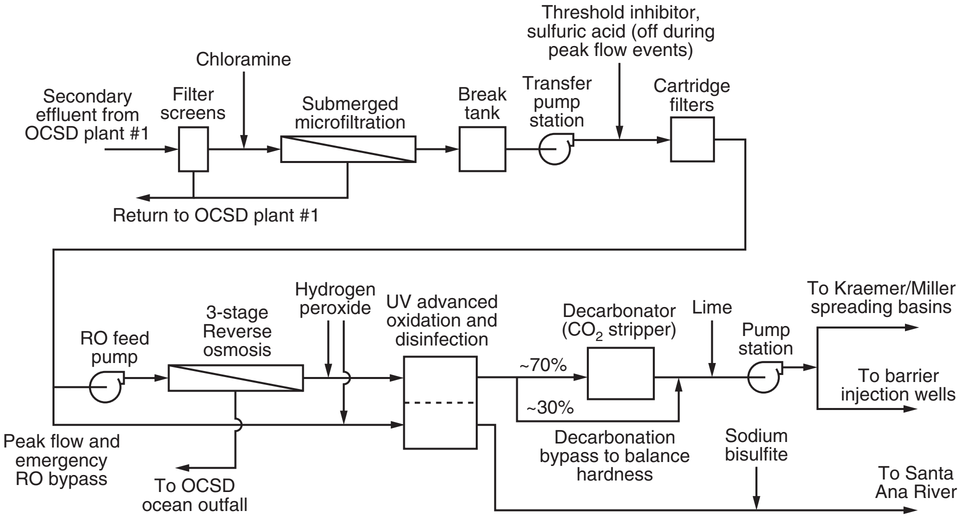

Table11–27

Methods of pretreatment for nanofiltration and reverse osmosis systems

Material to be removed	Method of pretreatment	Description or discussion
Particulate matter and colloidal	Depth or surface filtration, microfiltration, or ultrafiltration	Particulate matter can be removed by various methods of filtration. Fouling agents may pass through these filtration systems, thus the potential for membrane fouling should be verified by pilot testing.
Particulate matter	Cartridge filter	Cartridge filters are pressure-driven filters with pore sizes varying from 5 to 15 μm and are commonly installed ahead of RO membranes. Cartridge filters provide a final level of protection against the intrusion of relatively large solids into the reverse osmosis system. When antiscalants are used, cartridge filters are used to remove the colloidal material and impurities found in antiscalent chemicals. The filters do not remove dissolved substances. Generally, the pressure drop across a clean cartridge filter is between 0 and 35 kPa. As the solids accumulate and the pressure drop reaches a threshold range of 70 to 80 kPa, the cartridge has to be removed and replaced (Paranjape et al., 2003).
Microorganisms	Disinfection	Disinfection of the feed water may be accomplished using either chlorine, ozone, or UV irradiation to limit bacterial activity. Ultrafiltration can also be used to reduce the number of microorganisms.
Scale formation	pH adjustment	To inhibit scale formation, the pH of the feed water is adjusted (usually with sulfuric acid) within the range from 4.0 to 7.5. A low pH enhances conversion of carbonate into bicarbonate species, which are much more soluble. Cellulose acetate RO membranes have an optimum pH range of 5 to 7 as they are prone to hydrolysis below a pH of 5. Newer polyamide RO membranes can be used over a broader pH range of 2 to 11 (Paranjape et al., 2003).
	Antiscalants	Antiscalants are compounds that either prevent scale formation entirely or permit formation of scales that can be removed easily during cleaning. Certain antiscalants, however, may increase the fouling caused by humic acids (Richard et al., 2001).
Iron and manganese	Ion exchange or chemical treatment	Removal of iron and manganese will decrease scaling potential. The exclusion of oxygen may be necessary to prevent oxidation of iron and manganese.
Sparingly soluble salts	Chemical treatment	Sparingly soluble salts such as silica can be removed by chemical treatment for industrial purposes, i.e., removal of silica may be required to prevent precipitation on heat exchangers. Chemical treatment may include the addition of aluminum and iron oxides, zinc chloride, magnesium oxide, ozone (when ozone-resistant membranes are used), and ultra-high lime clarification. Lime clarification, however, may not be as effective as other pretreatment methods in removing materials that foul RO membranes thus resulting in more frequent cleaning of the membranes (Gagliardo, 2000).

Ultrafiltration is used typically in industrial applications for the production of high purity process rinse water. Typical operating and performance data are presented in Tables 11–30 and 11–31, respectively. Performance variability data are presented in Table 11–32.

Nanofiltration. Nanofiltration, also known as "loose" RO or low pressure RO, can reject particles as small as 0.001 μm. Nanofiltration is used for the removal of selected dissolved constituents from wastewater such as the multivalent metallic ions responsible for hardness (i.e., calcium and magnesium). For this reason, NF is the preferred membrane

Table 11–28

Typical applications for membrane technologies in wastewater treatment[a]

Applications	Description
Microfiltration and Ultrafiltration	
Aerobic biological treatment	Membranes are used to separate the treated wastewater from the active biomass in an activated sludge process. The membrane separation unit can be internal (immersed in the bioreactor) or external to the bioreactor (see Fig. 8–2 in Chap. 8). Such processes are known as membrane bioreactor (MBR) processes
Anaerobic biological treatment	Membrane is used to separate the treated wastewater from the active biomass in an anaerobic complete-mix reactor
Membrane aeration biological treatment	Plate and frame, tubular, and hollow membranes are used to transfer pure oxygen to the biomass attached to the outside of the membrane. Such processes are known as membrane aeration bioreactor (MABR) processes
Membrane extraction biological treatment	Membranes are used to extract degradable organic molecules from inorganic constituents such as acids, bases, and salts from the waste stream for subsequent biological treatment [see Fig. 11–47(b)]. Such processes are known as extractive membrane bioreactor (EMBR) processes
Pretreatment for effective disinfection	Membranes are used to remove residual suspended solids from settled secondary effluent or from the effluent from depth or surface filters to achieve effective disinfection with either chlorine or UV radiation for reuse applications.
Pretreatment for nanofiltration and reverse osmosis	Microfilters are used to remove residual colloidal and suspended solids as a pretreatment step for additional processing
Nanofiltration	
Effluent reuse	Used to treat prefiltered effluent (typically with microfiltration) for indirect potable reuse applications such as groundwater injection. Credit is also given for disinfection when using nanofiltration
Wastewater softening	Used to reduce the concentration of multivalent ions contributing to hardness for specific reuse applications
Reverse osmosis	
Effluent reuse	Used to treat prefiltered effluent (typically with microfiltration) for indirect potable reuse applications such as groundwater injection. Credit is also given for disinfection when using reverse osmosis
Effluent dispersal	Reverse osmosis processes have proven capable of removing sizable amounts of selected compounds such as NDMA.
Two-stage treatment for boiler use	Two-stages of reverse osmosis are used to produce water suitable for high pressure boilers.

[a] Adapted in part from Stephenson et al. (2000).

for membrane softening. The advantages of nanofiltration over lime softening include the production of a product water that meets the most stringent reuse water quality requirements. Because both inorganic and organic constituents and bacteria and viruses are removed, disinfection requirements are minimized. Typical operating and performance data are presented in Tables 11–30 and 11–33, respectively. Performance variability data are presented in Table 11–32.

Reverse Osmosis. Worldwide, reverse osmosis (RO) is used primarily for desalination (Voutchkov, 2013). In wastewater treatment, RO is used for the removal of dissolved constituents from wastewater, remaining after advanced treatment with depth filtration or

[a] Specific removal rates will depend on the composition and constituent concentrations in the treated wastewater.

[b] Variable performance, depending on the membrane nominal pore size and operating conditions.

microfiltration. The membranes exclude ions, but require high pressures to produce deionized water. The Orange County Water District flow diagram involving the use of reverse osmosis for the production of potable water for groundwater recharge is shown on Fig. 11–41. Typical operating information for reverse osmosis used for wastewater including operating pressures and flux rate rates is reported in Table 11–30. Corresponding performance data and variability data are presented in Tables 11–34 and 11–32. As noted above, care should be used in applying the performance data reported in Table 11–34 as it has been found that the performance of RO is also site specific, especially with respect to fouling (see Table 11–25). Important process design considerations for NF and RO membranes are reported in Table 11–35.

Depending on the level of dissolved solids removal, the product water from NF and RO processes may be corrosive to equipment and piping. Typical postreatments will involve the addition of chemical to adjust the stability of the treated water, in some reuse applications, the removal or addition of gases (see Fig. 11–41), and the addition of chemicals to meet disinfection requirements and to control the growth of microorganisms in pipelines. The types and use of chemicals to stabilize NF and RO product water are considered in Chap. 6. In some cases, blending with other waters, especially in potable reuse applications, may be appropriate.

Membrane Energy Consumption. Typical product recovery and energy consumption values for various membrane systems are presented in Table 11–30 for the processing of wastewater. Corresponding data for seawater desalination are also given for the

Table 11–30

Typical operating characteristics of membrane technologies used in wastewater treatment applications and for desalination[a]

		Operating pressure[c]		Rate of flux		Energy consumption[c]	
Membrane technology	**Product recovery[b], %**	**lb/in.^{2}**	**kPa**	**gal/ft^2·d**	**L/m^2·h**	**kWh/10^3 gal**	**kWh/m^3**
Wastewater with TDS from 800 to 1200 mg/L							
Microfiltration (vacuum type)	85–95	−3–−14	−28–−100	15–25	25–42	0.75–1.1	0.2–0.3
Microfiltration (pressure type)	85–95	5–30	34–200	24–35	40–60	0.75–1.1	0.2–0.3
Ultrafiltration	85–95	10–35	68–350	24–35	40–60	0.75–1.1	0.2–0.3
Nanofiltration	85–90	100–200	700–1400	8–12	14–20	1.5–1.9	0.4–0.5
Reverse osmosis (without energy recovery)	80–85	125–230	800–1900	8–12	14–20	1.9–2.5	0.5–0.65
Reverse osmosis (with energy recovery)[d]	80–85	125–230	800–1900	8–12	14–20	1.7–2.3	0.46–0.6
Electrodialysis	75–95			20–25	33–42	4.2–8.4	1.1–2.2
Seawater with TDS of about 35,000 mg/L							
Ultrafiltration (pretreatment)	85–95	10–35	68–350	24–47	40–80	0.75–1.1	0.2–0.3
Reverse osmosis (without energy recovery)[e]	30–55	700–1000	4800–6900	8–12	14–20	34–45	9–12
Reverse osmosis (with turbine/pump energy recovery)	30–55	700–1000	4800–6900	8–12	14–20	19–26	5–7
Reverse osmosis (with pressure exchange energy recovery)	30–55	700–1000	4800–6900	8–12[f]	14–20	9.5–15	~2.5–4

[a] Adapted in part from Patel (2013), Voutchkov (2013), Wetterau (2013).

[b] Cross-flow mode [see Fig, 11–33(a)]. In dead end mode [see Fig, 11–33(c)] all of the water passes through the membrane.

[c] The operating pressure and energy consumption will vary with the influent water quality and temperature of the feed water.

[d] Overall total energy reduction will vary from 6 to 12 percent, depending on the energy recovery device (ERD) and process configuration.

[e] At 50 percent recovery, the minimum theoretical energy required is 1.06 kWh/m^3; the corresponding practical limit is about 1.56 kWh/m^3 (Elimelech and Phillip, 2007).

[f] Flux rate with open intake is in the range from 12–17 L/m^2·h (7–10 gal/ft^2·d).

Note:
kPa × 0.1450 = lb$_f$/in.^{2}
L/m^2·h × 0.5890 = gal/ft^2·d
kWh/m^3 × 3.785 = kWh/10^3 gal
Bar = 100 kPa.

Table 11–31

Expected performance of microfiltration and ultrafiltration membranes on secondary effluent

		Value	
Constituent	**Rejection**	**Microfiltration**	**Ultrafiltration**
TOC	%	45–65	50–75

TDS	%	0–2	0–2
NH_3-N	%	5–15	5–15
NO_3-N	%	0–2	0–2
PO_4^-	%	0–2	0–2
SO_4^{2-}	%	0–1	0–1
Cl^-	%	0–1	0–1
Total coliform[a]	log	2–5	3–6
Fecal coliform[a]	log	2–5	3–6
Protozoa[a]	log	2–5	>6
Viruses[a]	log	0–2	2–7[b]

[a] The reported values reflect observed practice and integrity concerns (see Example 8–4 in Chap. 8) and also a wide range of performance differences between membranes, as given in following footnote.

[b] The low and corresponding mean removal values for four different UF membranes treating the same water were 2.5, 4.0, 5.3, and 6.1 and 3.8, 5.0, 6.5, and 7.5, respectively (Sakaji, R. H., 2006).

purpose of comparison. The impact of water quality on energy consumption can be seen by comparing the energy requirement for wastewater with TDS ~1000 mg/L (~0.6 kWh/m^3) versus seawater with TDS ~35,000 mg/L (~10.5 kWh/m^3, without energy recovery). The importance of energy recovery, as discussed below, especially in seawater desalination, is also clearly evident.

In reviewing the information presented in Table 11–30, it is important to note that the reported operating pressure values for all of the membrane processes are considerably lower than comparable values of ten years ago. It is anticipated that operating pressures will continue to go down as new membranes and operating techniques are developed, but at a considerably lower rate as compared to the last ten years. At the present time, where the use of membranes is being considered, special attention must be devoted to the characteristics of the wastewater to be processed.

Energy Recovery from Nanofiltration and Reverse Osmosis. Because NF and RO in particular produce a high-pressure retentate flowrate , especially in seawater desalination, various methods have been developed or are under development to recover the energy lost in depressurizing the retentate flowrate. Energy recovery devices (ERDs) are designed to recover energy from the retentate flowrate and transfer it to the feed water to reduce the overall process energy (see Fig. 11–42 on page 1213). Typical devices that have been used operate on the following principles.

- Reverse running pumps
- Pelton wheel turbines

Table 11–32

Typical effluent quality variability observed with processes used for the removal of from dissolved constituents from reclaimed wastewater

Particulate removal process	Unit	Range of effluent values[a]	Geometric standard deviation, s_g[b]	
			Range	Typical
Microfiltration				
Turbidity	NTU	0.1–0.4	1.1–1.4	1.3
TSS	mg/L	0–1	1.3–1.9	1.5
Ultrafiltration				
Turbidity	NTU	0.1–0.4	1.1–1.4	1.3
TSS	mg/L	0–1	1.3–1.9	1.5
Nanofiltration				
TDS	mg/L	50–100	1.3–1.5	1.4
TOC	mg/L	1–5	1.2–1.4	1.5
Turbidity	NTU	0.01–0.1	1.5–2.0	1.75
Reverse osmosis[c]				
TDS	mg/L	25–50	1.3–1.8	1.6
TOC	mg/L	0.1–1	1.2–2.0	1.8
Turbidity	NTU	0.01–0.1	1.2–2.2	1.8
Electrodialysis				
TDS	mg/L	na	1.2–1.75	1.5

[a] Typical effluent values are not given for the processes because they will vary widely and depend on the operating conditions and water quality requirements.

[b] s_g = geometric standard deviation; $s_g = P_{84.1}/P_{50}$.

[c] Because measured effluent values are typically near the constituent detection limits, the error in the detection method can contribute to the observed effluent variability.

- Hydraulic turbocharger
- Isobaric energy recovery – piston type
- Isobaric energy recovery – rotary type
- Pressure amplifying pump

Pumps, Turbines, and Hydraulic Turbochargers. The reverse running pumps (i.e., Francis turbines), Pelton wheel turbines, and hydraulic turbochargers are adaptations of well know hydraulic machinery applied for the recovery of energy from NF and RO installations. Functionally, as shown on Fig. 11–42(a), the Pelton wheel turbine shaft is coupled to the motor used to drive the pump that pressurizes the feed water. The operation of the hydraulic turbocharger is similar to the Pelton turbine, with the exception that a pump impeller is mounted on the same shaft as the turbine, and a motor is not used.

Isobaric Devices. Isobaric energy recovery devices (also known as flow work exchangers) [see Fig. 11–42(b)] utilize the principles of positive displacement and isobaric

Table 11–33

Typical rejection rates for NF and "loose" RO membranes used to treat wastewater

chambers to transfer energy from a high pressure stream (the brine stream in the case of NF and RO) to a low pressure incoming feed water (Stover, 2007). The dual work exchange energy recovery (DWEER)® is an alternating piston driven device with two isobaric chambers. The PX® technology combines an isobaric positive displacement device with a centrifugal ERD; the transfer of energy is accomplished without the use of a piston. Isobaric ERDs, because of their ease of operation and flexibility, are used extensively throughout the world in desalination installations and are replacing and/or reducing the use of centrifugal type ERDs.

Performance of Energy Recovery Devices. Because of the relatively low feed water pressures used in the RO treatment of wastewater, energy recovery efficiency is relatively low. Typical recoveries for Pelton wheels and isobaric devices vary from 25 to 45 and 45 to 65 percent, respectively. The overall process energy reduction is about 6 to 12 percent, depending on the device and process configuration. By comparison, in seawater desalination, recovery efficiencies as high as 95 percent have been achieved, depending on the ERD (Voutchkov, 2013). The overall total energy reductions that can be achieved in seawater desalination will vary from 30 to 75 percent. On a relatively small scale, the Clark® pressure amplifying pump employs two opposing cylinders and pistons on a single rod to pressurize the feed water in conjunction with a small feed pump.

Forward Osmosis: An Emerging Membrane Technology

The membrane processes discussed in this section are based on reversing the natural osmosis process through the addition of a driving force greater than the osmotic pressure to produce purified water. Although not used commonly for water purification, a number of alternative processes based on the utilization of the osmotic pressure are under development. Processes that utilize the natural osmotic pressure [see Fig. 11–43(a)] are termed forward osmosis (FO) or direct osmosis (DO). In the FO process, illustrated on Fig. 11–43(b), water from the feed solution permeates through the membrane to dilute a more concentrated solution, known by a variety of names including draw solution, osmotic agent, and driving agent. The draw solution is the name used most commonly for this solution.

The principal requirement for the draw solution is that its osmotic pressure must be greater than that of the feed solution. Another requirement for the draw solution is that it must be easy to reconcentrate after being diluted by the water from the feed solution. A solution of sodium chloride (NaCl) has been used as the draw solution because it can be reconstituted easily by reverse osmosis without the problems associated with scaling. A draw solution comprised of multivalent ions has been used where high rejection is required. Based on the results of preliminary testing, advantages of the FO process include minimal pressure requirements and high rejection for a variety of constituents. The FO process may also result in less membrane clogging, but more research is needed to define the controlling conditions that will minimize clogging.

Table 11–35

Process design considerations for NF and RO[a]

Design consideration	Discussion
Feed water characterization	Complete characterization of the feed water is essential for identifying constituents that produce a high potential for membrane fouling. The effect of residual suspended solids in the influent to the membranes especially should be evaluated
Pretreatment	Pretreatment must be evaluated to extend membrane life, and issues such as flow equalization, pH control, chemical treatment, and residual solids removal should be considered
Flux rate	Flux rate influences system costs by establishing the filter area, affecting polarization control, and affecting membrane life
Recovery	Recovery rate affects solute rejection, membrane performance, and brine generation volumes
Membrane fouling	Parameters should be developed based on pilot plant testing. Acid, antiscalants, and biocides are used to control membrane fouling, as are staging and operational conditions
Membrane cleaning	Cleaning procedures and frequency need to be established
Membrane life	The principal economic consideration that governs successful application of membrane technology
Operating and maintenance costs	High pressure systems require significant energy costs, high capital costs for high pressure pumps, and high maintenance costs associated with equipment wear. After membrane replacement, energy is the next major operating expense
Recycle flows	Provisions for recycling a portion of the product water should be included as an operating consideration to control membrane velocity, influent concentration, and equalizing influent flow variations
Retentate and backwash disposal	Retentate and backwash characteristics need to be considered especially, if chemicals are used in pretreatment or membrane cleaning and large volumes of waste require disposal

[a] Adapted in part from Celenza (2000).

For example, potential applications in the wastewater management field include concentration of dilute industrial wastewater, concentration of RO brines, concentration of digester supernatant, and the concentration of the return flows from sludge thickening processes. By reducing the volume of RO brines that must be processed,

technologies such as evaporation and crystallization become technically and economically feasible. An excellent review article has been prepared by Cath and his associates (Cath et al., 2006).

Pilot-Plant Studies for Membrane Applications

Because every wastewater is unique with respect to its constituent characteristics, it is difficult to predict *a priori* how a given membrane process will perform. As a result, the selection of the best membrane for a given application is based usually on the results of pilot studies. Membrane fouling indexes (see Table 11–26) can be used to assess the need for pretreatment. In some situations, manufacturers of membranes will provide a testing service to identify the most appropriate membrane for a specific feed water. Typical pilot scale facilities used to evaluate the performance of NF and RO treatment processes are shown on Fig. 11–44.

The elements that comprise a pilot plant include (1) the pretreatment system; (2) tankage for flow equalization and cleaning; (3) pumps for pressurizing the membrane, recirculation, and backflushing with appropriate controls; (4) the membrane test module; (5) facilities for monitoring the performance of the test module; and an appropriate membrane backflushing system. Typical membrane operating parameters and water quality

measurements are presented in Table 11–36. Additional specific parameters selected for evaluation will depend on the final use of the product water.

Management of Retentate

Management of the retentate produced by membrane processes represents the major problem that must be dealt with in their applications. Methods that can be used for the treatment and disposal of the retentate are reported in Table 11–37. While small facilities can dispose of small quantities of retentate by blending with other wastewater flows, this approach is not suitable for large facilities. The retentate from NF and RO facilities will contain hardness, heavy metals, high molecular weight organics, microorganisms, and often hydrogen sulfide gas. The pH is usually high due to the concentration of alkalinity, which increases the likelihood of metal precipitation in disposal wells. As a result, most of the large-scale desalination facilities are located along coastal regions, both in the United States and in other parts of the world. For inland locations, long transmission lines to coastal regions are being considered. While controlled evaporation is technically feasible, because of high operating and maintenance costs, this approach is used where no other alternatives are available and the value of product water is high. The quality and quantity of the concentrated retentate produced from nanofiltration, reverse osmosis and electrodialysis can be estimated using simplified recovery and rejection computations as illustrated in Example 11–8.

Table 11–37

Treatment methods and disposal options for concentrated brine solutions from membrane processes

Disposal option	Description
Treatment options	
Concentration by using multistage membrane arrays	Concentration of brine stream
Falling film evaporators	Thicken and concentrate brine streams
Crystallizers	Concentration of brine stream into a crystalized form for processing or disposal
Forward osmosis	Concentration of brine stream
Membrane distillation	Concentration of brine stream
Solar evaporators	Thicken and concentrate brine streams
Spray dryers	Concentration of brine stream
Vapor compression evaporators	Concentration of brine stream
Disposal options	
Deep well injection	Depends on whether subsurface aquifer is brackish water or is otherwise unsuitable for domestic uses.
Discharge to wastewater collection system	This option is only suitable for very small discharges such that the increase in TDS is not significant (e.g., less than 20 mg/L).
Evaporation ponds	Large surface area required in most areas with the exception of some southern and western states.
Land application	Land application has been used for some low concentration brine solutions.
Ocean discharge	The disposal option of choice for facilities located in the coastal regions of the United States. Typically, a brine line, with a deep ocean discharge, is used by a number of dischargers. Combined discharge with power plant cooling water has been used in Florida. For inland locations, truck, rail hauling or pipeline is needed for transportation.
Surface water discharge	Discharge of brines to surface waters is the most common method of disposal for concentrated brine solutions.

EXAMPLE 11–8 **Estimate Quantity and Quality of Waste Streams from a Reverse Osmosis Facility** Estimate quantity and quality of the retentate and the total quantity of water that must be processed, from a reverse osmosis facility that is to produce 4000 m^3/d of water to be used for industrial cooling operations. Assume that both the recovery and rejection rates are equal to 90 percent and that the TDS concentration of the feed steam is 400 mg/L.

Solution

1. Determine the flowrate of the concentrated retentate and the total amount of water that must be processed.
   a. Combining Eqs. (11–36) and (11–40) results in the following expression for the retentate flowrate.

$$Q_r = \frac{Q_p(1 - r)}{r}$$

b. Determine the retentate flowrate.

$$Q_r = \frac{(4000\ \text{m}^3/\text{d})(1 - 0.9)}{0.9} = 444\ \text{m}^3/\text{d}$$

c. Determine the total amount of water that must be processed to produce 4000 m^3/d of RO water. Using Eq. (11–43) the required amount of water is

$$Q_f = Q_p + Q_r = 4000\ \text{m}^3/\text{d} + 444\ \text{m}^3/\text{d} = 4444\ \text{m}^3/\text{d}$$

2. Determine the concentration of the permeate. The permeate concentration is obtained by writing Eq. (11–41) in decimal form as follows:

$$C_p = C_f(1 - R) = 400\ \text{mg/L}\ (1 - 0.9) = 40\ \text{mg/L}$$

3. Determine the concentration of the retentate. The required value is obtained by solving Eq. (11–44).

$$C_r = \frac{Q_f\,C_f - Q_p\,C_p}{Q_r}$$

$$C_r = \frac{(4444\ \text{m}^3/\text{d})(400\ \text{mg/L})C_f - (4000\ \text{m}^3/\text{d})(40\ \text{mg/L})}{(444\ \text{m}^3/\text{d})}$$

$$C_r = 3643\ \text{mg/L}$$

Comment A variety of concentration methods are currently under investigation to reduce the volume of the retentate that must be treated.

11–8 ELECTRODIALYSIS

Electrodialysis (ED) is an electrochemical separation process in which mineral salts and other ionic species are transported through ion-selective membranes from one solution to another under the driving force of a direct current (DC) electric potential. As compared to NF and RO, which transport pure water through the membrane leaving the salts behind, with ED salt is gradually stripped from solution leaving a dilute solution behind containing particulate matter and neutral species not removed by the ED process. The salt transferred through the membrane then forms the concentrate. A typical flow diagram employing electrodialysis for the control of dissolved solids is shown on Fig. 11–45.

Description of the Electrodialysis Process

The key to the ED process is the ion selective membranes that are essentially ion exchange resins cast in sheet form. Ion exchange membranes that allow passage of positively charged ions such as sodium and potassium are called cation membranes. Membranes that allow passage of negatively charged ions such as chloride and phosphate are called anion membranes. To demineralize a solution using ED, cation and anion membranes are arranged alternately between plastic spacers in a stacked configuration with a positive electrode (anode) at one end and a negative electrode (cathode) at the other (see Fig. 11–46). When a DC voltage is applied, the electrical potential created becomes the driving force to move ions, with the membranes forming barriers to the ions of opposite charge. Therefore, anions attempting to migrate to the anode will pass through the adjacent anion membrane but will be stopped by the first cation membrane they encounter. Cations trying to

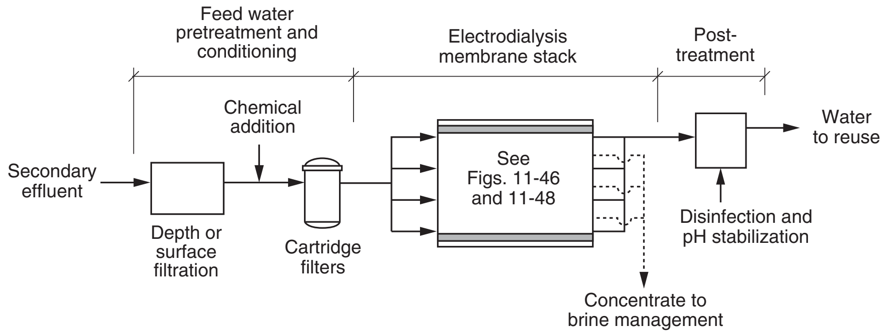

Figure 11–45

Typical process flow diagram employing electrodialysis for the removal of total dissolved solids (TDS) from secondary effluent.

migrate to the cathode will pass through the cation membrane but will be stopped by the anion membrane. The membranes, therefore, form ion diluting compartments and ion concentrating compartments (www.gewater.com).

An ED assembly, known as a *stack*, consists of multiple cell pairs located between an anode and a cathode. A set of adjacent components consisting of a diluting compartment spacer, an anion membrane, a concentrating compartment spacer, and a cation membrane is called a *cell pair*. Electrolysis stacks can contain as many as 600 cell pairs. Feed water (filtered wastewater) is pumped through the stack assembly. Typical flux rates are from 35 to 45 $L/m^2 \cdot h$. Dissolved solids removals vary with the (1) wastewater temperature, (2) amounts of electric current passed, (3) type and amount of ions, (4) permeability/selectivity of the membrane, (5) fouling and scaling potential of the feed water, (6) feed water flowrates, and (7) number and configuration of stages.

Electrodialysis Reversal

In the early 1970s, the electrodialysis reversal (EDR) process was introduced. An EDR unit operates on the same principle as ED technology, except that both the product and concentrate channels are identical in construction (see Fig. 11–47). The same membranes are used to provide a continuous self-cleaning ED process that uses periodic reversal of the DC polarity to allow systems to run at high recovery rates. Polarity reversal causes the concentrating

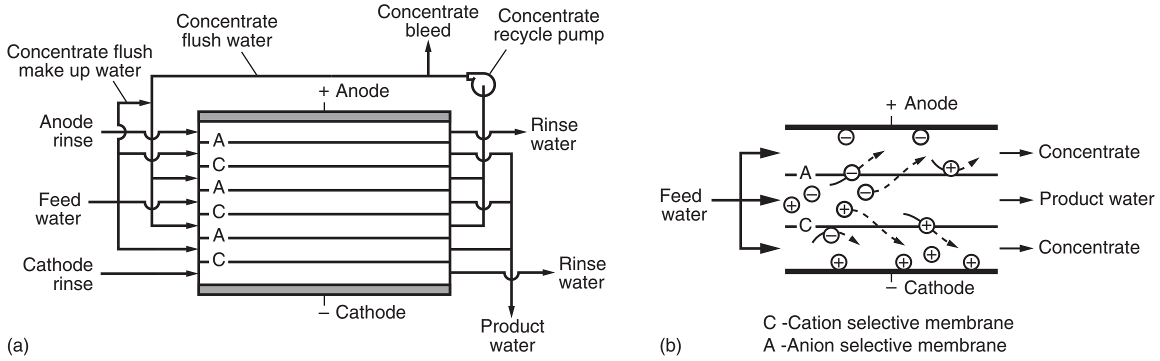

Figure 11–46

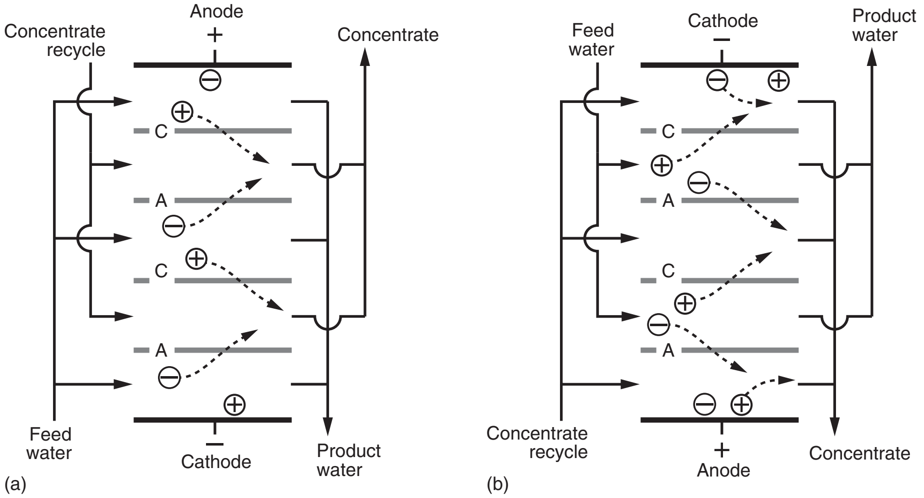
Conventional electrodialysis: (a) schematic of electrodialysis membrane stack with anode and cathode rinse and (b) schematic illustration of ion migration within the membrane stack. Note: The conventional electrodialysis process has been largely replaced the electrodialysis reversal (EDR) process (see Fig 11–47).

Figure 11–47

Schematic of electrodialysis reversal (EDR) process: (a) negative polarity and (b) positive polarity. Because the polarity is reversed, the anode and cathode rinse shown on Fig. 11–46 is not needed.



and diluting flow to switch after every cycle. Any fouling or scaling constituents are removed when the process reverses, sending fresh product water through the compartments filled previously with concentrated waste. The reversal process is useful in breaking up and flushing out scales, slimes, and other deposits in the cells before they buildup. Product water is not collected during a short interval of time following reversal.

EDR systems are able to reduce dissolved ions in feed water containing 10,000 to 12,000 mg/L of total dissolved solids, but because of energy requirements are ideally suited for the treatment of brackish water in the range from 800 to 5000 mg/L. As a rule of thumb, it takes about 1 to 1.2 kWh/m^3 to remove a kilogram of salt (see Table 11–38). Typical removal rates can range from 50 to 94 percent removal (www.gewater.com). A view of an EDR installation and an exposed membrane stack are shown on Fig. 11–48. The EDR facility shown on Fig. 11–48 is used to remove TDS from a portion (sidestream) of the reclaimed water produced at the North City plant in San Diego, CA. The treated water with a reduced TDS concentration is blended back into the main flow which has a TDS concentration that varies from 1200 to 1300 mg/L to produce a final reclaimed water with a TDS equal to or less than 1000 mg/L to meet contractual agreements with the users of the reclaimed water.

Table 11–38

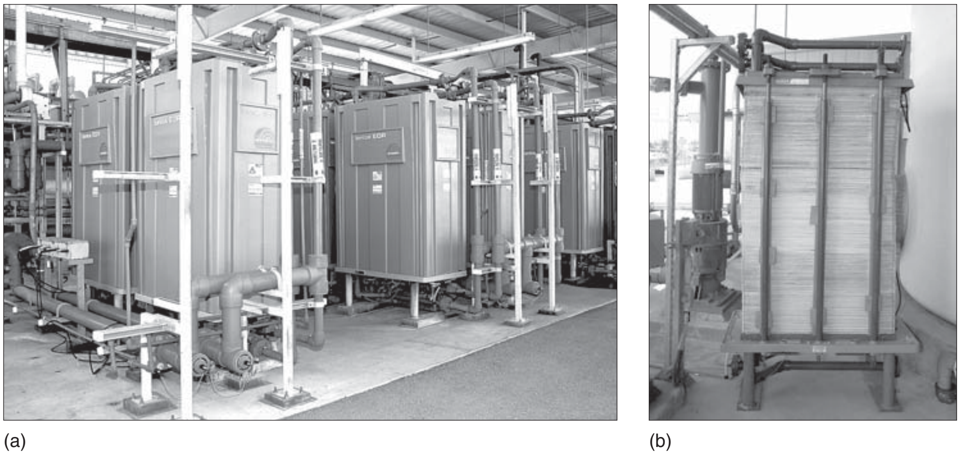
Typical operating parameters for electrodialysis units

Parameter	Unit	Range
Flux rate	m^3/m^2·d	0.8–1.0
Water recovery	%	75–90
Concentrate flowrate	% of feed	12–20
TDS removal	%	50–94
CD/N (current density to normality) ratio	(mA/cm^2)/(g-eq/L)	500–800
Membrane resistance, Ω	ohms	4–8
Current efficiency	%	85–95
Energy consumption[a]	kWh/m^3	1.5–2.6
Approximate energy per kg of salt removed	kWh/m^3·kg	1–1.2

[a] Based on treating reclaimed water with a TDS concentration in the range from 1000 to 2500 mg/L. Not recommended for TDS concentration values beyond 10,000 to 12,000 mg/L.

Figure 11–48

Electrodialysis reversal process used to remove TDS from reclaimed water at the North City plant in San Diego, CA: (a) view of full scale electrodialysis facility and (b) view of electrodialysis membrane stack with cover removed.



Power Consumption

The ED/EDR process uses electric power to transfer ions through the membranes and to pump water through the system. Two, or sometimes three, pumping stages are used typically.

Power Requirements for Ion Transfer. The current required for ED can be estimated using Faraday's laws of electrolysis. Because one Faraday of electricity will cause one gram equivalent of a substance to migrate from one electrode to another, the number of gram equivalents removed per unit time is given by:

$$\text{Gram-eq/unit time} = Q_p(N_{\text{inf}} - N_{\text{eff}}) = Q_p\Delta N = Q_pN_{\text{inf}}E_r \tag{11–48}$$

$$\text{where gram/eq} = \frac{\text{Mass of solute, g}}{\text{Equivalent weight of solute, g}}$$

Q_p = product water flowrate, L/s
N_{inf} = normality of influent (feed), g-eq/L
N_{eff} = normality of effluent (product), g-eq/L
ΔN = change in normality between the influent and effluent, g-eq/L
E_r = efficiency of salt removal, % (expressed as a decimal)

The corresponding expression for the current for a stack of membranes is given by:

$$i = \frac{FQ_p(N_{\text{inf}} - N_{\text{eff}})}{nE_c} = \frac{FQ_pN_{\text{inf}}E_r}{nE_c} \tag{11–49}$$

where i = current, A, ampere
F = Faraday's constant, 96,485 A·s/g-eq
n = number of cell pairs in the stack
E_c = current efficiency, % (expressed as a decimal)

In the analysis of the ED process, it has been found that the capacity of the membrane to pass an electrical current is related to the current density (CD) and the normality (N) of the feed solution. Current density is defined as the current in milliamperes that flows through a square centimeter of membrane perpendicular to the current direction. Normality corresponds to the concentration of a solution based on the number of gram equivalent weights of a solute per liter of solution. A solution containing one gram of equivalent weight per liter is referred to as *one normal* (1 N). The relationship between current density and the solution normality is known as the *current density to normality* (CD/N) ratio.

High values of the CD/N ratio are indicative that there is insufficient charge to carry the current. When high ratios exist, a localized deficiency of ions may occur on the surface of the membrane, causing a condition called *polarization*. Polarization should be avoided as it results in high electrical resistance leading to excessive power consumption. In practice, CD/N ratios will vary from 500 to 800 when the current density is expressed as mA/cm^2. The resistance of an ED unit used to treat a particular water must be determined experimentally. Once the resistance, R, and the current flow, i, are known, the power required can be computed using Ohm's law as follows:

$$P = E \times i = R(i)^2 \qquad (11\text{–}50)$$

where P = power, W
E = voltage, V
$= R \times i$
R = resistance, Ω
i = current, A

The application of the above relationships is considered in Example 11–9.

EXAMPLE 11–9 **Determine Power Requirements and Membrane Area for ED Treatment of Reclaimed Water** Determine the power and area required to reduce the TDS content of 4000 m^3/d of treated wastewater to be used for industrial cooling water. Assume the following data apply.

1. Number of cell pairs in stack = 500
2. Influent TDS concentration = 2500 mg/L (~ 0.05 g-eq/L)
3. TDS removal efficiency, E_r = 50%
4. Product water flowrate = 90% of feed water
5. Current efficiency, E_c = 90%
6. CD/N ratio = (500 mA/cm^2)/(g-eq/L)
7. Resistance = 5.0 Ω

Solution

1. Calculate the current using Eq. (11–49).

$$i = \frac{FQ_pN_{\text{inf}}E_r}{nE_c}$$

$$Q_p = (4000\text{ m}^3/\text{d})(10^3\text{ L}/1\text{ m}^3)/(86{,}400\text{ s/d}) = 46.3\text{ L/s}$$

$$i = \frac{(96{,}485\text{ A}\cdot\text{s/g-eq})(46.3\text{ L/s})(0.05\text{ g-eq/L})(0.5)}{(500)(0.90)}$$

$$i = 248\text{ A}$$

2. Determine the power required using Eq. (11–50).

$$P = R(i)^2$$
$$P = (5.0\ \Omega)(248\text{ A})^2 = 307{,}520\text{ W} = 308\text{ kW}$$

3. Determine the power requirement per m^3 of treated water.

$$\text{Power consumption} = \frac{(308\text{ kW})(24\text{ h/d})}{(4000\text{ m}^3/\text{d})(0.9)} = 2.05\text{ kWh/m}^3$$

4. Determine the required surface area per cell pair. The area is given by

$$A = \frac{i\text{, current}}{CD\text{, current density}}$$

a. Determine the current density from the CN/N ratio:

$CD = [(500\ \text{mA/cm}^2)/(\text{g-eq/L})](0.05\ \text{g-eq/L}) = 25\ \text{mA/cm}^2$

b. The required area is:

$$\text{Area} = \frac{i}{CD} = \frac{(248\ \text{A})(1000\ \text{mA/A})}{(25\ \text{mA/cm}^2)} = 9920\ \text{cm}^2 = 0.99\ \text{m}^2$$

Comment The actual performance will have to be determined from pilot tests. The computed value for the power required per unit volume, 2.05 kWh/m^3, is within the range of values reported in Table 11–38 (1.1 to 2.6 kWh/m^3) for water with 1000 to 2500 mg/L TDS.

Power Requirements for Pumping. For pumping, the power requirements depend on the concentrate recirculation rate, the need for both product and waste pumping for discharge, and the efficiency of the pumping equipment (USBR, 2003).

Operating Considerations

The ED process may be operated in either a continuous or a batch mode. The units can be arranged either in parallel to provide the necessary hydraulic capacity or in series to obtain the desired degree of demineralization. A typical three-stage, two-line ED flow diagram is shown on Fig. 11–49. The ED process should be protected from particulate fouling by a 10 micron cartridge filter [see Table 11–21(g) and Fig. 11–45].

A single electrodialysis stack can remove from 25 to 60 percent of the TDS, depending on the feed water characteristics. Further desalting requires that two or more stacks be used in series (USBR, 2003). A portion of the resulting concentrate is recycled to improve system performance. Makeup water, usually about 10 percent of the feed volume, is required to wash the membranes continuously. A portion of the concentrate flowrate is recycled to maintain nearly equal flowrates and pressures on both sides of each membrane. Typical operating parameters for the electrodialysis process are reported in Table 11–38.

Operating Issues. Problems associated with the ED process for wastewater treatment include chemical precipitation of salts with low solubility on the membrane surface and clogging of the membrane by the residual colloidal organic matter in wastewater treatment plant effluents. To reduce membrane fouling, some form of filtration may be necessary. With a properly designed plant, membrane cleaning should be infrequent. However, for both ED and EDR systems, clean-in-place (CIP) systems are provided normally to

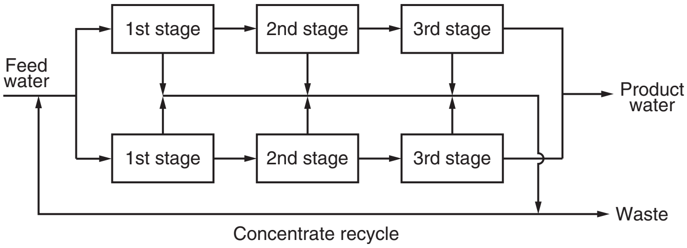


Figure 11–49

Schematic diagram for a three-stage, two-line electrodialysis process.

circulate either hydrochloric acid solution for mineral scale resolution or sodium chloride solution with pH adjustment for organics removal (USBR, 2003).

Membrane and Electrode Life. Membranes for ED and EDR applications have a life of about 10 years before they are replaced. Effective and timely cleaning-in place extends the membrane life and improves product quality and power consumption. Cation membranes typically last longer than anion membranes because anion membranes are particularly susceptible to oxidation by chlorine and other strong oxidants (USBR, 2003). With the development of the EDR process and new electrode design, the life of anode and cathode electrodes is typically 2 to 3 years. Anode life is typically less than cathode life. Electrodes can be reconditioned (USBR, 2003).

Electrodialysis Versus Reverse Osmosis

In a recently completed study, two advanced treatment processes were compared to reduce the salinity of reclaimed water from a TDS concentration of 750 ± 50 mg/L to 500 mg/L or less (Adham et al., 2004). The two advanced treatment processes evaluated were (1) MF followed by RO and (2) EDR. The study was conducted for a period of about six months. Based on the results of the side-by-side testing, it was found that the EDR process with cartridge prefiltration was more cost effective than the combined MF/RO process. Some of the advantages and disadvantages cited for each advanced treatment process are reported in Table 11–39. As more of the potential applications of EDR are currently under investigation, the current literature should be consulted.

Table 11–39

Comparison of advantages and disadvantages of electrodialysis and reverse osmosis for desalination[a]

Advantages	Disadvantages
Electrodialysis (EDR)	
• Minimal pretreatment may be required (cartridge filtration is recommended) • Operates at a low pressure • Process is much quieter because high pressure pumps are not required • Antiscalant is not required • Membrane life expectancy is longer because foulants are removed continuously during the reversal process • Requires less maintenance than RO due to reversal process	• Limited to 50 percent salt rejection for a single membrane stack (stage) • Requires larger footprint to produce similar quantity and quality of water if multiple staging is used • Electrical safety requirements • Less experience for wastewater demineralization in the U.S. • Not as effective at removing microorganisms and many anthropogenic organic contaminants
Reverse osmosis	
• RO membranes provide a barrier to microorganisms and many anthropogenic organic contaminants (for the treated portion of the water produced) • More demonstrated experience for wastewater demineralization • RO membranes can remove more than 90 percent of TDS • Source water blending will reduce size of systems • Flexibility to provide higher quality water, if desired	• Requires high pressure to achieve high salt rejection • Requires pretreatment processes to minimize scaling and fouling • Requires chemical addition for MF & RO fouling control • More routine maintenance may be required to maintain performance

[a] Adapted from Adham et al. (2004).

11–9 ADSORPTION

In wastewater treatment adsorption is used for the removal of substances that are in solution by accumulation of those substances on a solid phase. Adsorption is considered to be a mass transfer operation as a constituent is transferred from a liquid phase to a solid phase (see Table 11–2). The *adsorbate* is the substance that is being removed from the liquid phase at the interface. The *adsorbent* is the solid, liquid, or gas phase onto which the adsorbate accumulates. Although adsorption is used at the air-liquid interface in the flotation process (see Sec. 5–8), only the case of adsorption at the liquid-solid interface is considered in this section. Activated carbon is the primary adsorbent used in adsorption processes. The basic concepts of adsorption are presented in this section along with elements of design and limitations of the adsorption process.

Applications for Adsorption

Adsorption treatment of wastewater is usually thought of as a polishing process for water that has already received normal biological treatment. Adsorption has been used for the removal of refractory organic constituents; residual inorganic constituents such as nitrogen, sulfides, and heavy metals; and odor compounds from wastewater. Under optimum conditions, it appears that adsorption can be used to reduce the effluent COD to less than 10 mg/L. In water reclamation applications adsorption is used for (1) the continuous removal of organics and (2) as a barrier against the breakthrough of organics from other unit processes. In some cases, adsorption is used for the control of precursors that may form toxic compounds during disinfection.

Representative compounds that are readily and poorly adsorbed onto activated carbon are listed in Table 11–40. As shown in Table 11–40, activated carbon is known to have a low adsorption affinity for low molecular weight polar organic compounds. If biological activity is low in the carbon contactor or in other biological unit processes, low molecular weight polar organic compounds may be difficult to remove with activated carbon.

Types of Adsorbents

Treatment with adsorbent materials involves either (1) passing a liquid to be treated through a bed of adsorbent material held in a reactor/contactor (either fixed or fluidized) or (2) blending the adsorbent material into a unit process followed by sedimentation or filtration for removal of the spent adsorbent. The principal types of adsorbents include activated carbon, granular ferric hydroxide (GFH), and activated alumina. Carbon-based adsorbents are used most commonly for wastewater adsorption because of their relatively low cost. Other adsorbents that may prove to be effective with further research include manganese greensand, manganese dioxide, hydrous iron oxide particles, and iron oxide coated sand. Regardless of the adsorbent selected for a particular application, pilot testing will be necessary for determination of process performance and design parameters. The characteristics of materials used for adsorption are summarized in Table 11–41.

Activated Carbon. Activated carbon is derived by subjecting an organic base material, such as wood, coal, almond, coconut, or walnut hulls to a pyrolysis process followed with activation by exposure to oxidizing gases such as steam and CO_2 at high temperatures. The resulting carbon structure is porous, as illustrated on Fig. 11–50, on page 1226, with a large internal surface area. The resulting pore sizes are defined as follows:

Macropores > 500 nm
Mesopores > 20 nm and < 500 nm
Micropores < 20 nm

Table 11–40

Readily and poorly adsorbed organics on activated carbon[a]

Readily adsorbed organics	Poorly adsorbed organics
Aromatic solvents	Low-molecular weight ketones, acids, and aldehydes
Benzene	Sugars and starches
Toluene	Very high molecular weight or colloidal organics
Nitrobenzenes	Low–molecular weight aliphatics
Chlorinated aromatics	
PCBs	
Chlorophenols

Gasoline	
Amines	
Humics	

[a] From Froelich (1978).

The surface properties, pore size distribution, and regeneration characteristics that result are a function of both the initial material used and the preparation procedure, therefore many variations are possible. The two size classifications of activated carbon are granular activated carbon (GAC), which has a diameter greater than 0.1 mm (~140 sieve) and is used in pressure or gravity filtration, and powdered activated carbon (PAC), which typically has a diameter of less than 0.074 mm (200 sieve) and is added directly to the activated sludge process or solids contact processes.

Granular Ferric Hydroxide. Granular ferric hydroxide (GFH) is manufactured from a ferric chloride solution by neutralization and precipitation with sodium hydroxide. The adsorption capacity of GFH depends on water quality parameters, including pH, temperature, and other constituents in the water. Constituents that have been removed using GFH include arsenic, chromium, selenium, copper, and other metals. The process performance is reduced by suspended solids and precipitated iron and manganese, and by

Table 11–41

Comparison of various adsorbent materials[a]

Parameter	Unit	Activated carbon Granular (GAC)	Activated carbon Powdered (PAC)	Activated alumina	Granular ferric hydroxide
Total surface area	m^2/g	700–1300	800–1800	280–380	250–300
Bulk density	kg/m^3	400–500	360–740	600–800	1200–1300
Particle density, wetted in water	kg/L	1.4–1.5	1.3–1.4	3.97	1.59
Particle size range	μm	100–2400	5–50	290–500	150–2000
Effective size	mm	0.6–0.9	na		
Uniformity coefficient	UC	≤ 1.9	na		
Mean pore radius	Â	16–30	20–40		
Iodine number		600–1100	800–1200

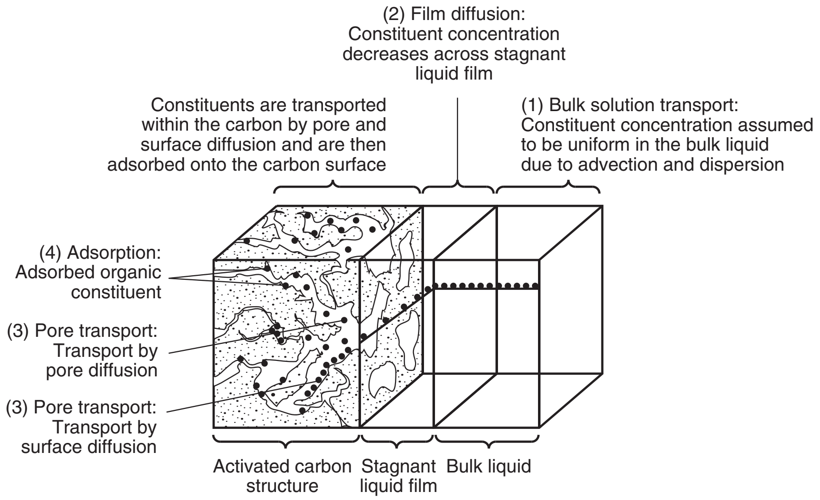
[a] Specific values will depend on the source material used for the production of activated carbon.

constituents that compete for adsorption sites, including organic matter and other ions (e.g., phosphate, silicate, sulfate). While GFH adsorbents can be effective from a performance standpoint for removal of specific constituents (e.g., arsenic), the cost associated with GFH the GFH process is often prohibitive for large systems. The adsorption capacity of GFH media is reduced significantly following regeneration; thus after reaching capacity, GFH adsorbents are typically disposed of in a landfill and replaced with new media. However, because GFH is not regenerated, the costs associated with management of the waste regenerant can be avoided, making the process viable in some situations, especially where the waste regenerant must be handled as a hazardous waste.

Figure 11–50

Definition sketch for the adsorption of an organic constituent onto an activated carbon particle.



Activated Alumina. Activated alumina is derived from a naturally occurring mineral processed from bauxite that has been treated to remove molecules of water from its crystalline structure. Activated alumina is used in drinking water treatment for the removal of arsenic and fluoride (Clifford, 1999) and may have application in water reclamation for specific constituents. Activated alumina can be regenerated with a strong-base followed by a strong-acid. The regeneration of activated alumina and subsequent waste management issues result in significant operation and maintenance costs. As mentioned for GFH, pH (best performance at pH of 5.5 to 6), temperature, and competing constituents will affect the performance of activated alumina adsorption. The use of powdered activated alumina coupled with membranes (microfiltration and ultrafiltration) may also be a promising treatment process.

Fundamentals of Adsorption Processes

The adsorption process, as illustrated on Fig. 11–50, takes place in four, more or less definable steps: (1) bulk solution transport, (2) film diffusion transport, (3) pore and surface transport, and (4) adsorption (or sorption). The adsorption step involves the attachment of the material to be adsorbed to the adsorbent at an available adsorption site (Snoeyink and Summers, 1999). Additional details on the physical and chemical forces involved in the adsorption process may be found in Crittenden et al. (2012). Adsorption can occur on the outer surface of the adsorbent and in the macropores, mesopores, micropores, and submicropores, but the surface area of the macro and mesopores is small compared with the surface area of the micropores and submicropores and the amount of material adsorbed there is usually considered negligible.

Because the adsorption process occurs in a series of steps, the slowest step in the series is identified as the rate-limiting step. When the rate of adsorption equals the rate of desorption, equilibrium has been achieved, and the capacity of the adsorbent has been reached. The theoretical adsorption capacity for a given adsorbent for a particular contaminant can be determined by developing adsorption isotherms, as described below. Because activated carbon is the most common adsorbent used in advanced wastewater treatment applications, the focus of the following discussion is on activated carbon.

Development of Adsorption Isotherms

The quantity of adsorbate that can be taken up by an adsorbent is a function of both the characteristics and concentration of adsorbate and the temperature. The characteristics of the adsorbate that are of importance include: solubility, molecular structure, molecular weight, polarity, and hydrocarbon saturation. Generally, the amount of material adsorbed is determined as a function of the concentration at a constant temperature, and the resulting function is called an adsorption isotherm. Adsorption isotherms are developed by exposing a given amount of absorbate in a fixed volume of liquid to varying amounts of activated carbon. Typically, more than ten containers are used, and the minimum time allowed for the samples to equilibrate where powdered activated carbon is used is seven days. If activated carbon is used, it is usually in the powdered form (as opposed to granular) to minimize adsorption times.

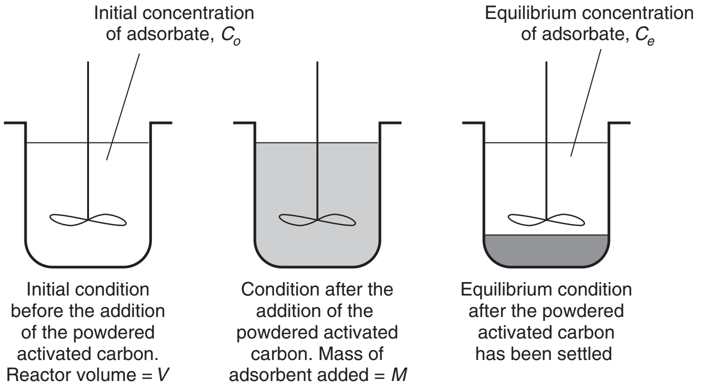
Mass Balance. If a mass balance is performed for a batch reactor into which a quantity of powdered activated carbon has been added (see Fig. 11–51), the resulting expression at equilibrium at the completion of the mass transfer process is given by

1. General word statement:

$$\begin{array}{c}\text{Amount of reactant}\\ \text{adsorbed within the}\\ \text{system boundary}\end{array} = \begin{array}{c}\text{initial amount of}\\ \text{reactant within the}\\ \text{system boundary}\end{array} - \begin{array}{c}\text{final amount of}\\ \text{reactant within the}\\ \text{system boundary}\end{array} \qquad (11\text{–}51)$$

Figure 11–51

Definition sketch for mass balance of carbon adsorption.



2. Simplified word statement:

$$\begin{array}{l}\text{Amount}\\\text{adsorbed}\end{array} = \begin{array}{l}\text{initial amount}\\\text{of adsorbate}\\\text{present}\end{array} - \begin{array}{l}\text{final amount}\\\text{of adsorbate}\\\text{present}\end{array} \tag{11–52}$$

3. Symbolic representation at equilibrium (refer to Fig. 11–51):

$$q_e M = VC_o - VC_e \tag{11–53}$$

where q_e = adsorbent phase concentration after equilibrium, mg adsorbate/g adsorbent
M = mass of adsorbent, g
V = volume of liquid in the reactor, L
C_o = initial solution concentration of adsorbate, mg/L
C_e = final solution equilibrium concentration of adsorbate after adsorption has occurred, mg/L

Equation (11–53) can be written as follows:

$$q_e = -\frac{V}{M}(C_e - C_o) \tag{11–54}$$

The adsorbent phase concentration data computed using Eq. (11–54) are then used to develop adsorption isotherms as described below.

Freundlich Isotherm. Equations used to describe the experimental isotherm data were developed by Freundlich, Langmuir, and Brunauer, Emmet, and Teller (BET isotherm) (Shaw, 1966). Of the three, the Freundlich isotherm is used most commonly to describe the adsorption characteristics of the activated carbon used in water and wastewater treatment. Derived empirically in 1912, the Freundlich isotherm is defined as follows:

$$\frac{x}{m} = K_f C_e^{1/n} \tag{11–55}$$

where x/m = mass of adsorbate adsorbed per unit mass of adsorbent, mg adsorbate/g activated carbon
K_f = Freundlich capacity factor, (mg absorbate/g activated carbon) × (L water/mg adsorbate)$^{1/n}$ = (mg/g)(L/mg)$^{1/n}$
C_e = equilibrium concentration of adsorbate in solution after adsorption, mg/L
$1/n$ = Freundlich intensity parameter

Table 11–42

Freundlich adsorption isotherm constants for selected organic compounds[a,b]

Compound	pH	$K(mg/g)(L/mg)^{1/n}$	1/n
Benzene	5.3	1.0	1.6–2.9
Bromoform	5.3	19.6	0.52
Carbon tetrachloride	5.3	11	0.83
Chlorobenzene	7.4	91	0.99
Chloroethane	5.3	0.59	0.95
Chloroform	5.3	2.6	0.73
DDT	5.3	322	0.50
Dibromochloromethane	5.3	4.8	0.34
Dichlorobromomethane	5.3	7.9	0.61
1, 2–Dichloroethane	5.3	3.6	0.83
Ethylbenzene	7.3	53	0.79
Heptachlor	5.3	1,220	0.95
Hexachloroethane	5.3	96.5	0.38
Methylene chloride	5.3	1.3	1.16
N-Dimethylnitrosamine	na	6.8×10^{-5}	6.60
N-Nitrosodi-n-propylamine	na	24	0.26
N-Nitrosodiphenylamine	3–9	220	0.37
PCB	5.3	14,100	1.03

PCB 1232	5.3	630	0.73
Phenol	3–9	21	0.54
Tetrachloroethylene	5.3	51	0.56
Toluene	5.3	26.1	0.44
1, 1, 1–Trichloroethane	5.3	2–2.48	0.34
Trichloroethylene	5.3	28	0.62

[a] Adapted from Dobbs and Cohen (1980) and LaGrega et al. (2001).

[b] The adsorption isotherm constants reported in this table are meant to be illustrative of the wide range of values that will be encountered for various organic compounds. It is important to note that the characteristics of the activated carbon used as well as the analytical technique used for the analysis of the residual concentrations of the individual compounds will have a significant effect on the coefficient values obtained for specific organic compounds.

The constants in the Freundlich isotherm can be determined by plotting log (x/m) versus log C_e and making use of the linear form of Eq. (11–55) rewritten as

$$\log\left(\frac{x}{m}\right) = \log K_f + \frac{1}{n}\log C_e \tag{11–56}$$

The U.S. EPA (1980) has developed adsorption isotherms for a variety of toxic organic compounds, some of which are presented in Table 11–42. As shown in Table 11–42, the variation in the Freundlich capacity factor for the various compounds is extremely wide (e.g., 14,100 for PCB to 6.8×10^{-5} for N-Dimethylnitrosamine). Because of the wide variation, the Freundlich capacity factor must be determined for each new compound. Application of the Freundlich adsorption isotherm is illustrated in Example 11–10.

EXAMPLE 11–10 **Activated Carbon Required to Treat a Wastewater** As a result of effluent chlorination, the amount of chloroform formed was found to be 0.12 mg/L. How much powdered activated carbon will be required to treat an effluent flowrate of 4000 m^3/d to reduce the chloroform concentration to 0.05 mg/L? The Freundlich adsorption isotherm coefficients for chloroform are: $K_f = 2.6\ (\text{mg/g})(\text{L/mg})^{1/n}$ and $1/n = 0.73$.

Solution

1. Combine Eqs. (11–54) and (11–55) to obtain an expression for V/M as follows:

$$q_e = \frac{V}{M}(C_e - C_o)$$

$$q_e = \frac{x}{m} K_f C_e^{1/n}$$

$$-\frac{V}{M} = \frac{K_f C_e^{1/n}}{(C_e - C_o)}$$

2. Substitute the isotherm coefficients and solve for M/V:

$$-\frac{V}{M} = \frac{K_f C_e^{1/n}}{(C_e - C_o)} = \frac{2.6(0.05)^{0.73}}{0.05 - 0.12} = -4.17\ \text{L/g}$$

$$M/V = 1/4.17 = 0.24\ \text{g/L}$$

3. Determine the amount of carbon required to treat 4000 m^3/d.

$$\text{PAC required} = \frac{(0.24\ \text{g/L})(4000\ \text{m}^3/\text{d})(10^3\ \text{L}/1\ \text{m}^3)}{(10^3\ \text{g}/1\ \text{kg})} = 960\ \text{kg/d}$$

Comment Due to the cost and the amount of PAC required to treat the effluent to reduce the residual chloroform to 0.05 mg/L, carbon adsorption is a poor choice for the removal of residual chloroform.

Langmuir Isotherm. Derived from rational considerations, the Langmuir adsorption isotherm is defined as:

$$\frac{x}{m} = \frac{abC_e}{1 + bC_e} \qquad (11\text{–}57)$$

where x/m = mass of adsorbate adsorbed per unit mass of adsorbent, mg adsorbate/ g activated carbon
a, b = empirical constants
C_e = equilibrium concentration of adsorbate in solution after adsorption, mg/L

The Langmuir adsorption isotherm was developed by assuming (1) a fixed number of accessible sites are available on the adsorbent surface, all of which have the same energy, and

(2) adsorption is reversible. Equilibrium is reached when the rate of adsorption of molecules onto the surface is the same as the rate of desorption of molecules from the surface. The rate at which adsorption proceeds is proportional to the driving force, which is the difference between the amount adsorbed at a particular concentration and the amount that can be adsorbed at that concentration. At the equilibrium concentration, this difference is zero.

Correspondence of experimental data to the Langmuir equation does not mean that the stated assumptions are valid for the particular system being studied because deviations from the assumptions can have a canceling effect. The constants in the Langmuir isotherm can be determined by plotting $C_e/(x/m)$ versus C_e and making use of the linear form of Eq. (11–57) rewritten as:

$$\frac{C_e}{(x/m)} = \frac{1}{ab} + \frac{1}{a}C_e \tag{11–58}$$

For the case where the Langmuir adsorption isotherm best represents a set of experimental isotherm data, a plot of $C_e/(x/m)$ vs. C_e will be linear, with a slope of $1/a$ and a y-intercept of $1/(ab)$. Application of the Langmuir adsorption isotherm is illustrated in Example 11–11.

EXAMPLE 11–11 **Analysis of Activated Carbon Adsorption Data** Determine which isotherm equation (i.e., Freundlich and Langmuir) best fits the isotherm coefficients for the following GAC adsorption test data. Also determine the corresponding coefficients for the isotherm equation. The liquid volume used in the batch adsorption tests was 1 L. The initial concentration of the adsorbate in solution was 3.37 mg/L. Equilibrium was obtained after 7 d.

Mass of GAC, m, g	Equilibrium concentration of adsorbate in solution, C_e, mg/L
0.0	3.37
0.001	3.27
0.010	2.77
0.100	1.86
0.500	1.33

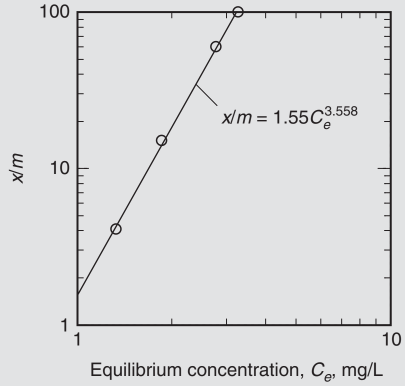
Solution

1. Derive the values needed to plot the Freundlich and Langmuir adsorption isotherms using the batch adsorption test data.

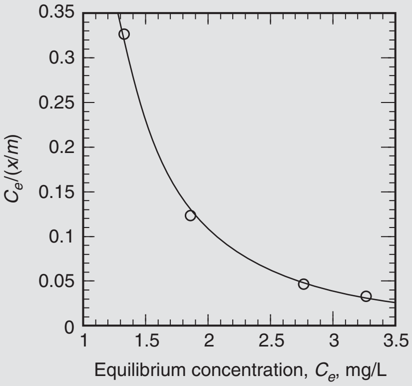
Adsorbate concentration, mg/L					
C_o	C_e	$C_o - C_e$	m, g	x/m,[a] mg/g	$C_e/(x/m)$
3.37	3.37	0.00	0.000	—	—
3.37	3.27	0.10	0.001	100	0.0327
3.37	2.77	0.60	0.010	60	0.0462
3.37	1.86	1.51	0.100	15.1	0.1232
3.37	1.33	2.04	0.500	4.08	0.3260

[a] $\frac{x}{m} = \frac{(C_o - C_e)V}{m}$

2. Plot the Freundlich and Langmuir adsorption isotherms using the data developed in Step 1 and determine which isotherm best fits the data.
   a. The required plots are given below.



Freundlich isotherm plot



Langmuir isotherm plot

   b. From the above plots, the experimental data are best represented by the Freundlich isotherm. Because the plot for the Langmuir isotherm is curvilinear, use of the Langmuir adsorption isotherm is inappropriate.
3. Determine the Freundlich adsorption isotherm coefficients.
   a. When x/m versus C_e is plotted on log-log paper, the intercept on the x/m axis when $C_e = 1.0$ is the value of K_f and the slope of the line is equal to $1/n$. Thus, $x/\mathrm{m} = 1.55$, and $K_f = 1.55$
   b. When $x/\mathrm{m} = 1.0$, $C_e = 0.89$, and $1/n = 3.6$
   c. The form of the resulting isotherm is $\frac{x}{\mathrm{m}} = 1.55C_e^{3.6}$
   d. The Freundlich adsorption isotherm equation may also be determined using a power-type best fit through the data.

Adsorption of Mixtures

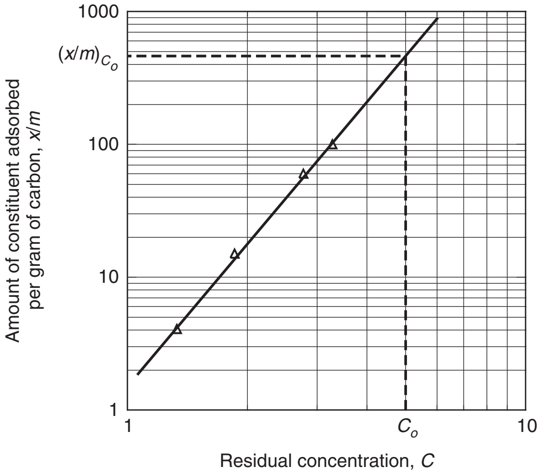
In the application of adsorption in water reclamation, mixtures of organic compounds in reclaimed water are always encountered. Typically, there is a depression of the adsorptive capacity of any individual compound in a solution of many compounds, but the total adsorptive capacity of the adsorbent may be larger than the adsorptive capacity with a single compound. The amount of inhibition due to competing compounds is related to the size of the molecules being adsorbed, their adsorptive affinities, and their relative concentrations. It is important to note that adsorption isotherms can be determined for a heterogeneous mixture of compounds including total organic carbon (TOC), dissolved organic carbon (DOC), chemical oxygen demand (COD), dissolved organic halogen (DOH), UV absorbance, and fluorescence (Snoeyink and Summers, 1999). The adsorption from mixtures is considered further in Crittenden et al. (1985, 1987a, 1987b, 1987c,) and Sontheimer and Crittenden (1988).

Adsorption Capacity

The adsorptive capacity of a given adsorbent is estimated from isotherm data as follows. If isotherm data are plotted, the resulting isotherm will be as shown on step 2 of Example 11–11. As shown on Fig. 11–52, the adsorptive capacity of the carbon can be estimated by

Figure 11–52

Plot of Freundlich isotherm used for determination of breakthrough adsorption capacity.



extending a vertical line from the point on the horizontal axis corresponding to the initial concentration C_o, and extrapolating the isotherm to intersect this line. The value at the point of intersection $[(x/m)_{C_o}]$ can be read from the vertical axis. The value represents the amount of constituent adsorbed per unit weight of carbon when the carbon is at equilibrium with the initial concentration of constituent, C_o. The equilibrium condition generally exists in the upper section of a carbon bed during column treatment, and it, therefore, represents the ultimate capacity of the carbon for a particular reclaimed water. The value of the breakthrough adsorption capacity $(x/m)_b$ can be determined using the small-scale column test described later in this section. Typically, breakthrough is said to have occurred when the effluent concentration reaches 5 percent of the influent value. Exhaustion of the adsorption bed is assumed to have occurred when the effluent concentration is equal to 95 percent of the influent concentration. A number of equations have been developed to describe the breakthrough curve including those by Bohart and Adams (1920) and Crittenden et al. (1987a).

Mass Transfer Zone. The area of the GAC bed in which sorption is occurring is called the mass transfer zone (MTZ), as shown on Fig. 11–53. After the water containing the constituent to be removed passes through a region of the bed whose depth is equal to the MTZ, the concentration of the contaminant in the water will have been reduced to its minimum value. No further adsorption will occur within the bed below the MTZ. As the top layers of carbon granules become saturated with organic material, the MTZ will move down in the bed until breakthrough occurs. The volume of a given water processed until breakthrough and exhaustion is designated as V_{BT} and V_E, respectively, as shown on Fig. 11–53. The length of the MTZ is typically a function of the hydraulic loading rate applied to the column and the characteristics of the activated carbon. In the extreme, if the loading rate is too great the length of the MTZ will be larger than the GAC bed depth, and the adsorbable constituents will not be removed completely by the carbon. At complete exhaustion, the effluent concentration is equal to the influent concentration.

Breakthrough Curve. In addition to the applied hydraulic loading rate, the shape of the breakthrough curve will also depend on whether the applied liquid contains nonadsorbable and biodegradable constituents. The impact of the presence of nonadsorbable and biodegradable organic constituents on the shape of the breakthrough curve is illustrated on

Figure 11–53

Typical breakthrough curve for activated carbon showing movement of mass transfer zone (MTZ) with throughput volume.

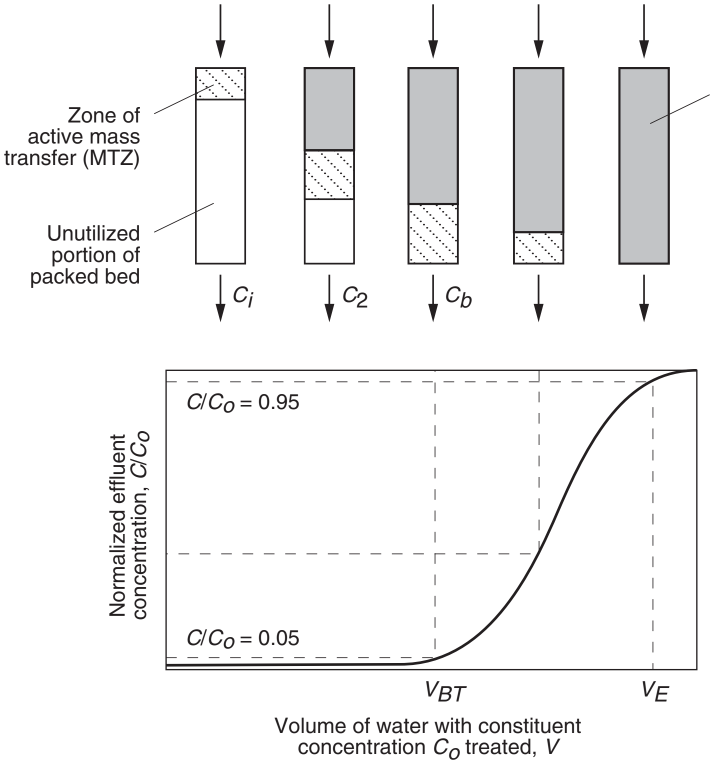


Fig. 11–54. As shown on Fig. 11–54, if the liquid contains nonadsorbable constituents, the nonadsorbable constituents will appear in the effluent as soon as the carbon column is put into operation (ignoring the short period of time for hydraulic conductivity). If adsorbable and biodegradable constituents are present in the applied liquid, the breakthrough curve will not reach a C/C_o value of 1.0 but will be depressed, and the observed C/C_o value will depend on the biodegradability of the influent constituents because biological activity continues even though the adsorption capacity has been utilized. If the liquid contains nonadsorbable and biodegradable constituents, the observed breakthrough curve will not

Figure 11–54

Impact of the presence of adsorbable, nonadsorbable, and biodegradable organic constituents on the shape of the activated carbon breakthrough curve. (Adapted from Snoeyink and Summers, 1999.)

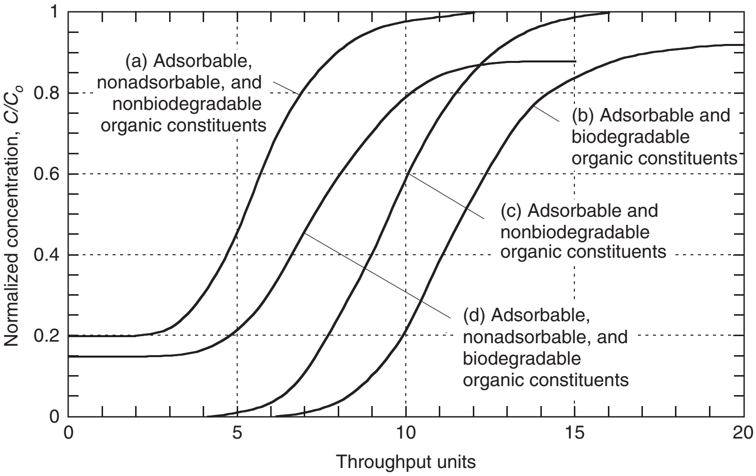

Figure 11–55

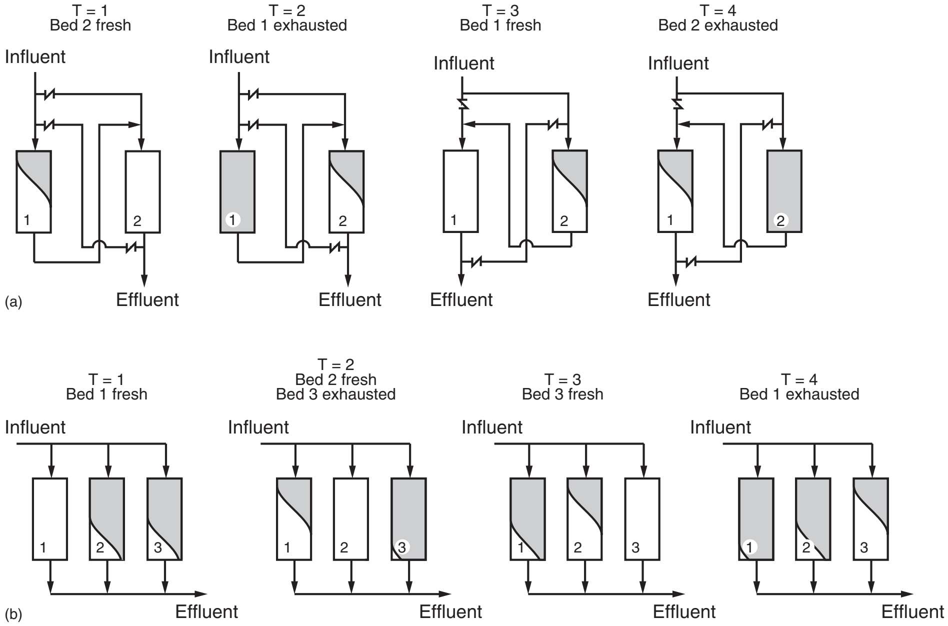
Activated carbon contactor configurations: (a) series and (b) parallel operation.



start at zero and will not terminate at a value of 1.0 (Snoeyink and Summers, 1999). The above effects are observed commonly in wastewater adsorption applications, especially with respect to the removal of COD.

In practice, the only way to use the capacity at the bottom portion of the carbon adsorption column is to have two or more columns in series and switch them as they are exhausted (lead-lag), or to use multiple columns in parallel so that breakthrough in one column does not affect the combined effluent quality. This mode of operation is referred to as the carousel technique, where multiple columns can be rotated so that only one column reaches exhaustion at a given time. The arrangement of adsorption columns in series and parallel configurations is shown on Fig. 11–55(a) and (b), respectively. A minimum of two parallel or series carbon contactors is recommended for design. Multiple units permit one or more units to remain in operation while one unit is taken out of service for removal and regeneration of spent carbon, or for maintenance. The optimum flowrate and bed depth, as well as the operating capacity of the carbon, must be established to determine the dimensions and the number of columns necessary for continuous treatment. These parameters can be determined from dynamic column tests, as discussed below.

Adsorption Contactors. Several types of activated carbon contactors are used for trace constituent removal, including fixed and expanded beds, addition of PAC to the activated sludge process, and separate mixed systems with subsequent carbon separation, as summarized in Table 11–43. A typical pressurized, down-flow carbon contactor is shown on Fig. 11–56. The sizing of carbon contactors is based on a number of factors, as summarized in Table 11–44 for a downflow packed bed contactor. For the case where the mass transfer rate is fast and the mass transfer zone is a sharp wave front, a steady-state mass balance around a fixed bed carbon contactor may be written as:

Accumulation = inflow − outflow − amount adsorbed

Table 11–43

Application of activated carbon for the removal of trace constituents from wastewater

Configuration	Description
(a) Fixed bed GAC column (downflow)  	Fixed-bed downflow columns can be operated singly, in series, or in parallel (see Fig. 11–55). Granular medium filters are used commonly upstream of the activated carbon contactors to remove the organics associated with the suspended solids present in secondary effluent, however the adsorption of organics and filtration of suspended solids can also be accomplished in a single step. In the downflow design, the water to be treated is applied to the top of the column and withdrawn at the bottom. The carbon is held in place with an underdrain system at the bottom of the column. Provision for backwashing and surface washing is often provided in wastewater applications to limit the headloss buildup due to the removal of particulate suspended solids within the carbon column. Unfortunately, backwashing has the effect of destroying the adsorption front. Although upflow fixed-bed reactors have been used, downflow beds are used more commonly to lessen the chance of accumulating particulate material in the bottom of the bed, where the particulate material would be difficult to remove by backwashing.
(b) Expanded bed GAC (upflow)  	In the expanded (or fluidized) bed system, the influent is introduced at the bottom of the column and the activated carbon is allowed to expand, much as a filter bed expands during backwash. When the adsorptive capacity of the carbon at the bottom of the column is exhausted, the bottom portion of carbon is removed, and an equivalent amount of regenerated or virgin carbon is added to the top of the column. In such a system, headloss does not build up with time after the operating point has been reached. In general, expanded bed upflow contactors may have more carbon fines in the effluent than downflow contactors because bed expansion leads to the creation of fines as the carbon particles collide and abrade, and allows the fines to escape through passageways created by the expanded bed. While not used commonly, continuous backwash moving-bed and pulsed-bed carbon contactors have been used (see Table 8–4 for filter configurations).
(c) Activated Sludge with PAC addition  	The use of powdered activated carbon with the activated sludge process, where activated carbon is added directly to the aeration tank, results in simultaneous biological oxidation and physical adsorption. A feature of this process is that it can be integrated into existing activated sludge systems at nominal capital cost. The addition of powdered activated carbon has several process advantages, including: (1) system stability during shock loads, (2) reduction of refractory priority pollutants, (3) color and ammonia removal, and (4) improved sludge settleability. In some industrial waste applications where nitrification is inhibited by toxic organics, the application of powdered activated carbon may reduce or limit this inhibition.
(d) Mixed PAC contactor with gravity separation  	Powdered activated carbon can be applied to the effluent from biological treatment processes in a separate contacting basin. The contactor can operate in a batch or continuous flow mode. In the batch mode, after a specified amount of time for contact, the carbon is allowed to settle to the bottom of the tank, and the treated water is then removed from the tank. The continuous flow operation consists of a basin divided for contacting and settling. The settled carbon may be recycled to the contact tank. Because carbon is very fine, a coagulant, such as a polyelectrolyte, may be needed to aid in the removal of the carbon particles, or filtration through rapid sand filters may be required. In some treatment processes, PAC is used in conjunction with chemicals used for the precipitation of specific constituents.

(*continued*)

Table 11–43 (*Continued*)

Configuration	Description
(e) Mixed PAC contactor with membrane separation  	The removal of trace constituents in a complete mix or plug flow contactor may be combined with separation by micro or ultrafiltration membranes. The PAC is added to the secondary effluent by continuous or pulse addition, followed by concentration of the PAC on the membrane. When the headloss across the membrane reaches a given value, a backwash cycle is initiated. The backwash containing the PAC retentate may be wasted or recycled to the contact basin. A number of full-scale plants have used this process (Snoeyink et al., 2000, Anselme et al., 1997).

$$0 = QC_o t - QC_e t - m_{\mathrm{GAC}} q_e \tag{11–59}$$

where Q = volumetric flowrate, L/h
C_o = initial concentration of adsorbate, mg/L
t = time, h
C_e = final equilibrium concentration of adsorbate, mg/L
m_{GAC} = mass of adsorbent, g
q_e = adsorbent phase concentration after equilibrium, mg adsorbate/g adsorbent

From Eq. (11–59), the adsorbent usage rate is defined as

$$\frac{m_{\mathrm{GAC}}}{Qt} = \frac{C_o - C_e}{q_e} \tag{11–60}$$

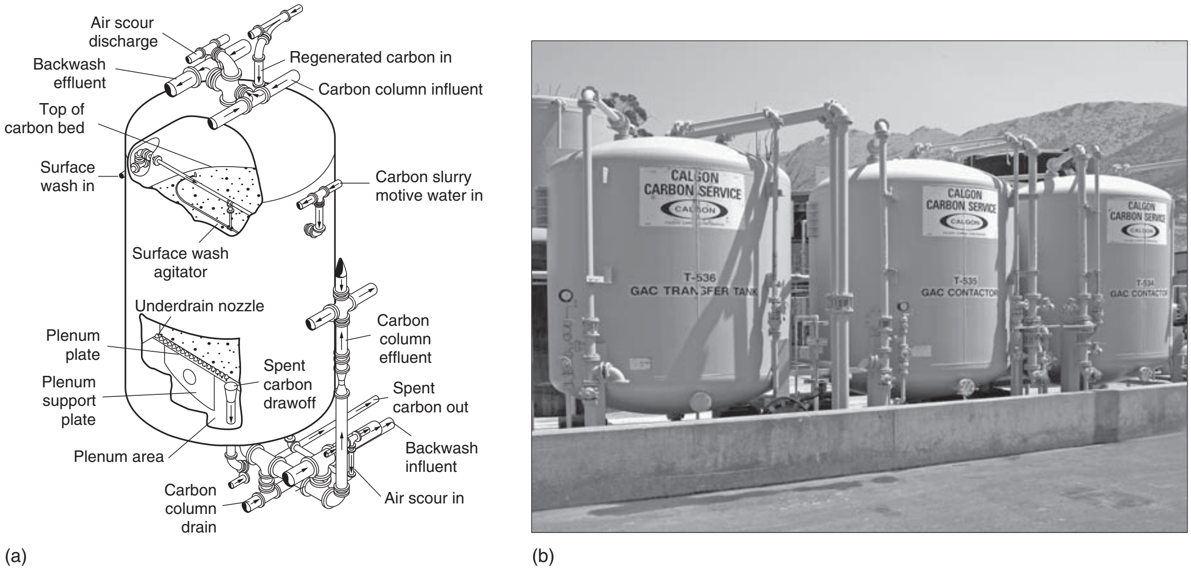


Figure 11–56

Table 11–44

Typical design values for GAC contactors[a]

Parameter	Symbol	Unit	Value
Volumetric flowrate	V	m^3/h	50–400
Bed volume	V_b	m^3	10–50
Cross-sectional area	A_b	m^2	5–30
Carbon depth	D	m	1.8–4
Void fraction	α	m^3/m^3	0.38–0.42
GAC density	ρ	kg/m^3	350–550
Approach velocity	v_f	m/h	5–15
Effective contact time	t	min	2–10
Empty bed contact time	EBCT	min	5–30
Operation time	t	d	100–600
Throughput volume	V_L	m^3	10–100
Specific throughput	V_{sp}	m^3/kg	50–200
Bed volumes[b]	BV	m^3/m^3	2000–20,000

[a] Adapted from Sontheimer et al. (1988).

[b] Total volume of water processed expressed in terms of the reactor bed volume.

If it is assumed that the mass of the adsorbate in the pore space is small compared to the amount adsorbed, then the term $QC_e t$ in Eq. (11–60) can be neglected without serious error and the adsorbent usage rate is given by:

$$\frac{m_{\text{GAC}}}{Qt} \approx \frac{C_o}{q_e} \tag{11–61}$$

To quantify the operational performance of GAC contactors, the following terms have been developed and are used commonly.

1. Empty bed contact time (EBCT)

$$EBCT = \frac{V_b}{Q} = \frac{A_b D}{v_f A_b} = \frac{D}{v_f} \tag{11–62}$$

where EBCT = empty bed contact time, h
V_b = volume of contactor occupied by GAC, m^3
Q = volumetric flowrate, m^3/h
A_b = cross-sectional area of GAC filter bed, m^2
D = depth of GAC in contactor, m
v_f = linear approach velocity, m/h

2. Activated carbon density.
The density of the activated carbon is defined as

$$\rho_{\text{GAC}} = \frac{m_{\text{GAC}}}{V_b} \tag{11–63}$$

where ρ_{GAC} = density of granular activated carbon, g/L
m_{GAC} = mass of granular activated carbon, g
V_b = volume of contactor occupied by GAC, L

3. Specific throughput, expressed as m^3 of water treated per gram of carbon:

$$\text{Specific throughput, m}^3\text{/g} = \frac{Qt}{m_{\text{GAC}}} = \frac{V_b t}{\text{EBCT} \times m_{\text{GAC}}} \tag{11–64}$$

Using Eq. (11–63), Eq. (11–64) can be written as

$$\text{Specific throughput} = \frac{V_b t}{\text{EBCT}(\rho_{\text{GAC}} \times V_b)} = \frac{t}{\text{EBCT} \times \rho_{\text{GAC}}} \tag{11–65}$$

4. Carbon usage rate (CUR) expressed as gram of carbon per m^3 of water treated:

$$\text{CUR, g/m}^3 = \frac{m_{\text{GAC}}}{Qt} = \frac{1}{\text{Specific throughput}} \tag{11–66}$$

5. Volume of water treated for a given EBCT, expressed in liters, L:

$$\text{Volume of water treated, m}^3 = \frac{\text{Mass of GAC for given EBCT}}{\text{GAC usage rate}} \tag{11–67}$$

6. Bed life, expressed in days, d:

$$\text{Bed life, d} = \frac{\text{Volume of water treated for given EBCT}}{Q} \tag{11–68}$$

The application of these terms is illustrated in Example 11–12.

EXAMPLE 11–12 **Estimation of Activated Carbon Adsorption Breakthrough Time** A fixed-bed activated carbon adsorber has a fast mass transfer rate and the mass transfer zone is essentially a sharp wave front. Assuming the following data apply, determine the carbon requirements to treat a flowrate of 1000 L/min, and the corresponding bed life.

1. Compound to be treated = Trichloroethylene (TCE)
2. Initial concentration, $C_o = 1.0$ mg/L
3. Final concentration $C_e = 0.005$ mg/L
4. GAC density = 450 g/L
5. Freundlich capacity factor, $K_f = 28\ (\text{mg/g})(\text{L/mg})^{1/n}$ (see Table 11–42)
6. Freundlich intensity parameter, $1/n = 0.62$ (see Table 11–42)
7. EBCT = 10 min

Ignore the effects of biological activity within the column.

Solution

1. Estimate the GAC usage rate for TCE. The GAC usage rate is estimated using Eq. (11–60) and Eq. (11–55).

$$\frac{m_{\text{GAC}}}{Qt} = \frac{C_o - C_e}{q_e} = \frac{C_o - C_e}{K_f C_o^{1/n}}$$

$$= \frac{(1.0\ \text{mg/L}) - (0.005\ \text{mg/L})}{28(\text{mg/g})(\text{L/mg})^{0.62}\ (1.0\ \text{mg/L})^{0.62}}$$

$$= 0.036\ \text{g GAC/L}$$

2. Determine the mass of carbon required for a 10 min EBCT.

   The mass of GAC in the bed = $V_b \rho_{GAC}$ = (EBCT)(Q)(ρ_{GAC})

   Carbon required = 10 min (1000 L/min) (450 g/L) = 4.5×10^6 g

3. Determine the volume of water treated using a 10 min EBCT.

$$\text{Volume of water treated} = \frac{\text{Mass of GAC for given EBCT}}{\text{GAC usage rate}}$$

$$\text{Volume of water treated} = \frac{4.5 \times 10^6 \text{ g}}{(0.036 \text{ g GAC/L})} = 1.26 \times 10^8 \text{ L}$$

4. Determine the bed life.

$$\text{Bed life} = \frac{\text{Volume of water treated for given EBCT}}{Q}$$

$$\text{Bed life} = \frac{1.26 \times 10^8 \text{ L}}{(1000 \text{ L/min})(1440 \text{ min/d})} = 87.5 \text{ d}$$

Comment In this example, the full capacity of the carbon in the contactor was utilized based on the assumption that two columns in series are used. If a single column is used, then a breakthough curve must be used to arrive at the bed life. The Freundlich isotherm parameters, *K* and 1/*n*, are a function of the initial concentration, the actual carbon that is used, as well as the water quality (temperature, pH). Equilibrium isotherms are used to determine these parameters for the conditions of interest.

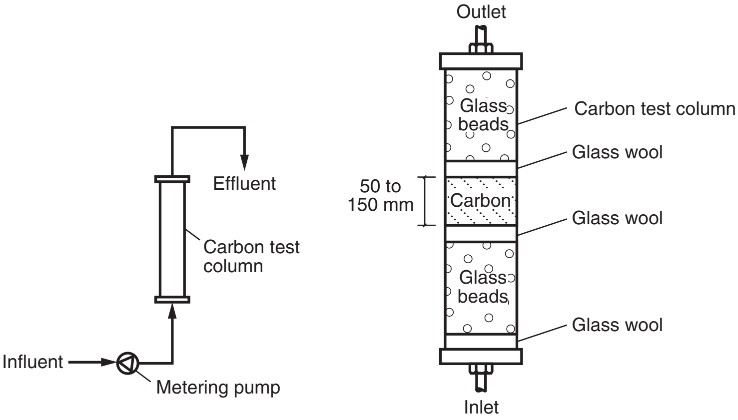
Small Scale Column Tests

Over the years, a number of small scale column tests have been developed to simulate the results obtained with full scale reactors. One of the early column tests was the high-pressure minicolumn (HPMC) technique developed by Rosene et al. (1980), and later modified by Bilello and Beaudet (1983). In the HPMC test procedure, a high-pressure liquid chromatography column loaded with activated carbon is used. Typically the HPMC test procedure is used to determine the capacity of activated carbon for the adsorption of volatile organic compounds. The principal advantage of the HPMC test procedure is that it allows for the rapid determination of the GAC adsorptive capacity under conditions similar to those encountered in the field.

An alternative procedure known as the *rapid small-scale column test* (RSSCT) has been developed by Crittenden et al. (1986, 1987d, 1991). The test procedure allows for the scaling of data obtained from small columns (see Fig. 11–57) to predict the performance of pilot or full-scale carbon columns. In developing the procedure, mathematical models were used to define the relationships between the breakthrough curve for small and large columns. In adsorption columns, the mass transfer mechanisms that are responsible for the spreading of the mass transfer zone are (1) dispersion, (2) film diffusion, and (3) intraparticle diffusion. Two different design relationships were developed, one for constant diffusivity and one for proportional, or non-constant, diffusivity. In the constant diffusivity model, it is assumed that dispersion is negligible because the hydraulic loading rate is high in the RSSCT, and that mass transfer occurs as a result of film diffusion. Further, it is

Figure 11–57

Schematic of column used for rapid small scale column testing (RSSCT) to develop data for pilot or full scale carbon columns.



Column to particle diameter = 20:1 (or greater)
Column diameter = 20 to 40 mm
Column length = 300 mm

assumed that the intraparticle diffusivity is the same for both the small and large columns. In the proportional diffusivity model, it is assumed that dispersion is negligible because the hydraulic loading rate is high in the RSSCT, and that mass transfer occurs as a result of intraparticle diffusion. The relationships for the two cases can be generalized as follows:

$$\frac{\mathrm{EBCT}_{SC}}{\mathrm{EBCT}_{LC}} = \left(\frac{d_{SC}}{d_{LC}}\right)^{2-x} = \frac{t_{SC}}{t_{LC}} \tag{11–69}$$

$$\frac{v_{SC}}{v_{LC}} = \frac{d_{LC}}{d_{SC}} \tag{11–70}$$

where d_{SC} = diameter of particle in small-scale column, mm
d_{LC} = diameter of particle in large-scale column, mm
t_{SC} = time in small-scale column, min
t_{LC} = time in large-scale column, min
v_{SC} = superficial velocity in small-scale column, m/h
v_{LC} = superficial velocity in large-scale column, m/h

For constant and proportional diffusivity, the value of x in the exponent in Eq. (11–69) is 0 and 1, respectively. The application of the above equations is illustrated in Example 11–13.

EXAMPLE 11–13 **Comparison of Rapid Small-scale Column Test Parameters to Pilot Scale Parameters** Determine the corresponding parameters for a RSSCT based on the following data proposed for a pilot scale column. Assume that film diffusion is the controlling mechanism.

Parameter	Unit	Pilot column (LC)	RSSCT (SC)
Particle diameter	mm	0.5	0.1
Carbon density	g/L	450	450
EBCT	min	10	

(continued)

(*Continued*)

Parameter	Unit	Pilot column (LC)	RSSCT (SC)
Loading rate	m/h	5.0	
Flowrate	mL/min	200	
Column diameter	mm	75	10[a]
Column length	mm	1000	
Mass adsorbent	g		
Time of operation	d	100	
Water volume	L	28,800	

[a] Assumed value for small column.

Solution

1. Estimate the EBCT for the RSSCT.

$$\mathrm{EBCT}_{SC} = \mathrm{EBCT}_{LC}\left(\frac{d_{SC}}{d_{LC}}\right)^2$$

$$\mathrm{EBCT}_{SC} = 10\ \mathrm{min}\left(\frac{0.1}{0.5}\right)^2 = 0.4\ \mathrm{min}$$

2. Estimate the loading rate for the RSSCT.

$$v_{SC} = v_{LC}\frac{d_{LC}}{d_{SC}}$$

$$v_{SC} = 5\ \mathrm{m/h}\,\frac{0.5}{0.1} = 25\ \mathrm{m/h}$$

3. Estimate flowrate for the RSSCT.

$$A = \frac{\pi}{4}d_{SC}^2 = \frac{\pi}{4}(10\ \mathrm{mm})^2 = 78.5\ \mathrm{mm}^2$$

$$Q_{SC} = (v_{SC})(A)$$

$$Q_{SC} = \frac{(25\ \mathrm{m/h})(10^3\ \mathrm{mm/1\ m})(78.5\ \mathrm{mm}^2)}{(60\ \mathrm{min/h})(10^3\ \mathrm{mm}^3/1\ \mathrm{mL})} = 32.7\ \mathrm{mL/min}$$

4. Estimate column length for the RSSCT.

$$L_{SC} = \frac{Q_{SC} \times \mathrm{EBCT}_{SC}}{A} = \frac{(32{,}700\ \mathrm{mm}^3/\mathrm{min})(0.4\ \mathrm{min})}{78.5\ \mathrm{mm}^2} = 166.7\ \mathrm{mm}$$

5. Estimate mass of adsorbent required for the RSSCT.

$$M_{SC} = \mathrm{EBCT}_{LC}\left(\frac{d_{SC}}{d_{LC}}\right)^2(Q_{SC})(\rho_{SC})$$

$$M_{SC} = 10\ \mathrm{min}\left(\frac{0.1\ \mathrm{mm}}{0.5\ \mathrm{mm}}\right)^2\left[\frac{(32.7\ \mathrm{mL/min})(450\ \mathrm{g/L})}{(10^3\ \mathrm{mL/1\ L})}\right] = 5.9\ \mathrm{g}$$

6. Estimate time of operation for the RSSCT.

$$t_{SC} = t_{LC}\frac{\mathrm{EBCT}_{SC}}{\mathrm{EBCT}_{LC}}$$

$$t_{SC} = 100\left(\frac{0.4\ \mathrm{min}}{10\ \mathrm{min}}\right) = 4\ \mathrm{d}$$

7. Estimate volume of water required for the RSSCT.

$$\upsilon_W = Q_{SC} \times t_{SC}$$

$$\upsilon_W = \frac{(32.7\ \text{mL/min})(4\ \text{d})(1440\ \text{min/d})}{(10^3\ \text{mL/1 L})} = 188.4\ \text{L}$$

8. Summarize the findings for the RSSCT.

Parameter	Unit	Pilot column	RSSCT
Particle radius	mm	0.5	0.1
Carbon density	g/L	450	450
EBCT	min	10	0.4
Loading rate	m/h	5.0	25.0
Flowrate	mL/min	200	32.7
Column diameter	mm	75	10[a]
Column length	mm	1000	166.7
Mass adsorbent	g		5.9
Time of operation	d	100	4
Water volume	L	28,800	188.4

[a] Assumed value for small column.

Comment The time savings in conducting the RSSCT versus the pilot column is apparent. Furthermore, many more tests can be conducted to test alternative configurations and carbon types. Often RSSCT's are performed in advance of piloting to narrow the list of the most appropriate carbon media for use in piloting.

Analysis of Powdered Activated Carbon Contactor

For a powdered activated carbon (PAC) application, the isotherm adsorption data can be used in conjunction with a materials mass balance analysis to obtain an approximate estimate of the amount of carbon that must be added as illustrated below. Here again, because of the many unknown factors involved, column and bench scale tests are recommended to develop the necessary design data. If a mass balance is written around the contactor (i.e., a batch reactor) after equilibrium has been reached, the resulting expression is given by Eq. (11–54), as derived previously. Estimation of the of powdered activated carbon (PAC) dose for adsorption is illustrated in Example 11–14.

EXAMPLE 11–14 **Estimation of Powdered Activated Carbon (PAC) Adsorption Dose and Cost** A treated wastewater with a flowrate of 1000 L/min is to be treated with PAC to reduce the concentration of residual organics measured as TOC from 5 to 1 mg/L. The Freundlich adsorption isotherm parameters were developed as discussed previously. Assuming the following data apply, determine the PAC requirements to treat the wastewater flow. If PAC costs \$0.50/kg, estimate the annual cost for treatment, assuming the PAC will not be regenerated.

1. Compound = mixed organics
2. Initial concentration, $C_o = 5.0$ mg/L
3. Final concentration, $C_e = 1.0$ mg/L
4. GAC density = 450 g/L
5. Freundlich capacity factor, $K_f = 150\ (\text{mg/g})(\text{L/mg})^{1/n}$
6. Freundlich intensity parameter, $1/n = 0.5$

Solution

1. Estimate the PAC dose based on the isotherm data. The PAC dose can be estimated by writing Eq. (11–54) as follows:

$$\frac{m}{V} = \frac{(C_o - C_e)}{q_e} = \frac{(C_o - C_e)}{K_f C_e^{1/n}}$$

Substituting the given values in the expression yields:

$$\frac{m}{V} = \frac{(5\ \text{mg/L} - 1\ \text{mg/L})}{150(\text{mg/g})(\text{L/mg})^{0.5}(1.0\ \text{mg/L})^{0.5}} = 0.0267\,\text{g/L}$$

2. Estimate the annual cost for the PAC treatment.

Annual cost =

$$= \frac{(0.0267\ \text{g/L})(1000\ \text{L/min})(1440\ \text{min/d})(365\ \text{d/y})(\$0.50/\text{kg})}{(10^3\ \text{g/1 kg})}$$

Annual cost = \$7008/y

Comment For small wastewater flows, it is not usually cost effective to plan for carbon regeneration.

Activated Sludge Powdered Activated Carbon Treatment

Powdered activated carbon treatment (PACT), a proprietary process, is described in Table 11–43 along with other applications. The dosage of powdered activated carbon and the mixed liquor-powdered activated carbon suspended solids concentration are related to the SRT as follows:

$$X_p = \frac{X_i\,\text{SRT}}{\tau} \tag{11–71}$$

where X_p = equilibrium powdered activated carbon-MLSS content, mg/L
X_i = powdered activated carbon dosage, mg/L
SRT = solids retention time, d
τ = hydraulic retention time, d

Carbon dosages typically range from 20 to 200 mg/L. With higher SRT values, the organic removal per unit of carbon is enhanced, thereby improving the process efficiency. Reasons cited for this phenomenon include (1) additional biodegradation due to decreased toxicity, (2) degradation of normally nondegradable substances due to increased exposure time to the biomass through adsorption on the carbon, and (3) replacement of low molecular weight compounds with high molecular weight compounds, resulting in improved adsorption efficiency and lower toxicity.

Carbon Regeneration

In many situations, the economical application of activated carbon depends on an efficient means of regenerating and reactivating the carbon after its adsorptive capacity has been reached. Regeneration is the term used to describe all of the processes that are used to recover the adsorptive capacity of the spent carbon, exclusive of reactivation. Typically, some of the adsorptive capacity of the carbon (about 4 to 10 percent) is lost in the regeneration process, while a loss of 2 to 5 percent is expected during the reactivation process, and a 4 to 8 percent loss of carbon is assumed due to attrition, abrasion, and mishandling. In general, regenerated activated carbon is not used in reclaimed water applications because of the potential for residual constituents, not removed in the regeneration process, to desorb and contaminate the reclaimed water. Additional details on carbon reactivation and regeneration may be found in Sontheimer and Crittenden (1988).

Adsorption Process Limitations

The adsorption process in water reuse applications is limited by (1) the logistics involved with transport of large volumes of adsorbent materials, (2) the area requirements for the carbon contactors, and (3) the production of waste adsorbent that can be difficult to regenerate and may need to be disposed of as hazardous waste due to the presence of toxic constituents. In particular, PAC contributes directly to the residuals solid loading and must be considered in terms of the impact on residuals handling. Further, the regeneration of some adsorbents is not feasible, resulting in potentially high media replacement costs. Process monitoring and control is essential, as the performance of carbon contactors will be affected by variations in pH, temperature, and flowrate.

11–10 GAS STRIPPING

Gas stripping involves the mass transfer of a gas from the liquid phase to the gas phase. The transfer is accomplished by contacting the liquid containing the gas that is to be stripped with a gas (usually air) which does not contain the gas initially. The removal of dissolved gases from wastewaters by gas (usually air) stripping has received considerable attention, especially for the removal of ammonia and odorous gases and volatile organic compounds (VOCs). Early work on the air stripping of ammonia from wastewater was conducted at Lake Tahoe, CA (Culp and Slechta, 1966; Slechta and Culp, 1967). The removal of VOCs by aeration is considered in Sec. 16–4 in Chap. 16.

The purpose of this section is to introduce the fundamental principles involved in gas stripping and to illustrate the general application of these principles. A design procedure is also presented. The material presented in this section is applicable to the removal of ammonia (NH_3), carbon dioxide (CO_2), oxygen (O_2), hydrogen sulfide (H_2S), and a variety of VOCs. The focus of the discussion in this section is on the analysis of facilities designed specifically for the removal of gaseous constituents as opposed to the removal of odorous gases (see Section 16–3, Chap. 16) and VOCs in aeration systems designed for the biological treatment of wastewater (see Sec. 16–4 in Chap. 16).

Analysis of Gas Stripping

Important factors that must be considered in the analysis of gas stripping include (1) the characteristics of the compound(s) to be stripped, (2) the type of contactor to be used and the required number of stages, (3) the materials mass balance analysis of the stripping tower, and (4) the required physical features and dimensions of the required stripping tower.

Characteristics of the Compound(s) to be Stripped. As noted above, the removal of volatile dissolved compounds by stripping involves contacting the liquid with a gas that does not contain the compound initially. The compound that is to be stripped will come out of solution and enter the gas phase to satisfy the Henry's law equilibrium as discussed in Chap. 2. Compounds such as benzene, toluene, and vinyl chloride which have Henry's law constants greater than 500 atm are especially amenable to stripping. Compounds with Henry's law constants values greater than 0.1 atm are classified as volatile and are considered amenable to stripping. Compounds with Henry's law constants between 0.001 and 0.1 atm are classified as semi-volatile and are marginally amenable to stripping. Compounds with Henry's law constants less than 0.001 atm are essentially not amenable to stripping.

The air stripping of ammonia from wastewater requires that the ammonia be present as a gas. Ammonium ions in wastewater exist in equilibrium with gaseous ammonia, as given by Eq. (2–38):

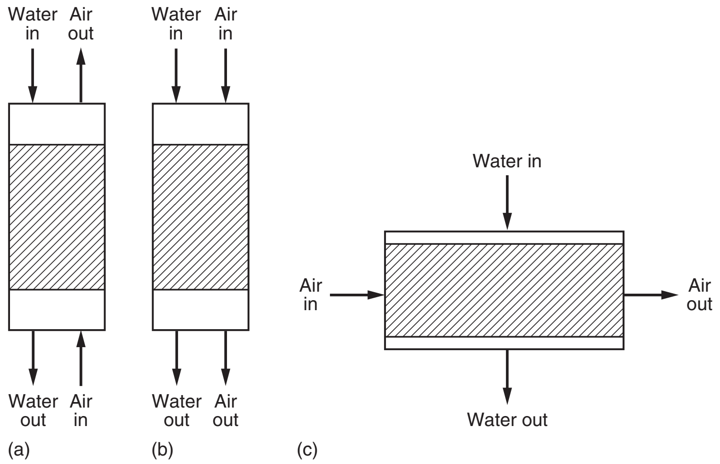
$$NH_4^+ \rightleftarrows NH_3 + H^+ \tag{2–38}$$

As the pH of the wastewater is increased above 7, the equilibrium is shifted to the right and the ammonium ion is converted to ammonia, which may be removed by gas stripping. The amount of lime required to raise the pH of wastewater to 11 as a function of the alkalinity is given on Fig. 6–12 in Chap. 6.

Methods Used to Contact Phases. In practice, two methods are used to achieve contact between phases so that mass transfer can occur: (1) continuous contact and (2) staged contact. As shown on Fig. 11–58, three flow patterns are used in practice: (1) cocurrent, (2) countercurrent, and (3) cross-flow. In addition, the contact packing may be fixed or mobile (Crittenden, 1999). The most common flow pattern in mass transfer operations is the countercurrent mode, in which the liquid to be stripped is pumped to the top of the tower and sprayed over the packing surface. Air is introduced into the bottom of the tower (i.e., counter current) and either blown or sucked up through the packing material. The packing material is used to distribute the applied liquid in a thin film to enhance the stripping process. In the cross-flow stripper, not used commonly, air is introduced along the side. One of the most critical issues in the design and operation of stripping towers is maintaining uniform airflow across the packing surface. To achieve a more uniform

Figure 11–58

Typical water and air flow patterns for gas stripping towers: (a) countercurrent flow, (b) cocurrent flow, and (c) cross-flow.



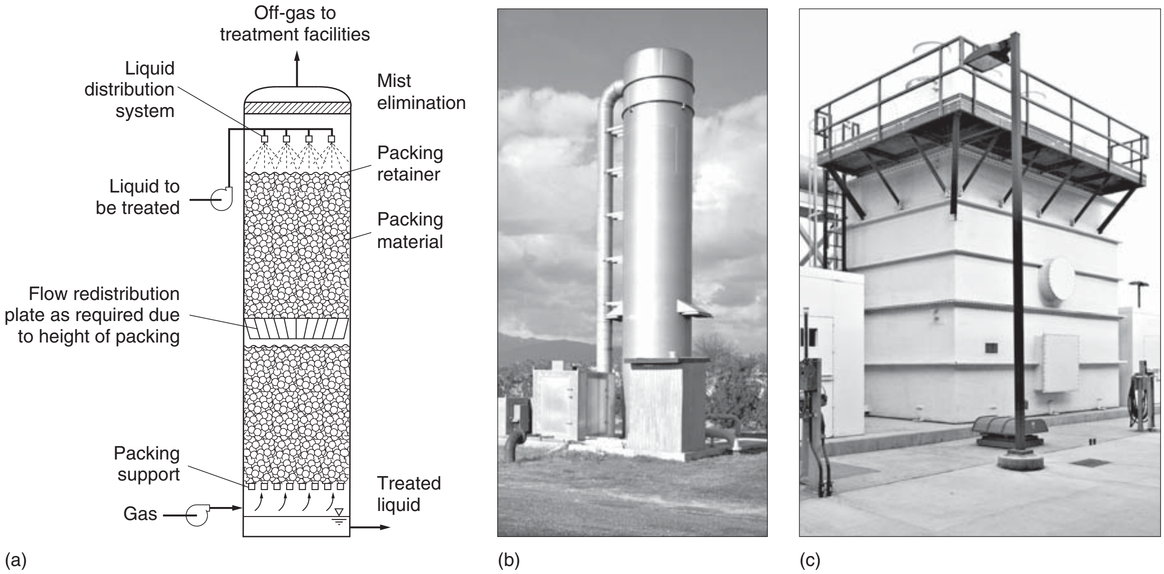


Figure 11–59

Typical examples of stripping towers: (a) schematic of packed bed stripping tower used for the removal of volatile gases from water, (b) view of stripping tower shown schematically in (a), and (c) typical stripping tower used for the removal of carbon dioxide from water following reverse osmosis treatment.

distribution of both air and water flow through the tower, packing is placed in individual stages on flow redistribution plates within the tower. A variety of packing materials are used in stripping towers including Raschig rings (cylinders), Berl saddles, or other proprietary plastic packings. Although a wide range of packing sizes is available, the most common size range is from 25 to 50 mm. A schematic and photograph of a typical gas stripping tower is shown on Fig. 11–59.

Mass Balance Analysis for a Continuous Stripping Tower. A steady-state materials balance for the lower portion of a countercurrent continuous stripping tower used for the removal of a dissolved gas from wastewater (see Fig. 11–60) is given by

1. General word statement:

$$\begin{array}{c} \text{Moles of solute} \\ \text{entering in} \\ \text{liquid stream} \end{array} + \begin{array}{c} \text{moles of solute} \\ \text{entering in} \\ \text{gas stream} \end{array} = \begin{array}{c} \text{moles of solute} \\ \text{leaving in} \\ \text{liquid stream} \end{array} + \begin{array}{c} \text{moles of solute} \\ \text{leaving in} \\ \text{gas stream} \end{array} \tag{11–72}$$

2. Simplified word statement:

$$\text{inflow} = \text{outflow} \tag{11–73}$$

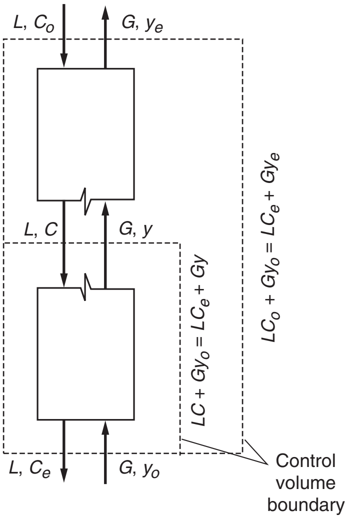
3. Symbolic representation (refer to Fig. 11–61):

$$LC + Gy_o = LC_e + Gy \tag{11–74}$$

where L = liquid flowrate, moles per unit time
C = concentration of solute in liquid at point within the tower, moles of solute per mole of liquid
G = gas flowrate, moles per unit time

Figure 11–60

Definition sketch for the analysis of a continuous countercurrent flow gas stripping tower.



y_o = concentration of solute in gas entering the bottom of the tower, moles of solute per mole of solute-free gas

C_e = concentration of solute in liquid leaving the bottom of the tower, moles of solute per mole of liquid

y = concentration of solute at a point within the tower, moles of solute per mole of solute-free gas

Figure 11–61

Operating lines for various gas stripping conditions: (a) general case, (b) condition when $y_o = 0$, (c) condition when $y_o = 0$ and y_e is in equilibrium with C_o, the constituent concentration in the incoming water, and (d) condition when $y_o = 0$, $C_e = 0$, and y_e is in equilibrium with C_o.

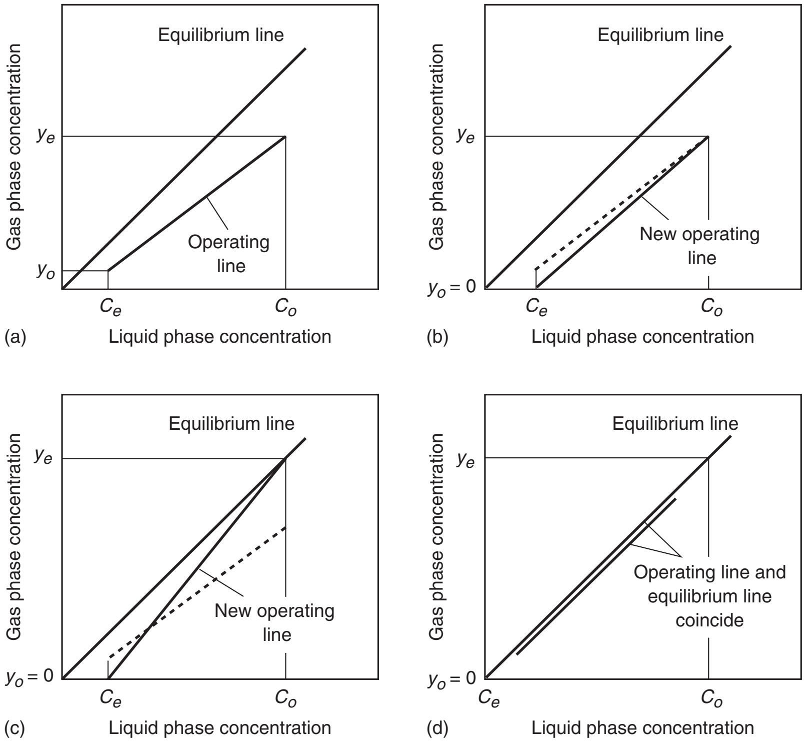


Figure 11–62

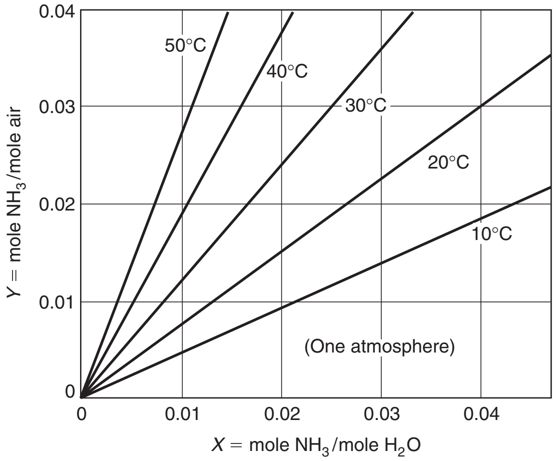
Equilibrium curves for ammonia in water as a function of temperature based on Henry's law.



Combining terms, Eq. (11–74) can be written as:

$$(y_o - y) = L/G(C_e - C) \tag{11–75}$$

If the overall tower is considered, Eq. (11–74) can be written as:

$$LC_o + Gy_o = LC_e + Gy_e \tag{11–76}$$

Combining terms, Eq. (11–76) can be written as:

$$(y_o - y_e) = L/G(C_e - C_o) \tag{11–77}$$

where C_o = concentration of solute in liquid entering at the top of the tower, moles of solute per mole of liquid

y_e = concentration of solute in gas leaving the top of the tower, moles of solute per mole of gas

Because Eq. (11–77) is derived solely from a consideration of the equality of input and output, it holds regardless of the internal equilibria that may control the mass transfer. Equation (11–77) represents the equation of a straight line with slope L/G which passes through the point (C_o, y_e) and point (C_e, y_o). The line passed through these two points [see Fig. 11–61(a)] is known as the *operating line* and represents the conditions at any point within the column. The equilibrium line is based on Henry's law. For example, equilibrium lines defined by Henry's law for ammonia as a function of temperature are presented on Fig. 11–62. It should be noted that when a gas is being stripped from solution, the operating line will lie below the equilibrium line. If a gas is being absorbed into solution the operating line will lie above the equilibrium line.

If it is assumed that the air entering the bottom of the tower contains no solute (i.e, $y_o = 0$), then Eq. (11–77) can be written as

$$y_e = L/G(C_o - C_e) \tag{11–78}$$

The new operating line for the condition defined by Eq. (11–78) is shown on Fig. 11–61(b). Using Henry's law [see Eq. (2–46)], y_e is defined as follows

$$y_e = \frac{H}{P_T} C'_o \tag{11–79}$$

where y_e = concentration of solute in gas leaving the top of the tower, moles of solute per mole of gas

H = Henry's law constant, $\dfrac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}$

P_T = total pressure, usually 1.0 atm

C'_o = the concentration of solute in liquid that is in equilibrium with the gas leaving the tower, moles of solute per mole of liquid

Using Eq. (11–79), Eq. (11–78) can be written as follows:

$$C'_o = \frac{P_T}{H} \times \frac{L}{G}(C_o - C_e) \tag{11–80}$$

If it is assumed that the concentration of solute in the liquid entering the tower is in equilibrium with the gas leaving the tower, Eq. (11–80) can be written as:

$$\frac{G}{L} = \frac{P_T}{H} \times \frac{(C_o - C_e)}{C_o} \tag{11–81}$$

The operating line for the condition defined by Eq. (11–81) is shown on Fig. 11–61(c). The value of G/L (air to liquid ratio) defined by Eq. (11–81) represents the minimum amount of air that can be used for stripping for the given conditions (i.e, $y_o = 0$ and $y_e = HC_o/P_T$). In practice, from one and a half to three times the theoretical minimum air to liquid ratio is used to achieve effective stripping of most constituents. The application of this relationship is illustrated in Example 11–15.

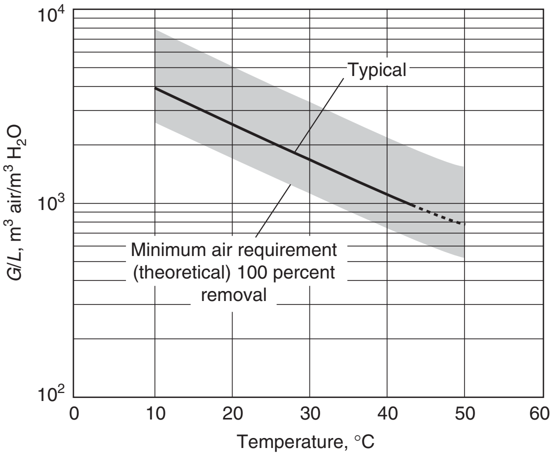
If it is assumed further that the liquid leaving and the air entering the bottom of the tower contains no solute, then Eq. (11–81) can be written as

$$\frac{G}{L} = \frac{P_T \times C_o}{H \times C_o} = \frac{P_T}{H} \tag{11–82}$$

The value of G/L for this condition corresponds to the equilibrium line defined by Henry's law [see Fig. 11–61(d)], and represents the theoretical minimum amount of air that can be used for stripping for the given conditions (i.e., $y_o = 0$, $C_e = 0$, and $y_e = HC_o/P_T$). The range of air-to-liquid ratios for stripping ammonia from wastewater as a function of temperature is plotted on Fig. 11–63. The theoretical ratio is derived by assuming the process

Figure 11–63

Air requirements for ammonia stripping as function of temperature.



to be 100 percent efficient with a stripping tower of infinite height—obviously unachievable in practice. Computation of the theoretical air to water ratio is illustrated in Example 11–15.

EXAMPLE 11–15 **Air Requirements for Ammonia Stripping** Determine the theoretical amount of air required at 20°C to reduce the ammonia concentration from 40 to 1 mg/L in a treated wastewater with a flowrate of 4000 m³/d. Assume that the Henry's constant for ammonia at 20°C is 0.75 atm (see Table 2–7 in Chap. 2) and the air entering the bottom of the tower does not contain any ammonia.

Solution

1. Determine the influent and effluent mole fractions of ammonia in the liquid using Eq. (2–3).

$$x_B = \frac{n_B}{n_A + n_B}$$

where x_B = mole fraction of solute B
n_B = number of moles of solute B
n_A = number of moles of solute A

$$C_o = \frac{[(40 \times 10^{-3})/17]}{[55.5 + (40 \times 10^{-3})/17]} = 4.24 \times 10^{-5} \text{ mole NH}_3/\text{mole H}_2\text{O}$$

$$C_e = \frac{[(1 \times 10^{-3})/17]}{[55.5 + (1 \times 10^{-3})/17]} = 1.06 \times 10^{-6} \text{ mole NH}_3/\text{mole H}_2\text{O}$$

2. Determine the mole fraction of ammonia in the air leaving the tower using Eq. (11–79).

$$y_e = \frac{H}{P_T} C_o$$

$$H = \left[\frac{(0.75 \text{ atm})(\text{mole NH}_3/\text{mole air})}{(\text{mole NH}_3/\text{mole H}_2\text{O})}\right] = (0.75 \text{ atm})\left(\frac{\text{mole H}_2\text{O}}{\text{mole air}}\right)$$

$$y_e = \frac{H}{P_T} \times C_o = \frac{0.75 \text{ atm}}{1.0 \text{ atm}}\left(\frac{\text{mole H}_2\text{O}}{\text{mole air}}\right) \times (4.24 \times 10^{-5}) \text{ mole NH}_3/\text{mole H}_2\text{O}$$

$$= 3.18 \times 10^{-5} \frac{\text{mole NH}_3}{\text{mole air}}$$

3. Determine the gas to liquid ratio using Eq. (11–81) rearranged as follows:

$$\frac{G}{L} = \frac{P_T}{H} \times \frac{(C_o - C_e)}{C_o} = \frac{(C_o - C_e)}{y_e}$$

$$\frac{G}{L} = \frac{(4.24 \times 10^{-5} - 0.106 \times 10^{-5})(\text{mole NH}_3/\text{mole H}_2\text{O})}{(3.18 \times 10^{-6} \text{ mole NH}_3/\text{mole air})} = 1.3 \frac{\text{mole air}}{\text{mole H}_2\text{O}}$$

4. Convert the moles of air and water to liters of air and water.

   For air at 20°C:

   $$1.3 \text{ mole} \times 24.1 \text{ L/mole} = 31.33 \text{ L}$$

   For water:

   $$(1.0 \text{ mole } H_2O)(18 \text{ g/mole})(1\text{L}/1000 \text{ g}) = 0.018 \text{ L}$$

   $$\frac{G}{L} = \frac{31.33 \text{ L air}}{0.018 \text{ L water}} = 1741 \text{ L/L} = 1741 \text{ m}^3/\text{m}^3$$

6. Determine the total quantity of air required based on ideal conditions.

   $$\text{Air required} = \frac{(1741 \text{ m}^3/\text{ m}^3)\ (4000 \text{ m}^3/\text{d})}{(1440 \text{ min/d})} = 4835 \text{ m}^3/\text{min}$$

Comment The procedure followed to determine the height of the stripping tower is illustrated in Example 11–14 presented later in this section. Also, it should be noted that the ammonium must first be converted to ammonia gas for this process to be effective. Steam stripping of ammonia is considered in Chap. 15.

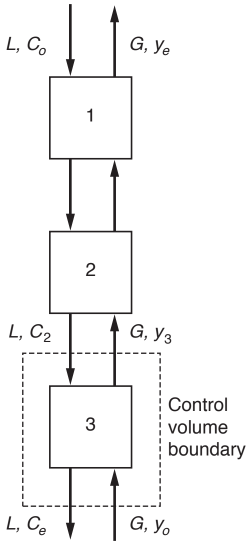


Figure 11–64

Definition sketch for the analysis of a three stage countercurrent flow gas stripping tower.

Mass Balance Analysis of a Multistage Stripping Tower. In the analysis of stripping towers, reference is often made to the number of ideal stages required for stripping. The analysis for the number of stages is analogous to the simulation of plug flow with a series of complete-mix reactors as detailed in Chap. 1. Separate stages are used to improve performance of stripping towers. Equilibrium conditions are assumed in each stage of the tower. A steady-state materials balance for the lower portion of a countercurrent staged stripping tower (see Fig. 11–64) is given by:

inflow = outflow

$$LC_e + Gy_3 = LC_2 + Gy_o \tag{11–83}$$

or

$$(y_3 - y_o) = L/G(C_2 - C_e) \tag{11–84}$$

If an overall mass balance is performed around the tower, the resulting equations are the same as derived above for the continuous stripping tower [see Eq. (11–76)].

In the 1920s McCabe and Theile (1925) developed a graphical procedure for determining the required number of ideal stages. The method is illustrated on Fig. 11–65 for a stripping tower comprised of three stages. The operating line for the three stages is shown on Fig. 11–65. The number of ideal stages required for stripping of a constituent is obtained as follows. The point C_o, y_e represents the air leaving and the water entering the top of the stripping column. The composition of the liquid in equilibrium with the constituent concentration in the air is found by extending a horizontal line from the

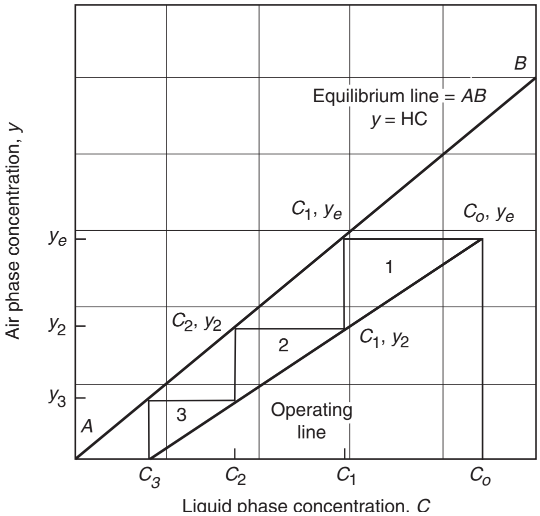

Figure 11–65

Operating line for three-stage countercurrent flow gas stripping tower.

point C_o, y_e to the point C_1, y_e. From the point C_1, y_e the value of y_2, the air entering stage 1 from stage 2, is obtained from the equation of the operating line. If a materials mass balance is performed between stages 1 and 2, the resulting expression for y_2 is:

$$y_2 = \frac{L}{G}C_1 + \frac{Gy_e - LC_o}{G} \tag{11–85}$$

The value of y_2 is obtained by drawing a vertical line from point C_1, y_e to the operating line at point C_1, y_2 as shown on Fig. 11–65. In a similar manner the value of C_2 is obtained by drawing a horizontal line from the point C_1, y_2 to the equilibrium line. This procedure is repeated until the point C_n, y_{n+1} is reached. The number of ideal stages is typically a fractional number (e.g., 4.2, 5.6, etc.). In practice, the number of stages is rounded to the next whole number.

Determination of Height of Stripping Tower Packing. The purpose of the following analysis is to illustrate how the height of a stripping tower packing is determined, based on an analysis of the mass transfer occurring within the tower. A mass balance performed on the liquid phase within the stripping tower shown on Fig. 11–66 is as follows.

Simplified word statement

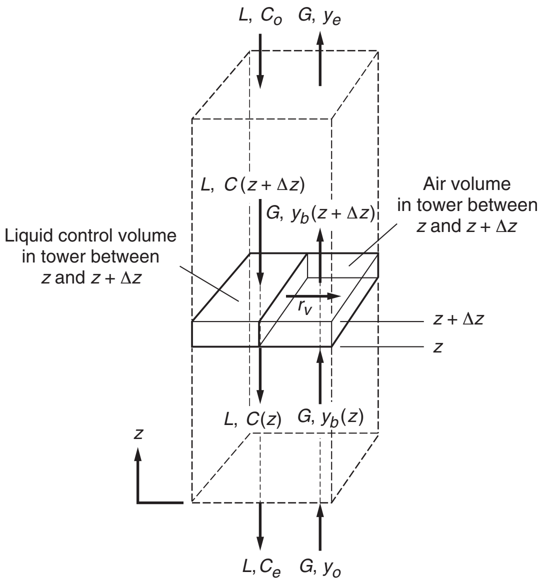
Accumulation = inflow − outflow + generation

$$\frac{\partial C}{\partial t}\Delta V = LC\big|_z - LC\big|_{z+\Delta z} + r_V \Delta V \tag{11–86}$$

where $\partial C/\partial t$ = change in concentration of constituent C with time, g/m^3·s
ΔV = differential volume, m^3
Δz = differential height, m
L = liquid volumetric flowrate, m^3/s
C = concentration of constituent C, g/m^3
r_V = rate of mass transfer of constituent C per unit volume per unit time, g/m^3·s

Figure 11–66

Definition sketch for the analysis of mass transfer within a stripping tower. Note: the packing material is not shown. (Adapted from Hand et al., 1999.) (LD)



Substituting area times the differential height ($A\Delta z$) for the differential volume (ΔV) and writing the differential form for the term $LC|_{Z+\Delta Z}$ in Eq. (11–86) results in the following expression:

$$\frac{\partial C}{\partial t}A\Delta z = LC - L\left(C + \frac{\Delta C}{\Delta z}\Delta z\right) + r_V A\Delta z \tag{11–87}$$

Simplifying Eq. (11–87) and taking the limit as Δz approaches zero yields

$$\frac{\partial C}{\partial t} = -\frac{L}{A}\frac{\partial C}{\partial z} + r_V \tag{11–88}$$

The rate of mass transfer as described in Chap. 5 [see Eq. (5–57)]:

$$r_V = K_L a(C_b - C_s) \tag{11–89}$$

where r_V = rate of mass transfer of constituent C per unit volume per unit time, g/m³·s
K_La = volumetric mass transfer coefficient which depends on water quality characteristics and temperature, 1/s
C_b = concentration of constituent C in liquid bulk phase at time t, g/m³
C_S = concentration of constituent C in liquid in equilibrium with gas as given by Henry's law, g/m³

Assuming steady-state conditions within the tower ($\partial C/\partial t = 0$) and substituting for r_V, Eq. (11–88) can now be written as:

$$\frac{dC_b}{dz} = \frac{K_L aA}{L}(C_b - C_s) \tag{11–90}$$

The height of the tower can be obtained by integrating the above expression:

$$\int_o^Z dz = \frac{L}{K_L aA} \int_{C_e}^{C_o} \frac{dC_b}{(C_b - C_s)} \tag{11–91}$$

To integrate the right hand side of the above equation, a relationship must be found between C_b and C_s because C_s is changing continuously throughout the height of the tower. From Henry's law, the value of C_s is given by:

$$C_s = \frac{P_T}{H} y \tag{11–92}$$

Substituting a modified form of Eq. (11–78) for y in Eq. (11–92) yields:

$$C_s = \frac{P_T}{H} \times \frac{L}{G}(C_b - C_e) \tag{11–93}$$

If Eq. (11–93) is substituted into Eq. (11–91) and the resulting expression is integrated, the following expression is obtained (Hand et al., 1999)

$$Z = \frac{L}{K_L a A}\left(\frac{C_o - C_e}{C_o - C_e - C_o'}\right) \text{In} \left(\frac{C_o - C_o'}{C_e}\right) \tag{11–94}$$

where Z = height of stripping tower packing, m

$C_o' = \frac{P_T}{H} \times \frac{L}{G}(C_o - C_e)$, given previously [see Eq. (11–80)]

It should be noted that if $C_o' = C_o$, Eq. (11–80) is the same as Eq. (11–81).

Design Equations for Stripping Towers. Utilizing the above equations, a number of process models and design equations have been developed. Equations that can be used to determine the height of a stripping tower are as follows:

$$Z = \text{HTU} \times \text{NTU} \tag{11–95}$$

where Z = height of stripping tower packing material, m
HTU = height of a transfer unit, m
NTU = number of transfer units

The height of a transfer unit is defined as:

$$\text{HTU} = \frac{L}{K_L a A} \tag{11–96}$$

where L = liquid volumetric flowrate, m^3/s
$K_L a$ = volumetric mass transfer coefficient, 1/s
A = cross-sectional area of tower, m^2

The HTU is a measure of the mass transfer characteristics of the packing material. The number of transfer units is defined as:

$$\text{NTU} = \left(\frac{C_o - C_e}{C_o - C_e - C_o'}\right) \text{In} \left(\frac{C_o - C_o'}{C_e}\right) \tag{11–97}$$

Substituting Eq. (11–93) in Eq (11–97) yields:

$$\text{NTU} = \left(\frac{S}{S - 1}\right) \text{In} \left[\frac{(C_o/C_e)(S - 1) + 1}{S}\right] \tag{11–98}$$

where S is known as the stripping factor and is defined as:

$$S = \frac{G}{L} \times \frac{H}{P_T} \tag{11–99}$$

A value of $S = 1$ corresponds to the minimum amount of air required for stripping. When $S > 1$ the amount of air is in excess and complete stripping is possible given a tower of infinite height. When $S < 1$, there is insufficient air for stripping. In practice, stripping factors vary from 1.5 to 5.0.

Values for $K_L a$ for specific compounds are best obtained from pilot plant studies or by using empirical correlations such as given in Chap. 16, and repeated here for convenience as Eq. (11–100). It should be noted that many other relationships have been proposed in the literature (Sherwood and Hollaway, 1940 and Onda et al., 1968).

$$K_L a_{\text{VOC}} = K_L a_{O_2} \left(\frac{D_{\text{VOC}}}{D_{O_2}}\right)^n \tag{11–100}$$

where $K_L a_{\text{VOC}}$ = system mass transfer coefficient, 1/h
$K_L a_{O_2}$ = system oxygen mass transfer coefficient, 1/h
D_{VOC} = diffusion coefficient of VOC in water, cm^2/s
D_{O_2} = diffusion coefficient of oxygen in water, cm^2/s
n = coefficient (0.5 for stripping towers)

Air and water temperature are significant factors in the design of stripping towers because of their effect on air and water viscosities, Henry's law constants, and volumetric mass transfer coefficients. The effect of temperature on the Henry's law constant is illustrated on Fig. 11–62. The value of $K_L a$ can be adjusted for temperature effects using Eq. (1–44) with a theta value of 1.024.

Design of Stripping Towers

In its simplest form a stripping tower consists of a tower (usually circular cross-section), a support plate for the packing material, a distribution system for the liquid to be stripped, located above the packing material, and an air supply located at the bottom of the stripping tower (see Fig. 11–59). The process design variables include (1) the type of packing material, (2) the stripping factor, (3) the cross-sectional area of the tower, and (4) the height of the packing material in the stripping tower. The cross-sectional area will depend on the pressure drop through the packing. Representative design values for stripping of VOCs and ammonia are presented in Table 11–45. The significant difference in the amount of air required for stripping is a clear illustration of the importance of the Henry's law constant.

Table 11–45

Typical design parameters for stripping towers for the removal of VOC and ammonia[a]

Item	Symbol	Unit	VOC removal[b]	Ammonia removal[c]
Liquid loading rate		$L/m^2 \cdot min$	600–1,800	40–80
Air to liquid ratio[d]	G/L	m^3/m^3	20–60:1	2,000–6,000:1
Stripping factor	S	unitless	1.5–5.0	1.5–5.0
Allowable air pressure drop,	ΔP	$(N/m^2)/m$	100–400	100–400
Height to diameter ratio	H/D	m/m	$\leq$10:1	$\leq$10:1
Packing depth[e]	D	m	1–6	2–6
Factor of safety	SF	%D, %H	20–50	20–50
Wastewater pH	pH	unitless	5.5–8.5	10.8–11.5
Approximate packing factors				
Pall rings, Intalox saddles				
12.5 mm[f]	C_f	1/m	180–240	180–240
25 mm[f]	C_f	1/m	30–60	30–60
50 mm[f]	C_f	1/m	20–25	20–25
Berl saddles, Raschig rings				
12.5 mm[f]	C_f	1/m	300–600	300–600
25 mm[f]	C_f	1/m	120–160	120–160
50 mm[f]	C_f	1/m	45–60	45–60

[a] Adapted in part from Eckert (1970, 1975), Kavanaugh and Trussell (1980), and Hand (1999).

[b] Typical data for VOCs with Henry's law constants greater than 500 atm (mole H_2O/mole air).

[c] Ammonia with a Henry's law constant of 0.75 atm (mole H_2O/mole air) is considered only marginally strippable, which accounts for the low loading rate and high air to liquid ratio.

[d] Ratio is highly temperature dependent.

[e] For packing depths greater than 5 to 6 m, redistribution of the liquid flow is recommended.

[f] Size of packing material.

The headloss through the packing is determined using a generalized gas pressure drop relationships such as plotted on Fig. 11–67 (Eckert, 1975). The pressure drop is expressed in Newton per square meter per meter of depth $(N/m^2)/m$. The upper line on Fig. 11–67 labeled *approximate flooding* represents the condition that occurs when the amount of water and air applied are so great that the pore spaces fill to the point where water starts to flood within the tower. The units for the x and y axis are as follows

X axis:

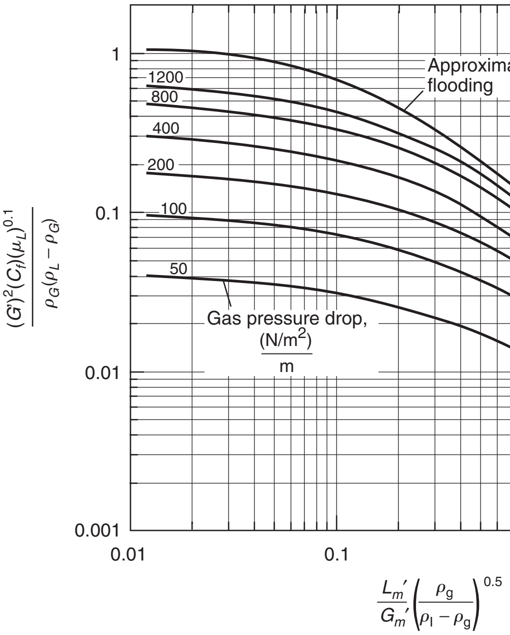
$$x = \frac{L'}{G'}\left(\frac{\rho_G}{\rho_L - \rho_G}\right)^{1/2} \approx \frac{L'}{G'}\left(\frac{\rho_G}{\rho_L}\right)^{1/2} \tag{11–101}$$

Y axis:

$$y = \frac{(G')^2(C_f)(\mu_L)^{0.1}}{(\rho_G)(\rho_L - \rho_G)} \tag{11–102}$$

Figure 11–67

Generalized pressure drop curves for packed bed stripping towers. Note the curves in this plot have been converted to metric units from US customary units in which the original curves were plotted. (Adapted from Eckert, 1975.)



Which can be rewritten as follows:

$$G' = \left[\frac{(\text{value from } y \text{ axis})(\rho_G)(\rho_L - \rho_G)}{(C_f)(\mu_L)^{0.1}}\right]^{1/2} \tag{11–103}$$

where L' = liquid loading rate, kg/m^2·s
G' = gas loading rate, kg/ m^2·s
ρ_G = density of gas, kg/m^3
ρ_L = density of liquid, kg/m^3
C_f = packing factor for packing material, 1/m
μ_L = viscosity of liquid, kg/m·s

The packing factor C_f depends on the type and size of the packing. Typical ranges for packing factors that can be used for preliminary assessments are reported in Table 11–35. For more detailed design calculations, current values should be obtained from manufacturers.

To use Fig. 11–67, select a value for G'/L' and compute the corresponding x value. Enter the plot at the computed value of x and move vertically upward to a preselected pressure drop line. Move horizontally from the point of intersection to the y axis and note the value on the y axis. Using the y-axis value, determine the gas loading rate, G', using Eq. (11–103) and the corresponding liquid loading rate, L'. To determine the required cross-sectional area, the liquid flowrate is divided by the liquid loading rate.

A generalized analysis procedure is as follows:

1. Select a packing material and its corresponding packing factor for use in Eq. (11–101).
2. Select several stripping factors for successive trials (e.g., 2.5, 3.0, 4.0, etc.).
3. Select acceptable pressure drop ΔP (typically a function of the packing material selected).
4. Determine the cross-sectional area of the tower, based on the allowable pressure drop, using the data presented on Fig. 11–67 or other appropriate relationships.

5. Determine the height of the transfer units using Eq. (11–96). To apply Eq. (11–96) the value of K_La must be known or estimated using Eq. (11–100).
6. Determine the number of transfer units using Eq. (11–98).
7. Determine the height of the stripping tower packing material using Eq. (11–95).
8. Determine the total height of the stripping tower. To account for the entrance plenum and exit gas collection system, an additional 2 to 3 m is added to the computed height of the packing to obtain the overall height of the stripping tower.

The design procedure outlined above is illustrated in Example 11–16. Representative design values for stripping towers are given in Table 11–45. To evaluate the stripping process more thoroughly, any of the commercially available software packages can be used.

EXAMPLE 11–16 **Determination of Height of Stripping Tower for the Removal of Ammonia** Determine the diameter and height of the stripping tower required to treat the wastewater in Example 11–15. The ammonia concentration in a treated wastewater from a flow of 4000 m^3/d is to be reduced from 40 to 1 mg/L. Assume that the Henry's law constant for ammonia at 20°C is 0.75 atm, and the air entering the bottom of the tower does not contain any ammonia. Assume the K_La value for ammonia is 0.0125 s^{-1}.

Solution

1. Select a packing material. Assume a packing factor of 20 for 50 mm Pall rings (see Table 11–45).
2. Select a stripping factor. Assume a stripping factor of 3.
3. Select an acceptable pressure drop. Assume a pressure drop of 400 $(N/m^2)/m$ (see Table 11–45).
4. Determine the cross-sectional area of the stripping tower using the pressure drop plot given on Fig. 11–67.
   a. Determine the value of the ordinate value for a stripping factor of 3.

$$S = \frac{G}{L} \times \frac{H}{P_T} = \frac{G \text{ mole air}}{L \text{ mole water}} \times \frac{0.75 \text{ atm}}{1.0 \text{ atm}} = \frac{G \text{ mole air}}{L \text{ mole water}} \times 0.75$$

$$S = 0.75 \times \left(\frac{G \text{ mole air}}{L \text{ mole water}}\right)\left(\frac{28.8 \text{ g}}{\text{mole air}}\right)\left(\frac{\text{mole water}}{18 \text{ g}}\right) = 1.2\frac{G \text{ g}}{L \text{ g}} = 1.2\frac{G' \text{ kg}}{L' \text{ kg}}$$

$$\frac{L'}{G'} = \frac{(1.2 \text{ kg/kg})}{3} = 0.4$$

$$\frac{L'}{G'}\left(\frac{\rho_G}{\rho_L - \rho_G}\right)^{1/2} \approx \frac{L'}{G'}\left(\frac{\rho_G}{\rho_L}\right)^{1/2} = (0.4 \text{ kg/kg})\left[\frac{(1.204 \text{ kg/m}^3)}{(998.2 \text{ kg/m}^3)}\right]^{1/2} = 0.0139$$

   b. For an abscissa value of 0.0139 and a pressure drop of 400 $(N/m^2)/m$, the ordinate value from Fig. 11–67 is 0.3.
   c. Using an ordinate value 0.3, determine the loading rate using Eq. (11–103). From Appendix *C*, $\mu_L = 1.002$ kg/m·s

$$G' = \left[\frac{(\text{value from } y \text{ axis})(\rho_G)(\rho_L - \rho_G)}{(C_f)(\mu_L)^{0.1}}\right]^{1/2}$$

$$G' = \left[\frac{(0.3)(1.204)(998.2 - 1.204)}{(20)(1.002)^{0.1}}\right]^{1/2} = 4.24 \text{ kg/m}^2\text{·s}$$

$L' = 0.4\,G' = 0.4 \times 4.24 \text{ kg/m}^2\text{·s} = 1.70 \text{ kg/m}^2\text{·s}$

d. Solve for the diameter of the tower, using the loading rate determined in Step 4.

$$D = \left[\frac{4}{3.14} \times \frac{(4000 \text{ m}^3/\text{d})(998.2 \text{ kg/m}^3)}{(4.24 \text{ kg/m}^2\text{·s})} \times \frac{1 \text{ d}}{86{,}400 \text{ s}}\right]^{1/2} = 3.73 \text{ m}$$

5. Determine the height of the transfer unit using Eq. (11–96).

$$\text{HTU} = \frac{L}{K_L a A}$$

$$\text{HTU} = \frac{L}{K_L a A} = \left[\frac{(4000 \text{ m}^3/\text{d})}{(0.0125/\text{s})[(3.14/4)(3.73)^2]} \times \frac{1 \text{ d}}{86{,}400 \text{ s}}\right] = 0.34 \text{ m}$$

6. Determine the number of transfer units using Eq. (11–98).

$$\text{NTU} = \left(\frac{S}{S - 1}\right) \ln\left[\frac{(C_o/C_e)(S - 1) + 1}{S}\right]$$

$$\text{NTU} = \left(\frac{3}{3 - 1}\right) \ln\left[\frac{(40/1)(3 - 1) + 1}{3}\right] = 4.94$$

7. Determine the theoretical height of the stripping tower packing using Eq. (11–95).

$Z = \text{HTU} \times \text{NTU} = 0.34 \times 4.94 = 1.68 \text{ m}$

8. Determine the total height of the stripping tower.

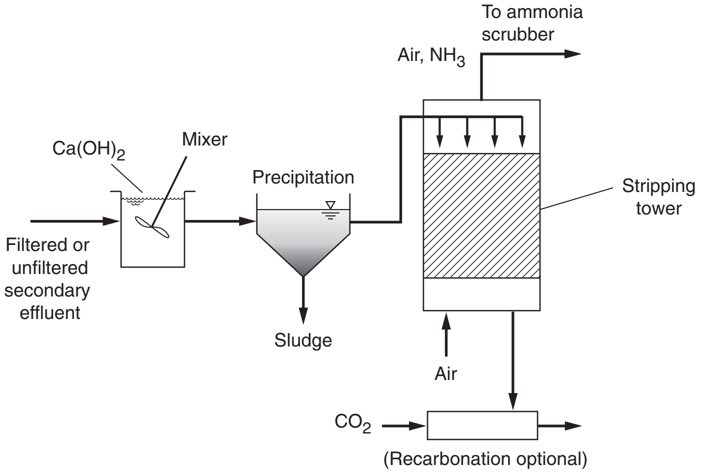
Add 3 m to obtain the total height of the stripper

Hstripper = Hpacking, m + 3 m = 1.68 m + 3 m = 4.68 m

Comment In this example, the value of $K_L a$ for ammonia was known. Quite often the required $K_L a$ value must be determined in the field, using pilot scale facilities. Alternatively Eq. (11–100) can be used to estimate a value for $K_L a$. In some cases, data from the literature or from manufacturers may be used to obtain preliminary sizing. Because of the relatively low Henry's law constant, a large surface area is required to achieve the desired ammonia removal. Further, because of the relatively large radius that is required, it is likely that two stripping towers, each with a radius and area of about 2.6 and 5.3 m^2, respectively would be used to optimize air flow. To optimize the design, various stripping ratios must be evaluated. Optimization is best accomplished using one of the commercially available stripping tower software packages. Because the Henry's law constant for ammonia is so low (0.75 atm), ammonia is often not considered amenable or suitable for stripping at ambient temperatures and is seldom done. Steam stripping of the concentrated ammonia present in return flows from sludge processing is considered in Chap. 15.

Figure 11–68

Typical flow diagram for the air stripping of ammonia from wastewater.



Air Stripping Applications

As noted previously, air stripping is used to remove a variety of gaseous constituents including VOCs, carbon dioxide (CO_2), oxygen (O_2), hydrogen sulfide (H_2S), and ammonia (NH_3). The removal and treatment of VOCs in aeration systems is considered in Sec. 16–4 in Chap. 16. The removal and treatment of odorous compounds (e.g., H_2S) is considered in Sec. 16–3 in Chap. 16. Air stripping has been used for the removal of ammonia from various wastewaters including untreated and treated wastewater, digester supernatant (also by steam stripping), and for the recovery of ammonia from return flows. The recovery of ammonia from return flows is considered in detail in Chap. 15. Ammonia stripping from wastewater is considered briefly below.

A typical flow diagram for the removal of ammonia from wastewater by air stripping is shown on Fig. 11–68. In most cases where ammonia stripping has been tried with wastewater, a number of operating problems have developed, the most serious being (1) maintaining the required pH for effective stripping, (2) calcium carbonate scaling within the tower and feed lines, and (3) poor performance during cold weather operation. Maintaining the required pH is a control problem that can be managed with multiple sensors. The amount and nature (soft to extremely hard) of the calcium carbonate scale formed varies with the characteristics of the wastewater and local environmental conditions and cannot be predicted a priori. Under conditions of icing, the liquid-air contact geometry in the tower is altered, which further reduces the overall efficiency. The best solution for cold weather conditions is to enclose the stripper. For the reasons cited above and cost, ammonia stripping from wastewater is seldom done. However, ammonia stripping is done on concentrated return flows resulting from the treatment of biosolids. The use of ammonia stripping for the recovery of nitrogen in the form of ammonium sulfate is considered in Chap. 15.

11–11 ION EXCHANGE

Ion exchange is a unit process in which ions of a given species are displaced from an insoluble exchange material by ions of a different species in solution. The most widespread use of this process is in domestic water softening, where sodium ions from a cationic exchange resin replace the calcium and magnesium ions in the treated water, thus reducing the hardness. Ion exchange has been used in wastewater applications for the removal of nitrogen, heavy metals, and total dissolved solids.

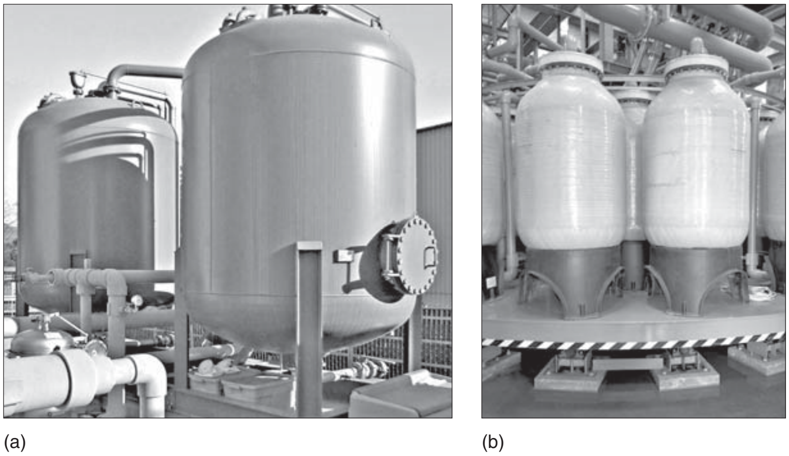


Figure 11–69

Two examples of full scale ion exchange installations: (a) large downflow packed-bed columns, and (b) ion exchange canisters on a rotating platform. The canisters are rotated so that one canister can be regenerated while the others are in operation.

(a) (b)

Ion exchange processes can be operated in a batch or continuous mode. In a batch process, the resin is stirred with the water to be treated in a reactor until the reaction is complete. The spent resin is removed by settling and subsequently is regenerated and reused. In a continuous process, the exchange material is placed in a bed or a packed column, similar to the one shown previously on Fig. 11–56(a), and the water to be treated is passed through it. Continuous ion exchangers are usually of the downflow, packed-bed column type. Wastewater enters the top of the column under pressure, passes downward through the resin bed, and is removed at the bottom. When the resin capacity is exhausted, the column is backwashed to remove trapped solids and is then regenerated. Two examples of commercial ion exchange reactors are shown on Fig. 11–69.

Ion Exchange Materials

Naturally occurring ion exchange materials, known as zeolites, are used for water softening and ammonium ion removal. Zeolites used for water softening are complex aluminosilicates with sodium as the mobile ion. Ammonium exchange is accomplished using a naturally occurring zeolite, clinoptilolite. Synthetic aluminosilicates are manufactured, but most synthetic ion exchange materials are resins or phenolic polymers. Five types of synthetic ion exchange resins are in use: (1) strong-acid cation, (2) weak-acid cation, (3) strong-base anion, (4) weak-base anion, and (5) heavy-metal selective chelating resins. The properties of these resins are summarized in Table 11–46.

Most synthetic ion exchange resins are manufactured by a process in which styrene and divinylbenzene are copolymerized. The styrene serves as the basic matrix of the resin and divinylbenzene is used to cross link the polymers to produce an insoluble tough resin. Important properties of ion exchange resins include exchange capacity, particle size, and stability. The exchange capacity of a resin is defined as the quantity of an exchangeable ion that can be taken up. The exchange capacity of resins is expressed as eq/L or eq/kg (meq/L or meq/g). The particle size of a resin is important with respect to the hydraulics of the ion exchange column and the kinetics of ion exchange. In general, the rate of exchange is proportional to the inverse of the square of the particle diameter. The stability of a resin is important to the long-term performance of the resin. Excessive osmotic swelling and shrinking, chemical degradation, and structural changes in the resin caused by physical stresses are important factors that may limit the useful life of a resin.

Table 11–46

Classification of ion exchange resins[a]

Type of resin	Characteristics
Strong-acid cation resins	Strong-acid resins behave in a manner similar to a strong-acid, and are highly ionized in both the acid (R–SO_3H) and salt (R–SO_3Na) form, over the entire pH range.
Weak-acid cation resins	Weak-acid resins have a weak-acid functional group (–COOH), typically a carboxylic group. These resins behave like weak organic acids that are weakly dissociated.
Strong-base anion resins	Strong-base resins are highly ionized having strong-base functional groups such as (OH^-); and can be used over the entire pH range. These resins are used in the hydroxide (OH^-) form for water deionization.
Weak-base anion resins	Weak-base resins have weak-base functional groups in which the degree of ionization is dependent on pH.
Heavy-metal selective chelating resins	Chelating resins behave like weak-acid cation resins, but exhibit a high degree of selectivity for heavy-metal cations. The functional group in most of these resins is EDTA, and the resin structure in the sodium form is R–EDTA–Na.

[a] Adapted in part from Ford (1992).

Typical Ion Exchange Reactions

Typical ion exchange reactions for natural and synthetic ion exchange materials are given below.

For natural zeolites used in water softening (Z):

$$ZNa_2 + \begin{bmatrix} Ca^{2+} \\ Mg^{2+} \\ Fe^{2+} \end{bmatrix} \rightleftarrows Z \begin{bmatrix} Ca^{2+} \\ Mg^{2+} \\ Fe^{2+} \end{bmatrix} + 2Na^+ \tag{11–104}$$

For synthetic resins (R):

Strong-acid cation exchange:

$$RSO_3H + Na^+ \rightleftarrows RSO_3Na + H^+ \tag{11–105}$$

$$2RSO_3Na + Ca^{2+} \rightleftarrows (RSO_3)_2Ca + 2Na^+ \tag{11–106}$$

Weak-acid cation exchange:

$$RCOOH + Na^+ \rightleftarrows RCOONa + H^+ \tag{11–107}$$

$$2RCOONa + Ca^{2+} \rightleftarrows (RCOO)_2Ca + 2Na^+ \tag{11–108}$$

Strong-base anion exchange:

$$RR'_3NOH + Cl^- \rightleftarrows RR'_3NCl + OH^- \tag{11–109}$$

Weak-base anion exchange:

$$RNH_3OH + Cl^- \rightleftarrows RNH_3Cl + OH^- \tag{11–110}$$

$$2RNH_3OCl + SO_4^{2-} \rightleftarrows (RNH_3)_2SO_4 + 2Cl^- \tag{11–111}$$

Exchange Capacity of Ion Exchange Resins

Reported exchange capacities vary with the type and concentration of regenerant used to restore the resin (see table 11–47.) Typical synthetic resin exchange capacities are in the range of 2 to 10 eq/kg of resin. Zeolite cation exchangers used for water softening have exchange capacities of 0.05 to 0.1 eq/kg. Exchange capacity is measured by placing the resin in a known form. A cationic resin would be washed with a strong-acid to place all of the exchange sites on the resin in the H^+ form or washed with a strong NaCl brine to place all of the exchange sites in the Na^+ form. A solution of known concentration of an exchangeable ion (e.g., Ca^{2+}) can then be added until exchange is complete and the amount of exchange capacity can be measured, or in the acid case, the resin is titrated with a strong- base. Determination of the capacity of an ion exchange resin based on titration is illustrated in Example 11–17.

Exchange capacities for resins often are expressed in terms of grams $CaCO_3$ per cubic meter of resin (g/m^3) or gram equivalents per cubic meter ($g\text{-eq}/m^3$). Conversion between these two units is accomplished using the following expression:

$$\frac{1\text{ g-eq}}{m^3} = \frac{(1\text{ g-eq})\left(\dfrac{100\text{ g CaCO}_3}{2\text{ g-eq}}\right)}{m^3} = 50\text{ g CaCO}_3/m^3 \tag{11–112}$$

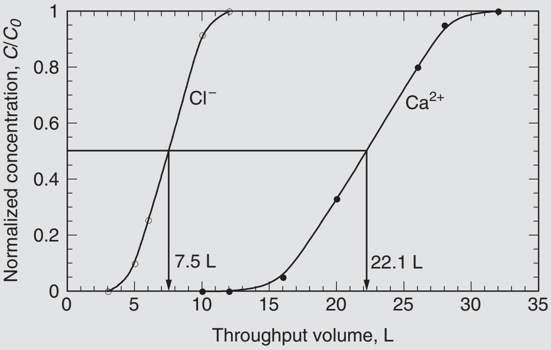
Calculation of the required resin volume for an ion-exchange process is also illustrated in Example 11–17.

EXAMPLE 11–17 **Determination of Ion Exchange Capacity for a New Resin** A column study was conducted to determine the capacity of a cation exchange resin. In conducting the study, 0.1 kg of resin was washed with NaCl until the resin was in the R-Na form. The column was then washed with distilled water to remove the chloride ion (Cl^-) from the intersticies of the resin. The resin was then titrated with a solution of calcium chloride ($CaCl_2$), and the concentrations of chloride and calcium were measured at various throughput volumes. The measured concentrations of Cl^- and Ca^{2+} and the corresponding throughput volumes are as given below. Using the data given below, determine the exchange capacity of the resin and the mass and volume of a resin required to treat 4000 m^3 of water containing 18 mg/liter of ammonium ion (NH_4^+). Assume the density of the resin is 700 kg/m^3.

Throughput volume, L	Constituent, mg/L	
	Cl^-	Ca^{2+}
2	0	0
3	trace	0
5	7	0
6	18	0
10	65	0
12	71	trace
20	71	13
26	71	32
28	71	38
32	$C_o = 71$	$C_o = 40$

Solution

1. Prepare a plot of the normalized concentrations of Cl^- and Ca^{2+} as a function of the throughput volume. The required plot is given below.



2. Determine the exchange capacity.
The exchange capacity (EC) of the resin in meq/kg is:

$$EC = \frac{VC_o}{R}$$

where V = throughput volume between the Cl^- and Ca^{2+} breakthrough curves at $C/C_o = 0.5$
C_o = initial calcium concentration in meq/L
R = amount of resin in kg

$$EC = \frac{(22.1\text{ L} - 7.5\text{ L})\left[\dfrac{(40\text{ mg/L})}{(20\text{ mg/meq})}\right]}{0.1\text{ kg of resin}} = 292\text{ meq/kg of resin}$$

3. Determine the mass and volume of resin required to treat 4000 m^3 of water containing 18 mg/liter of ammonium ion NH_4^+.
   a. Determine the meq of NH_4^+.

   $$NH_4^+\text{, meq/L} = \frac{(18\text{ mg/L as }NH_4^+)}{(18\text{ mg/meq})} = 1\text{ meq/L}$$

   b. The required exchange capacity is equal to

   $$(1.0\text{ meq/L})(4000\text{ m}^3)(10^3\text{ L/m}^3) = 4 \times 10^6\text{ meq}$$

   c. The required mass of resin is

   $$R_{\text{mass}}\text{, kg} = \frac{4 \times 10^6\text{ meq}}{(292\text{ meq/kg of resin})} = 13{,}700\text{ kg}$$

   d. The required volume of resin is

   $$R_{\text{vol}}\text{, m}^3 = \frac{13{,}700\text{ kg of resin}}{(700\text{ kg/m}^3)} = 19.6\text{ m}^3$$

Comment In practice, because of leakage and other operational and design limitations, the required volume of resin will usually be about 1.1 to 1.4 times that computed on the basis of exchange capacity. Also, the above computation is based on the assumption that the entire capacity of the resin is utilized.

Table 11–47

Characteristics of ion exchange resins used in wastewater treatment processes[a]

Resin Type	Acronym	Fundamental reaction[b]	Regenerant ions (X)	pK	Exchange capacity, meq/mL	Constituents removed
Strong-acid cation	SAC	$n[RSO_3^-]X^+ + M^{n+} \rightleftarrows$ $[nRSO_3^-]M^{n+} + nX^+$	H^+ or Na^+	<0	1.7 to 2.1	H^+ form: any cation; Na^+ form: divalent cations
Weak-acid cation	WAC	$n[RCOO^-]X^+ + M^{n+} \rightleftarrows$ $[nRCOO^-]M^{n+} + nX^+$	H^+	4 to 5	4 to 4.5	Divalent cations first, then monovalent cations until alkalinity is consumed
Strong-base anion (type 1)	SBA–1[c]	$n[R(CH_3)_3N^+]X^- + A^{n-} \rightleftarrows$ $[nR(CH_3)_3N^+]A^{n-} + nX^-$	OH^- or Cl^-	>13	1 to 1.4	OH^- form: any anion; Cl^- form: sulfate, nitrate, perchlorate, etc.
Stong-base anion (type 2)	SBA–2[d]	$n[R(CH_3)_2(CH_3CH_2OH)N^+]X^- + A^{n-} \rightleftarrows$ $[nR(CH_3)_2(CH_3CH_2OH)N^+]A^{n-} + nX^-$	OH^- or Cl^-	>13	2 to 2.5	OH^- form: any anion; Cl^- form: sulfate, nitrate, perchlorate, etc.
Weak-base anion	WBA	$[R(CH_3)_2N]HX + HA \rightleftarrows$ $[R(CH_3)_2N]HA + HX$	OH^-	5.7 to 7.3	2 to 3	Divalent anions first, then monovalent anions until strong-acid is consumed

[b] Term within the brackets represents the solid phase of the resin.

[c] Greater chemical stability than SBA–1.

[d] Greater regeneration efficiency and capacity than SBA–2.

Ion Exchange Chemistry

The chemistry of the ion exchange process may be represented by the following equilibrium expression for the reaction of constituent A on a cation exchange resin and constituent B in solution.

$$nR^-A^+ + B^{n+} \rightleftarrows R_n^-B^{n+} + nA^+ \qquad (11\text{–}113)$$

where R^- is the anionic group attached to an ion exchange resin and A and B are cations in solution. The generalized form of the equilibrium expression for the above reaction is

$$\frac{[A^+]_S^n[R_n^-B^{n+}]_R}{[R^-A^+]_R^n[B^{n+}]_S} = K_{A^+ \rightarrow B^{n+}} \qquad (11\text{–}114)$$

where $K_{A^+ \rightarrow B^{n+}}$ = selectivity coefficient
$[A^+]_S$ = concentration of A in solution
$[R^-A^+]_R$ = concentration A on the exchange resin

The reactions for the removal of sodium (Na^+) and calcium (Ca^{2+}) ions from water using a strong-acid synthetic cationic exchange resin R, and the regeneration of the exhausted resins with hydrochloric acid (HCl) and sodium chloride (NaCl) are as follows:

Reaction:

$$R^-H^+ + Na^+ \rightleftarrows R^-Na^+ + H^+ \tag{11–115}$$

$$2R^-Na^+ + Ca^{2+} \rightleftarrows R_2^-Ca^{2+} + 2Na^+ \tag{11–116}$$

Regeneration:

$$R^-Na^+ + HCl \rightleftarrows R^-H^+ + NaCl \tag{11–117}$$

$$R_2^-Ca^{2+} + 2NaCl \rightleftarrows 2R^-Na^+ + CaCl_2 \tag{11–118}$$

The corresponding equilibrium expressions for sodium and calcium are as follows:

For sodium:

$$\frac{[H^+][R^-Na^+]}{[R^-H^+][Na^+]} = K_{H^+ \rightarrow Na^+} \tag{11–119}$$

For calcium:

$$\frac{[Na^+]^2[R^-Ca^{2+}]}{[R^-Na^+]^2[Ca^{2+}]} = K_{Na^+ \rightarrow Ca^{2+}} \tag{11–120}$$

The selectivity coefficient depends primarily on the nature and valence of the ion, the type of resin and its saturation, and the ion concentration in wastewater and typically is valid over a narrow pH range. In fact, for a given series of similar ions, exchange resins have been found to exhibit an order of selectivity or affinity for the ions. Approximate selectivity coefficients for cationic and anionic resins are given in Tables 11–48 and 11–49,

Table 11–48

Approximate selectivity coefficients scale for cations on 8 percent cross-linked strong-acid ion exchange resins[a]

Cation	Selectivity coefficient	Cation	Selectivity coefficient
Li^+	1.0	Co^{2+}	3.7
H^+	1.3	Cu^{2+}	3.8
Na^+	2.0	Cd^{2+}	3.9
NH_4^+	2.6	Be^{2+}	4.0
K^+	2.9	Mn^{2+}	4.1
Rb^+	3.2	Ni^{2+}	3.9
Cs^+	3.3	Ca^{2+}	5.2
Ag^+	8.5	Sr^{2+}	6.5
Mg^{2+}	3.3	Pb^{2+}	9.9
Zn^{2+}	3.5	Ba^{2+}	11.5

[a] Adapted from Bonner and Smith (1957), see also Slater (1991).

Table 11–49

Approximate selectivity coefficients for anions on strong-base ion exchange resins[a]

Anion	Selectivity coefficient	Anion	Selectivity coefficient
HPO_4^{2-}	0.01	BrO_3^-	1.0
CO_3^{2-}	0.03	Cl^-	1.0
OH^- (Type I)	0.06	CN^-	1.3
F^-	0.1	NO_2^-	1.3
SO_4^{2-}	0.15	HSO_4^-	1.6
CH_3COO^-	0.2	Br^-	3.0
HCO_3^-	0.4	NO_3^-	3.0–4.0
OH^- (Type II)	0.05–0.65	I^-	18.0

[a] Adapted from Peterson (1953) and Bard (1966).

respectively. The use of the selectivity coefficients given in these tables is illustrated in Example 11–18.

Typical selectivity series for synthetic cationic and anionic exchange resins are as follows.

$$Li^+ < H^+ < Na^+ < NH_4^+ < K^+ < Rb^+ < Ag^+ \tag{11–121}$$

$$Mg^{2+} < Zn^{2+} < Co^{2+} < Cu^{2+} < Ca^{2+} < Sr^{2+} < Ba^{2+} \tag{11–122}$$

$$OH^- < F^- < HCO_3^- < Cl^- < Br^- < NO_3^- < ClO_4^- \tag{11–123}$$

In practice, the selectivity coefficients are determined by measurement in the laboratory and are valid only for the conditions under which they were measured. At low concentrations, the value of the selectivity coefficient for the exchange of monovalent ions by divalent ions is, in general, larger than the exchange of monovalent ions by monovalent ions. This fact has, in many cases, limited the use of synthetic resins for the removal of certain substances in wastewater, such as ammonia in the form of the ammonium ion. There are, however, certain natural zeolites that favor NH_4^+ or Cu^{2+}.

Anderson (1975), in a classic paper, developed a method that can be used to evaluate the effectiveness of a proposed ion exchange process using strong ionic resins. In the development proposed by Anderson, it is assumed that at 100 percent leakage, the effluent concentration of a constituent is equal to the influent concentration (i.e., equilibrium has been reached). The equilibrium condition can be assumed to be either the limiting operating exchange capacity of the resin or the capacity corresponding to the maximum regeneration level that can be attained. Using this assumption, Eq. (11–114) is converted from concentration units to units of equivalent fractions by making the following substitutions:

$$X_{A^+} = \frac{[A^+]_S}{C} \text{ and } X_{B^+} = \frac{[B^+]_S}{C} \tag{11–124}$$

$$X_{A^+} + X_{B^+} = 1 \tag{11–125}$$

where X_A^+ and X_B^+ are the equivalent fractions of A and B in solution and C is the total cationic or anionic concentration in solution.

$$\overline{X}_{A^+} = \frac{[R^-A^+]_R}{\overline{C}} \text{ and } \overline{X}_{B^+} = \frac{[R^-B^+]_R}{\overline{C}} \tag{11–126}$$

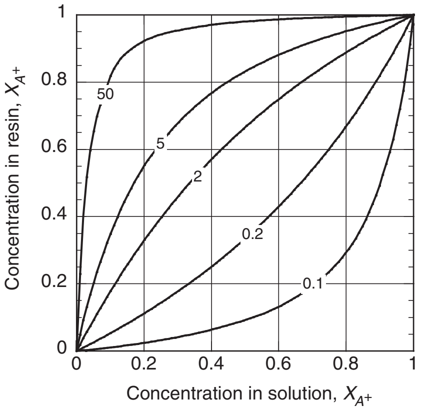

Figure 11–70

Distribution curves for a single monovalent ion A between the solution and the resin for different values of the selectivity coefficient.

$$\bar{X}_{A^+} + \bar{X}_{B^+} = 1 \tag{11–127}$$

Where $\bar{X}_A$ and $\bar{X}_B$ are the equivalent fractions of A and B in the resin and $\bar{C}$ is the total ionic concentration in the resin (i.e., the total resin capacity in eq/L). Substituting the above terms into Eq. (11–114) and simplifying results in the following expression:

$$\frac{\bar{X}_{B^+} X_{A^+}}{\bar{X}_{A^+} X_{B^+}} = K_{A^+ \rightarrow B^+} \tag{11–128}$$

Substituting for X_{A^+} and $\bar{X}_{A^+}$ in Eq. (11–128) results in:

$$\frac{\bar{X}_{B^+}}{1 - \bar{X}_{B^+}} = (K_{A^+ \rightarrow B^+})\left(\frac{X_{B^+}}{1 - X_{B^+}}\right) \tag{11–129}$$

It should be noted that Eq. (11–129) is only valid for exchanges between monovalent ions on fully ionized exchange resins. The distribution of a single monovalent ion A between the solution and the resin for different values of the selectivity coefficient is presented on Fig. 11–70. The distribution curves can be used to assess the effectiveness of a resin for the removal of a given ion, based on the selectivity coefficient.

The following three attributes of Eq. (11–129) were identified by Anderson (1975).

1. The term $\bar{X}_B/(1 - \bar{X}_B)$ corresponds to the state of the resin in an exchange column when the influent and effluent concentrations are the same.
2. The term $\bar{X}_B$ corresponds to the extent to which the resin can be converted to the B^+ form when the resin is in equilibrium with a solution of composition X_B.
3. The term $\bar{X}_B$ also corresponds to the maximum extent of regeneration that can be achieved with a regenerant composition of X_B.

The corresponding equation for exchanges between monovalent and divalent ions on a fully ionized exchange resin is:

$$\frac{\bar{X}_{B^{+2}}}{(1 - \bar{X}_{B^{+2}})^2} = (K_{A^+ \rightarrow B^{+2}})\left(\frac{\bar{C}}{C}\right)\frac{X_{B^{+2}}}{(1 - X_{B^{+2}})^2} \tag{11–130}$$

The application of these equations is illustrated in Example 11–18.

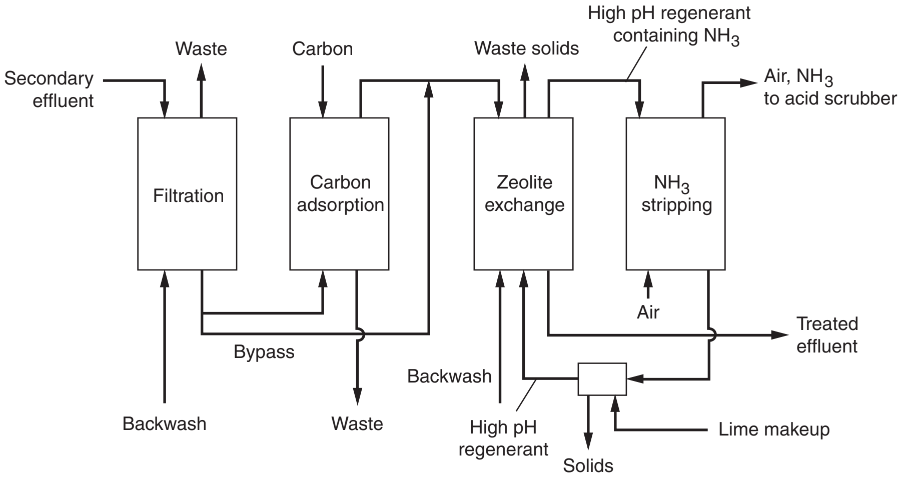

Figure 11–71

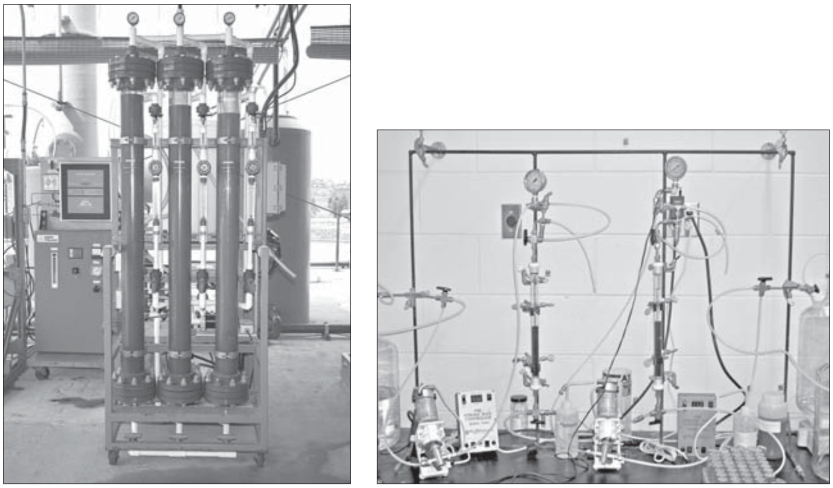
Typical flow diagram for the removal of ammonium by zeolite exchange. Note: the ammonium removed is recovered by high pH air stripping and acid scrubbing.

Application of Ion Exchange

As noted previously, ion exchange has been used in wastewater applications for the removal of nitrogen, heavy metals, and total dissolved solids.

For Nitrogen Control. For nitrogen control, the ions typically removed from the waste stream are ammonium, NH_4^+, and nitrate, NO_3^-. The ion that the ammonium displaces varies with the nature of the solution used to regenerate the bed. Although both natural and synthetic ion exchange resins are available, synthetic resins are used more widely because of their durability. Some natural resins (zeolites) have found application in the removal of ammonium from wastewater. Clinoptilolite, a naturally occurring zeolite, has proven to be one of the best natural exchange resins. In addition to having a greater affinity for ammonium ions than other ion exchange materials, it is relatively inexpensive when compared to synthetic media. One of the novel features of this zeolite is the regeneration system employed. Upon exhaustion, the zeolite is regenerated with lime [$Ca(OH)_2$] and the ammonium ion removed from the zeolite is converted to ammonia because of the high pH. A flow diagram for this process is shown on Fig. 11–71. The stripped liquid is collected in a storage tank for subsequent reuse. A problem that must be solved is the formation of calcium carbonate precipitates within the zeolite exchange bed and in the stripping tower and piping appurtenances. As indicated on Fig. 11–71, the zeolite bed is equipped with backwash facilities to remove the carbonate deposits that form within the filter.

When using conventional synthetic ion exchange resins for the removal of nitrate, two problems are encountered. First, while most resins have a greater affinity for nitrate over chloride or bicarbonate, they have a significantly lower affinity for nitrate as compared to sulfate, which limits the useful capacity of the resin for the removal of nitrate. The impact of the presence of sulfate on the nitrate removal capacity of conventional resins is illustrated in Example 11–18. Second, because of the lower affinity for nitrate over sulfate, a phenomenon known as *nitrate dumping* can occur. Nitrate dumping occurs when an ion exchange column is operated past the nitrate breakthrough, at which point the sulfate in the feed water will displace the nitrate on the resin causing a release of nitrate. To overcome the problems associated with low affinity and nitrate breakthrough, new types of resins have been developed within which the affinities for nitrate and sulfate have been exchanged. When significant amounts of sulfate are present (i.e., typically greater than 25 percent of the total of the sum of the sulfate and nitrate expressed in meq/L), the use of nitrate selective resins is advantageous. Because the performance of nitrate selective resins



(a) (b)

Figure 11–72

Typical ion exchange test columns (a) ion exchange columns used to study the removal of nitrate from water which has been processed with reverse osmosis and (b) bench scale ion exchange columns. (Courtesy of David Hand.)

will vary with the composition of the treated wastewater, pilot testing will usually be required (McGarvey et al., 1989; Dimotsis and McGarvey, 1995). Typical ion exchange test columns used to study the removal of nitrate from water which has been processed with reverse osmosis are shown on Fig. 11–72.

EXAMPLE 11–18 **Ion Exchange for the Removal of Nitrate without and with Sulfate Present in the Water** Nitrate is to be removed from two different treated wastewaters with the compositions given below. For the purpose of illustration, assume a conventional ion exchange resin will be used.

Wastewater A

Cation	Conc., mg/L	mg/meq	meq/L	Anion	Conc., mg/L	mg/meq	meq/L
Ca^{2+}	82.2	20.04	4.10	HCO_3^-	305.1	61.02	5.00
Mg^{2+}	17.9	12.15	1.47	SO_4^{2-}	0.00	48.03	0.00
Na^+	46.4	23.00	2.02	Cl^-	78.0	35.45	2.20
K^+	15.5	39.10	0.40	NO_3^-	50.0	62.01	0.81
		Σcations	7.99			Σanions	8.01

Wastewater B

Cation	Conc., mg/L	mg/meq	meq/L	Anion	Conc., mg/L	mg/meq	meq/L
Ca^{2+}	82.2	20.04	4.10	HCO_3^-	220.0	61.02	3.61
Mg^{2+}	17.9	12.15	1.47	SO_4^{2-}	79.2	48.03	1.65
Na^+	46.4	23.00	2.02	Cl^-	78.0	35.45	2.20
K^+	15.5	39.10	0.40	NO_3^-	50.0	62.01	0.81
		Σcations	7.99			Σanions	8.27

Determine the maximum amount of water that can be processed per liter of a strong-base anion exchange resin with an exchange capacity of 2.0 eq/L.

Solution: Wastewater A

1. Estimate the selectivity coefficient (see Table 11–49). To apply Eq. (11–129) the system must be reduced to two components. For this purpose, HCO_3^- and Cl^- are combined into a single component. Using a selectivity value of 4 for nitrate, the selectivity coefficient is estimated as follows:

$$K_{HCO_3^- \rightarrow NO_3^-} = \frac{4.0}{0.4} = 10.0$$

$$K_{Cl^- \rightarrow NO_3^-} = \frac{4.0}{1.0} = 4.0$$

$$K_{[(HCO_3^-)(Cl^-)] \rightarrow NO_3^-} = 7.0 \text{ (estimated)}$$

2. For the equilibrium condition ($C_e/C_o = 1.0$), estimate the nitrate equivalent fraction in solution.

$$X_{NO_3^-} = \frac{0.81}{8.01} = 0.101$$

3. Compute the equilibrium resin composition using Eq. (11–129).

$$\frac{\overline{X}_{B^+}}{1 - \overline{X}_{B^+}} = (K_{A^+ \rightarrow B^+})\left(\frac{X_{B^+}}{1 - X_{B^+}}\right)$$

$$\frac{\overline{X}_{NO_3^-}}{1 - \overline{X}_{NO_3^-}} = 7.0\left(\frac{0.101}{1 - 0.101}\right)$$

$$\overline{X}_{NO_3^-} = 0.44$$

Thus, 44 percent of the exchange sites on the resin can be used for the removal of nitrate.

4. Determine the limiting operating capacity of the resin for the removal of nitrate.

Limiting operating capacity = (2 eq/L of resin)(0.44) = 0.88 eq/L of resin

5. Determine the volume of water that can be treated during a service cycle.

$$\text{Vol} = \frac{\text{(nitrate removal capacity of resin, eq/L of resin)}}{\text{(nitrate in solution, eq/L of water)}}$$

$$= \frac{(0.88 \text{ eq/L of resin})}{(0.81 \times 10^{-3} \text{ eq/L of water})} = 1086 \frac{\text{L of water}}{\text{L of resin}}$$

Solution: Wastewater B

1. Estimate the selectivity coefficient (see Table 11–49). To apply Eq. (11–130) the system must be reduced to two components. For this purpose, HCO_3^-, Cl^-, and NO_3^- are combined into a single monovalent component. The selectivity coefficient is estimated as follows:

$$K_{HCO_3^- \rightarrow SO_4^{2-}} = \frac{0.15}{0.4} = 0.4$$

$$K_{Cl^- \rightarrow SO_4^{2-}} = \frac{0.15}{1.0} = 0.15$$

$$K_{\mathrm{NO_3^-} \rightarrow \mathrm{SO_4^{2-}}} = \frac{0.15}{4.0} = 0.04$$

$$K_{[(\mathrm{NO_3^-})(\mathrm{HCO_3^-})(\mathrm{Cl^-})] \rightarrow \mathrm{SO_4^{2-}}} = 0.2 \text{ (estimated)}$$

2. For the equilibrium condition ($C_e/C_o = 1.0$), estimate the sulfate equivalent fraction in solution.

$$X_{\mathrm{SO_4^{2-}}} = \frac{1.65}{8.27} = 0.2$$

3. Compute the equilibrium resin composition using Eq. (11–130).

$$\frac{\overline{X}_{B^{2-}}}{(1 - \overline{X}_{B^{2-}})^2} = (K_{A^- \rightarrow B^{2-}})\left(\frac{C}{C}\right)\left[\frac{X_{B^{2-}}}{(1 - X_{B^{2-}})^2}\right]$$

$$\frac{\overline{X}_{\mathrm{SO_4^{2-}}}}{(1 - \overline{X}_{\mathrm{SO_4^{2-}}})^2} = 0.2\frac{2}{0.00827}\left[\frac{0.2}{(1 - 0.2)^2}\right]$$

$\overline{X}_{\mathrm{SO_4^{2-}}} = 0.77$, determined by successive trials

Thus, 77 percent of the exchange sites on the resin will be in the divalent form at equilibrium. The relative amount of $\mathrm{NO_3^-}$ can be estimated by assuming that the remaining 23 percent of the resin sites are in equilibrium with a solution of $\mathrm{NO_3^-}$, $\mathrm{HCO_3^-}$, and $\mathrm{Cl^-}$ with the same relative concentration as the feed.

The equivalent fraction of nitrate in the solution will then be

$$X_{\mathrm{NO_3^-}} = \frac{0.81}{6.62} = 0.12$$

The selectivity coefficient for the monovalent system is estimated:

$$K_{\mathrm{HCO_3^-} \rightarrow \mathrm{NO_3^-}} = \frac{4.0}{0.4} = 10.0$$

$$K_{\mathrm{Cl^-} \rightarrow \mathrm{NO_3^-}} = \frac{4.0}{1.0} = 4.0$$

$$K_{[(\mathrm{HCO_3^-})(\mathrm{Cl^-})] \rightarrow \mathrm{NO_3^-}} = 7.0 \text{ (estimated)}$$

Compute the equilibrium resin composition using Eq. (11–129).

$$\frac{\overline{X}'_{B^+}}{1 - \overline{X}'_{B^+}} = (K_{A^+ \rightarrow B^+})\left(\frac{\overline{X}'_{B^+}}{1 - \overline{X}'_{B^+}}\right)$$

$$\frac{\overline{X}'_{\mathrm{NO_3^-}}}{1 - \overline{X}'_{\mathrm{NO_3^-}}} = 7.0\left(\frac{0.12}{1 - 0.12}\right)$$

$$\overline{X}'_{\mathrm{NO_3^-}} = 0.5$$

The fraction of the total resin capacity in the nitrate form is then computed.

$$\overline{X}_{\mathrm{NO_3^-}} = (1 - \overline{X}_{\mathrm{SO_4^{2-}}})(\overline{X}'_{\mathrm{NO_3^-}}) = (0.23)(0.5) = 0.115$$

4. Determine the limiting operating capacity of the resin for the removal of nitrate.

Limiting operating capacity = (2 eq/L of resin)(0.115) = 0.23 eq/L of resin.

5. Determine the volume of water that can be treated during a service cycle.

$$\text{Vol} = \frac{(\text{nitrate removal capacity of resin, eq/L of resin})}{(\text{nitrate in solution, eq/L of water})}$$

$$= \frac{(0.23\ \text{eq/L of resin})}{(0.81 \times 10^{-3}\ \text{eq/L of water})} = 284\ \frac{\text{L of water}}{\text{L of resin}}$$

Comment As illustrated in this problem, the ionic composition of the wastewater can have a significant effect on the amount of water that can be treated per unit volume of resin, especially where nitrate is to be removed. Because the sulfate is more than 25 percent of the sum of the sulfate and nitrate, the use of a nitrate selective resin would be advantageous in this application. The approximate nature of these calculations also demonstrates the importance of conducting pilot plant tests to establish actual throughput volumes.

Removal of Heavy Metals. Metal removal may be required as a pretreatment before discharge to a municipal sewer system. Because of the potential accumulation and toxicity of these metals, it is desirable to remove them from wastewater effluents before release to the environment. Ion exchange is one of the most common forms of treatment used for the removal of metals. Facilities and activities that may discharge wastewater containing high concentrations of metals include metal processing, electronics industries (semiconductors, printed circuit boards), metal plating and finishing, pharmaceuticals and laboratories, and vehicle service shops. High metal concentrations can also be found in leachate from landfills, and stormwater runoff.

Where industries produce effluents with widely fluctuating metal concentrations, flow equalization may be required to make ion exchange feasible. The economic feasibility of using ion exchange processes for metal removal greatly improves when the process is used for the removal and recovery of valuable metals. Because it is now possible to manufacture resins for specific applications, the use of resins that have a high selectivity for the desired metal(s) also improves the economics of ion exchange.

Materials used for the exchange of metals include zeolites, weak and strong anion and cation resins, chelating resins, and microbial and plant biomass. Biomass materials are generally more abundant, and therefore, less expensive when compared to other commercially available resins. Natural zeolites, clinoptilolite (selective for Cs), and chabazite (mixed metals background Cr, Ni, Cu, Zn, Cd, Pb) have been used to treat wastewater with mixed metal backgrounds (Ouki and Kavannagh, 1999). Chelating resins, such as aminophosphonic and iminodiacetic resins, have been manufactured to have a high selectivity for specific metals such as Cu, Ni, Cd, and Zn.

Ion exchange processes are highly pH dependent. Solution pH has a significant impact on the metal species present and the interaction between exchanging ions and the resin. Most metals bind better at higher pH due to less competition from protons for sites. Operating and wastewater conditions determine selectivity of the resin, pH, temperature, other ionic species, and chemical background. The presence of oxidants, particles, solvents, and polymers may affect the performance of ion exchange resins. The quantity and quality of regenerate produced and subsequently requiring management must also be considered.

Removal of Total Dissolved Solids. For the reduction of the total dissolved solids, both anionic and cationic exchange resins must be used (see Fig. 11–73). The wastewater is

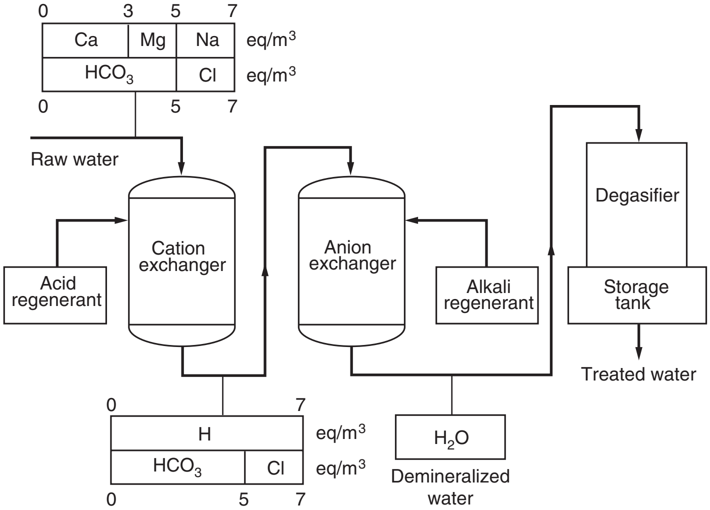


Figure 11–73

Typical flow diagram for the removal of hardness and for the complete demineralization of water using ion exchange resins.

first passed through a cation exchanger where the positively charged ions are replaced by hydrogen ions. The cation exchanger effluent is then passed over an anionic exchange resin where the anions are replaced by hydroxide ions. Thus, the dissolved solids are replaced by hydrogen and hydroxide ions that react to form water molecules.

Total dissolved solids removal can take place in separate exchange columns arranged in series, or both resins can be mixed in a single reactor. Wastewater application rates range from 0.20 to 0.40 $m^3/m^2 \cdot min$ (5 to 10 $gal/ft^2 \cdot min$). Typical bed depths are 0.75 to 2.0 m (2.5 to 6.5 ft). In reuse applications, treatment of a portion of the wastewater by ion exchange, followed by blending with wastewater not treated by ion exchange, would possibly reduce the dissolved solids to acceptable levels. In some situations, it appears that ion exchange may be as competitive as reverse osmosis.

Operational Considerations

To make ion exchange economical for advanced wastewater treatment, it would be desirable to use regenerants and restorants that would remove both the inorganic anions and the organic material from the spent resin. Chemical and physical restorants found to be successful in the removal of organic material from resins include sodium hydroxide, hydrochloric acid, methanol, and bentonite. To date, ion exchange has had limited application because of the extensive pretreatment required, concerns about the life of the ion exchange resins, and the complex regeneration system required.

High concentrations of influent TSS can plug the ion exchange beds, causing high headlosses and inefficient operation. Resin binding can be caused by residual organics found in biological treatment effluents. Some form of chemical treatment and clarification is required before ion exchange demineralization. This problem has been solved partially by prefiltering the wastewater or by using scavenger exchange resins before application to the exchange column.

11–12 DISTILLATION

Distillation is a unit process in which the components of a liquid solution are separated by vaporization and condensation. Along with reverse osmosis, distillation can be used to control the buildup of salts in critical reuse applications. Because distillation is expensive, its application is generally limited to applications where (1) a high degree of treatment is required, (2) contaminants cannot be removed by other methods, and (3) inexpensive heat is available. The purpose of this section is to introduce the basic concepts involved in distillation. As the use of distillation for wastewater reclamation is a recent development, the current literature must be consulted for the results of ongoing studies and more recent applications.

Distillation Processes

Over the past 20 years, a variety of distillation processes, employing a variety of evaporator types and methods of using and transferring heat energy, have been evaluated or used. The principal distillation processes are (1) boiling with submerged tube heating surface, (2) boiling with long-tube vertical evaporator, (3) flash evaporation, (4) forced circulation with vapor compression, (5) solar evaporation, (6) rotating-surface evaporation, (7) wiped-surface evaporation, (8) vapor reheating process, (9) direct heat transfer using an immiscible liquid, and (10) condensing-vapor-heat transfer by vapor other than steam. Of these types of distillation processes, multiple-effect evaporation, multistage flash evaporation, and vapor-compression distillation appear most feasible for the reclamation of municipal wastewater.

Multiple-Effect Evaporation Distillation. In multiple-effect evaporation distillation systems, several evaporators (boilers) are arranged in series, each operating at a lower pressure than the preceding one. In a three-stage, vertical-tube evaporator (see Fig. 11–74), preheated influent water to be demineralized is introduced into the first evaporation stage where it is evaporated with steam contained within heat exchange tubes. The vapor from the first stage enters the second stage where it is condensed within the evaporation tubes. Water from the first stage is the feed water for the second stage. The process is repeated in the next n^{th} stages. Heated vapor from the last stage is used to heat the influent feed water. In an alternative arrangement, the feed water for the second and subsequent stages is the preheated influent. Water which does not evaporate is taken off as brine at each stage. If air entrainment is kept low, almost all of the nonvolatile contaminants can be removed in a single evaporation step. Volatile contaminants, such as ammonia gas and low-molecular weight organic acids, may be removed in a preliminary evaporation step, but if their concentration is so small that their presence in the final product is not objectionable, this step with its added cost can be eliminated.

Multistage Flash Evaporation Distillation. Multistage flash evaporation distillation systems have been used commercially in desalination for many years. In the multistage flash process (see Fig. 11–75), the influent wastewater is first treated to remove TSS and deaerated before being pumped through heat transfer units in the several stages of the

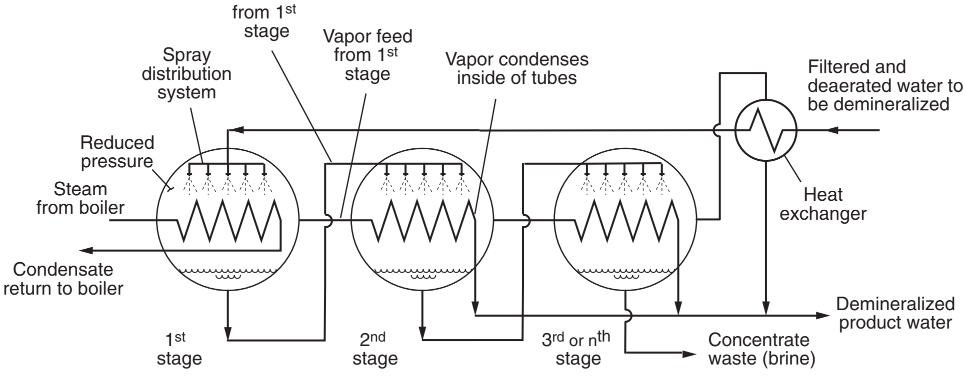

Figure 11–74

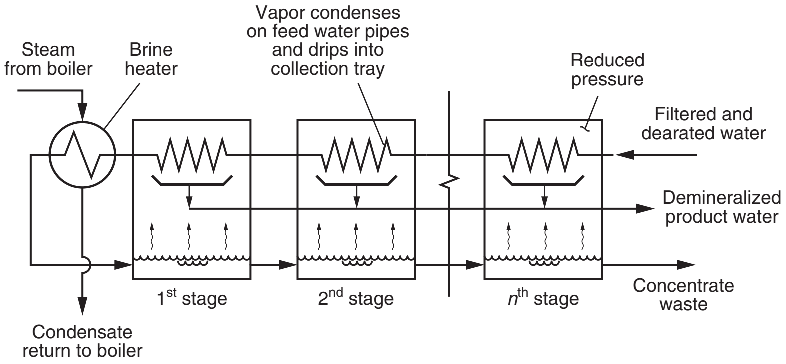
Schematic of multiple-effect evaporation distillation process.

Figure 11–75

Schematic of multistage flash evaporation distillation process.



distillation system, each of which is maintained at a lower pressure. Vapor generation or boiling caused by reduction in pressure is known as "*flashing*." As the water enters each stage through a pressure reducing nozzle, a portion of the water is flashed to form a vapor. In turn, the flashed water vapor condenses on the outside of the condenser tubes and is collected in trays (see Fig. 11–75). As the vapor condenses, its latent heat is used to preheat the wastewater that is being returned to the main heater where it will receive additional heat before being introduced to the first flashing stage. When the concentrated wastewater reaches the lowest pressure stage, it is pumped out. Thermodynamically, multistage flash evaporation is less efficient than ordinary evaporation. However, by combining a number of stages in a single reactor, external piping is eliminated and construction costs are reduced.

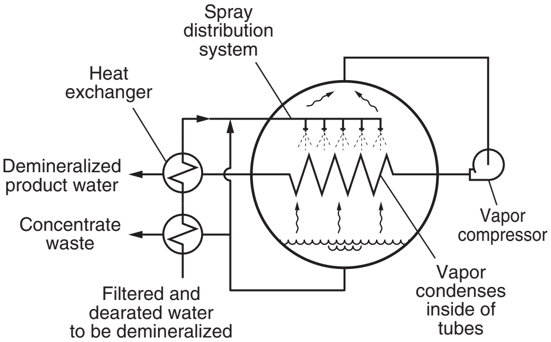
Vapor Compression Distillation. In the vapor compression process an increase in pressure of the vapor is used to establish the temperature difference for the transfer of heat. The basic schematic of a vapor compression distillation unit is shown on Fig. 11–76. After initial heating of the wastewater, the vapor pump is operated so that the vapor under higher pressure can condense in the condenser tubes, at the same time causing the release of an equivalent amount of vapor from the concentrated solution. Heat exchangers can conserve heat from both the condensate and the waste brine. The only energy input required during operation is the mechanical energy for the vapor pump. Hot concentrated wastewater must be discharged at intervals to prevent the buildup of excessive concentrations of salt in the boiler.

Performance Expectations in Reclamation Applications

The principal issues with the application of the distillation processes for wastewater reclamation are the carryover of volatile constituents found in treated wastewater and the degree of subsequent cooling and treatment that may be required to renovate the distilled

Figure 11–76

Schematic of vapor compression distillation process.



water. Typical water quality performance data for a multiple-effect distillation process have been reported for a pilot scale unit by Rose et al. (1999).

The theoretical thermodynamic minimum energy required to raise the temperature of wastewater and to provide the latent heat of vaporization is about 2260 kJ/kg. Typically, about 1.25 to 1.35 times the latent heat of vaporization will be required. Unfortunately, because of the many irreversibilities in an actual distillation processes, the thermodynamic minimum energy requirements are of little practical relevance in the practical evaluation of distillation processes. Typical energy requirements for the three distillation processes discussed above are (Voutchkov, 2013):

Multiple-effect evaporation: 5.7–7.8 kWh/m^3 (23–30 kWh/10^3 gal)

Multistage flash evaporation: 12.7–15.0 kWh/m^3 (48–57 kWh/10^3 gal)

Vapor compression: 8–12 kWh/m^3 (30–45 kWh/10^3 gal)

These values for distillation can be compared to the values given in Table 11–30 for reverse osmosis: 9–12 kWh/m^3 (34–45 kWh/10^3 gal) without energy recovery and $<$3–4 kWh/m^3 ($<$11–32 kWh/10^3 gal) with energy recovery. Based on this energy comparison it is clear why reverse osmosis used in seawater distillation has largely replaced distillation for seawater desalination.

Operating Problems

The most common operating problems encountered include scaling and corrosion. Due to temperature increases, inorganic salts come out of solution and precipitate on the inside walls of pipes and equipment. The control of scaling due to calcium carbonate, calcium sulfate, and magnesium hydroxide is one of the most important design and operational considerations in distillation desalination processes. Controlling the pH minimizes carbonate and hydroxide scales. Most inorganic solutions are corrosive. Cupronickel alloys are used most commonly in sea water desalination. Other metals that are used include aluminum, bronze, titanium, and monel.

Disposal of Concentrated Waste

All distillation processes reject part of the influent wastewater. Hence, all of these processes have concentrated wastewater disposal problems. The permissible maximum concentration in the wastewater depends on the solubility, corrosion, and vapor pressure characteristics of the wastewater. Therefore, the waste concentration is an important consideration in process optimization. Disposal of concentrated wastewater brines is essentially the same problem encountered with the membrane processes discussed in Sec. 11–5.

PROBLEMS AND DISCUSSION TOPICS

11–1 The following sieve analysis results were obtained for four different stock sands.

US sieve size designation[a]	Size of opening, mm	Cumulative weight passing, %. Sand sample 1	2	3	4
140	0.105	0.4	1.5	0.1	5.0
100	0.149	1.5	4.1	0.8	11.1
70	0.210	4.0	10.0	2.5	20.0

(*continued*)

(*Continued*)

US sieve size designation[a]	Size of opening, mm	Cumulative weight passing, %. Sand sample 1	2	3	4
50	0.297	9.5	21.0	8.2	32.0
40	0.420	18.5	40.6	18.5	49.5
30	0.590	31.0	61.0	32.0	62.3
20	0.840	49.0	78.3	58.1	78.3
16	1.190	63.2	90.0	76.3	88.5
12	1.680	82.8	96.0	90.0	94.4
8	2.380	89.0	99.0	96.7	97.8
6	3.360	98.0	99.9	99.0	99.0
4	4.760	100.0	100.0	100.0	100.0

[a] Note: sieve size number 18 has an opening size of 1.0 mm.

a. For sand sample 1, 2, 3, or 4 (to be selected by instructor) determine the geometric mean size, the geometric standard deviation, the effective size, and the uniformity coefficient for the stock sand.

b. It is desired to produce from the stock sand a filter sand with an effective size of 0.45 mm and a uniformity coefficient of 1.6. Estimate the amount of stock sand needed to obtain one ton of filter sand.

c. What U.S. Standard sieve size should be used to eliminate the excess coarse material?

d. If the sand remaining after sieving in Part c above is placed in a filter, what backwash rise rate would be needed to eliminate the excess fine material?

e. What depth of sieved material would have to be placed in the filter to produce 600 mm of usable filter sand?

f. On log-probability paper, plot the size distribution of the modified sand. Check against the required distribution and sizes.

g. Determine the headloss through 600 mm of the filter sand specified in part (b) for a filtration rate of 160 $L/m^2 \cdot min$ (4 $gal/ft^2 \cdot min$). Assume the sand is stratified and that the maximum and minimum sand sizes are 1.68 (sieve size 12) and 0.297 mm (sieve size 50), respectively. Assume also that $T = 20°C$, $\alpha = 0.4$ for all layers, and $\psi = 0.75$.

An excellent discussion of the procedures involved in developing a usable filter sand from a stock filter sand may be found in Fair et al. (1968).

11–2 Determine the sphericity and specific surface area of two of the following filter mediums (filter medium to be selected by instructor).

Item	Filter medium 1	2	3	4	5
Shape	Ellipsoid	Icosahedron	Cube	Rod	Isosceles tetrahedron
Dimensions	1 mm × 1.2 mm × 2 mm	Each face, 0.5 mm × 0.5 mm × 0.5 mm	1 mm × 1 mm × 1 mm	0.5 mm diameter × 2 mm in length	1.2 mm × 1.2 mm × 1.2 mm × 2.5 mm

11–3 Using the equations developed by Kozeny, Rose, and Ergun, given in Table 11–8, compare the headloss through a 600 mm sand bed. Assume that the sand bed is composed of spherical unisized sand with a diameter of 0.45, 0.55, or 0.6 mm (to be selected by instructor), the porosity of the sand is 0.40, the filtration rate is 240 L/m ^{2}•min (5 gal/ft^2•min) and the temperature is 15°C. The kinematic viscosity at 15°C is equal to 1.139×10^{-6} m^2/s (see Table C–1, Appendix C).

11–4 Using the equation developed by Rose, determine the headloss through a 750-mm sand bed for a filtration rate of 300 L/m^2•min. Assume that the sand bed is composed of spherical unisized sand with a diameter of 0.40, 0.45, 0.55, or 0.6 mm (size to be selected by instructor), the porosity of the sand is 0.40, and the temperature of the water is 10°C. The kinematic viscosity at 10°C is equal to 1.306×10^{-6} m^2/s (see Table C-1, Appendix C).

11–5 Solve Problem 11–4 assuming the bed is stratified. Assume that the given sand sizes correspond to the effective size (d_{10}) and that the uniformity coefficient for all of the sand sizes is equal to 1.5.

11–6 If a 0.3-m layer of uniform anthracite is placed on top of the sand bed in Prob. 11–3, determine the ratio of the headloss through the anthracite to that of the sand. Assume that the grain-size diameter of the anthracite is 2.0 mm and porosity is 0.50. Will intermixing occur?

11–7 Given the particle size distribution 1, 2, 3, or 4 (to be selected by instructor), determine the effective size (d_{10}) and uniformity coefficient UC, and clean-water headloss through a stratified bed 600 mm deep. If a layer of anthracite is to be added over 600 mm of sand determine the effective size required to minimize intermixing. Assume the filtration rate is 160 L/m^2•min, $\phi = 0.85$, and $\alpha = 0.4$.

	Percent of sand retained			
	Particle size distribution			
Sieve number	1	2	3	4
6–8	2	0	1	0.1
8–10	8	0.1	2	0.7
10–14	10	0.5	4	1.2
14–20	30	7.4	13	10
20–30	26	32	20	24
30–40	14	30	20	29
40–60	8	25	23	25
Pan	2	5	17	10

11–8 Four stratified sand beds with the size distribution given below are to be backwashed at a rate of 0.75 m^3/m^2•min. Determine the degree of expansion and whether the proposed backwash rate will expand all of the filter bed (to be selected by instructor). Assume the following data are applicable: sand specific gravity is 2.65, depth of the filer bed is 0.90 m, and the temperature is 20°C.

	Percent of sand retained			
	Stratified bed number			
Sieve size or number	1	2	3	4
8–10	10	2	0.1	0
10–12	10	4	0.5	0
12–18	30	14	4.4	0

(continued)

(*Continued*)

Sieve size or number	Percent of sand retained			
	Stratified bed number			
	1	2	3	4
18–20	10	8	7	1
20–30	34	40	48	28
30–40	5	22	30	41
40–50	1	9	9	27
Pan		1	1	3

11–9 Given the following granular medium filter effluent turbidity data collected at four different wastewater treatment plants, estimate the mean, the geometric standard deviation, s_g, and the probability of exceeding a turbidity reading of 2.5 NTU (treatment plant to be selected by instructor).

Turbidity, NTU			
Treatment plant			
1	2	3	4
1.7	1.7	1.0	1.2
1.8	1.1	1.8	1.4
2.2	0.9	1.5	1.5
2.0	1.4	1.1	1.6
	1.3	1.7	1.7
		1.3	1.9
			2.0
			2.1

11–10 Assuming the data for treatment plants 1 and 2 in Problem 11–9 were collected at the same treatment plant at different times, what is the impact of using all of the data given for 1 and 2 as one data set versus using the individual data sets? In general, what are the advantages or disadvantages of collecting more turbidity samples?

11–11 Gravity filters are to be used to treat 16,000, 20,000, or 24,000 m^3/d, to be selected by instructor, of settled effluent at a filtration rate of 200 L/m^2·min (5 gal/ft^2·min). The filtration rate with one filter taken out of service for backwashing is not to exceed 240 L/m^2·min (6 gal/ft^2·min). Determine the number of units and the area of each unit to satisfy these conditions. If each filter is backwashed for 30 min every 24 h at a wash rate of 960 L/m^2·min (24 gal/ft^2·min), determine the percentage of filter output used for washing if the filter is out of operation for a total of 30 min/d. What would be the total percentage of filter output used for backwashing if a surface washing system that requires 40 L/m^2·min (1 gal/ft^2·min) of filtered effluent is to be installed?

11–12 Using the performance data given in the following table for a microfiltration membrane, determine (water to be selected by instructor) the rejection and log rejection for each microorganism group.

	Microorganisms concentration, org/mL			
	Water 1		Water 2	
Microorganism	Feed water	Permeate	Feed water	Permeate
HPC	6.5×10^7	3.3×10^2	8.6×10^7	1.5×10^2
Total coliform	3.4×10^6	100	5×10^5	60
Enteric virus	7×10^3	6.6×10^3	2.0×10^3	9.1×10^2

11–13 A hollow-fiber membrane system with inside to outside flow is operated in a cross-flow arrangement. Each module contains 6000 fibers that have an inside diameter of 1.0 mm and a length of 1.25 m. Using this information determine

a. the feed water flowrate at the entrance to the module needed to achieve a cross-flow velocity of 1 m/s within the membrane fibers.
b. the permeate flowrate if the permeate flux of 100 L/m²·h is maintained.
c. the retentate cross-flow velocity at the exit from the membrane fibers.
d. the ratio of velocity of flow through the membrane surface to the average cross-flow velocity within an individual membrane fiber.
e. the ratio of permeate flowrate to feed water flowrate.

This problem was adapted from Crittenden et al., 2012.

11–14 Membrane filtration, operated in a dead-end mode, is used to treat secondary effluent. If the heterotrophic microorganism plate count (HPC) in the effluent increased from 5 org/L under normal operation to 200 org/L after an extended period of operation, estimate the number of broken fibers for the following conditions. The influent flowrate and organism count are 4000 m³/d and 6.7×10^7 org/L, respectively. The membrane bundle contains 5000 individual fibers. If the influent and effluent turbidity values under normal operation are 4 and 0.25 NTU respectively, estimate the increase in the effluent turbidity assuming the increase could be measured.

11–15 Contrast the advantages and disadvantages between depth filtration, surface filtration, and microfiltration. Cite a minimum of three recent articles (after 2000).

11–16 Four different waters are to be desalinized by reverse osmosis using a thin film composite membrane. For water 1, 2, 3, or 4 (water to be selected by instructor), determine the required membrane area, the rejection rate, and the concentration of the retentate.

		Water			
Item	Unit	1	2	3	4
Flowrate	m³/d	4000	5500	20,000	10,000
Influent TDS	g/m³	2850	3200	2000	2700
Permeate TDS	g/m³	200	500	400	225
Flux rate coefficient k_w	m/s·bar[a]	1.0×10^{-6}[a]	1.0×10^{-6}	1.0×10^{-6}	1.0×10^{-6}
Mass transfer rate coefficient, k_i	m/s	6.0×10^{-8}	6.0×10^{-8}	6.0×10^{-8}	6.0×10^{-8}
Net operating pressure	*kPa*	2750	2500	2800	3000
Recovery	%	88.0	90.0	89	86

[a] 1.0×10^{-6} m/s·bar = 1.0×10^{-8} s/m.

11–17 Using the data given below, determine the recovery and rejection rates for one of the following reverse osmosis units (unit to be selected by instructor).

		Reverse osmosis unit			
Item	Unit	1	2	3	4
Feed water flowrate	m³/d	4000	6000	8000	10,000
Retentate flowrate	m³/d	350	600	7500	9000
Permeate TDS	g/m³	65	88	125	175
Retentate TDS	g/m³	1500	2500	1850	2850

11–18 Using the data given below, determine the flux rate coefficient and the mass transfer rate coefficient.

		Reverse osmosis unit			
Item	Unit	1	2	3	1
Flowrate, Q_f	m^3/d	4000	5500	20,000	10,000
Influent TDS, C_f	g/m^3	2500	3300	5300	2700
Permeate TDS, C_p	g/m^3	20	50	40	23
Net operating pressure, ΔP	bar	28	25	28	30
Membrane area	m^2	1600	1700	9600	5500
Recovery, r	%	88.0	90.0	89	86

11–19 Estimate the SDI for the following filtered wastewater samples. If the water is to be treated with reverse osmosis will additional treatment be required?

	Volume filtered, mL			
	Wastewater sample number			
Test run time, min	1	2	3	4
2	315	480	180	500
5	575	895	395	700
10	905	1435	710	890
20	1425	2300	1280	1150

11–20 Calculate the modified fouling index (MFI) for the effluent from a microfiltration process (water sample to be selected by instructor) using the following experimental data:

	Volume filtered, L			Volume filtered, L	
	Water sample			Water sample	
Time, min	1	2	Time, min	1	2
0			3.5	6.78	7.17
0.5	1.50	1.50	4.0	7.48	8.03
1.0	2.50	2.50	4.5	8.08	8.87
1.5	3.45	3.48	5.0	8.57	9.67
2.0	4.36	4.40	5.5		10.34
2.5	5.22	5.37	6.0		10.97
3.0	6.03	6.28	6.5		11.47

11–21 Determine the cost (based on the current price of electricity) to treat a flowrate of 2500 m^3/d with a TDS concentration of 1300 g/m^3 and a cation and anion concentration of 0.13 g-eq/L using an electrodialysis unit. Assume the following typical values of operation for the electrodialysis unit.

Product flowrate = 90% of the feed water flowrate
Efficiency of salt removal = 50%
The current efficiency = 90%
Resistance = 5.0 ohms
Number of cell pairs in the stack = 350, 400, 450 (to be selected by instructor)
Assume an energy cost of \$0.13/kWh and 24 h/d operation.

11–22 Review and cite three current articles (within the last five years) dealing the disposal of nanofiltration, reverse osmosis, or electrodialysis brine. What types of process combinations are being proposed? What are the critical issues that stand out in your mind?

11–23 A wastewater is to be treated with activated carbon to remove residual COD. The following data were obtained from a laboratory adsorption study in which 1 g of activated carbon was added to a beaker containing 1 L of wastewater at selected COD values. Using these data, determine the more suitable isotherm (Langmuir or Fruendlich) to describe the data (sample to be selected by instructor).

Initial COD, mg/L	Equilibrium COD, mg/L			
	Wastewater sample number			
	1	2	3	4
140	5	10	0.4	5
250	12	30	0.9	18
300	17	50	2	28
340	23	70	4	36
370	29	90	6	42
400	36	110	10	50
450	50	150	35	63

11–24 Using the following isotherm test data, determine the type of model that best describes the data and the corresponding model parameters. Assume that a 1 L sample volume was used for each of the isotherm experiments.

Mass of GAC, mg	Equilibrium concentration of adsorbate in solution, C_e, μg/L			
	Test number			
	1	2	3	4
0	5.8	26	158.2	25.3
0.001	3.9	10.2	26.4	15.89
0.01	0.97	4.33	6.8	13.02
0.1	0.12	2.76	1.33	6.15
0.5	0.022	0.75	0.5	2.1

11–25 Using the results from Problem 11–23, determine the amount of activated carbon that would be required to treat a flowrate of 4800 m^3/d to a final COD concentration of 2 mg/L if the COD concentration after secondary treatment is equal to 30 mg/L.

11–26 Design a fixed-bed activated carbon process using the following data. Determine the number of contactors, mode of operation, carbon requirements, and corresponding bed life. Ignore the effects of biological activity within the column.

Parameter	Unit	Compound			
		Chloroform	Heptachlor	Methylene chloride	NDMA
Flowrate	m^3/d	4000	4500	5000	6000
C_o	ng/L	500	50	2000	200
C_e	ng/L	50	10	10	10
GAC density	g/L	450	450	450	450
EBCT	min	10	10	10	10

11–27 Referring to the data presented in Table 11–23, prepare a list of the top 5 most and least readily adsorbable substances.

11–28 Using the results from Prob. 11–13, determine the amount of activated carbon that would be required to treat a flowrate of 5000 m^3/d to a final COD concentration of 20 mg/L if the COD concentration after secondary treatment is equal to 120 mg/L.

11–29 Using the following carbon adsorption data (sample number to be selected by instructor) determine the Freundlich capacity factor (mg absorbate/g activated carbon) and Freundlich intensity parameter, $1/n$.

Carbon dose, mg/L	Residual concentration, mg/L — Sample number 1	2	3	4	5	6
0	25.9	9.20	9.89	27.5	20.4	9.88
5	17.4	7.36	9.39	24.8	19.3	7.95
10	13.2	6.86	8.96	24.2	18.6	7.02
25	10.2	3.86	7.83	18.9	16.1	3.66
50	3.6	1.13	5.81	11.8	12.2	0.98
100	2.5	0.22	4.45	2.3	6.7	0.25
150	2.1	0.18	2.98	1.1	3.1	0.09
200	1.4	0.11	2.01	0.9	1.1	0.04

11–30 Determine the theoretical air flowrate required to remove the following compounds in a stripping tower at the indicated concentrations (compound and water to be selected by instructor). Also estimate the height of the stripping tower for a water flowrate of 3000 m^3/d. Values of the Henry's law constant may be found in Table 16–12.

		Concentration μg			
		Water 1		Water 2	
Compound	K_La, s^{-1}	Influent	Effluent	Influent	Effluent
Clorobenzene	0.0163	100	5	120	7
Chloroethene	0.0141	100	5	150	5
TCE[a]	0,0176	100	5	180	10
Toluene	0.0206	100	5	200	15

[a] Henry's law constant for TCE is equal to 0.00553 m^3·atm/mole

11–31 A quantity of sodium-form ion exchange resin (5 g) is added to a water containing 2 meq of potassium chloride and 0.5 meq of sodium chloride. Calculate the residual concentration of potassium if the exchange capacity of the resin is 4.0 meq/g of dry weight and the selectivity coefficient is equal to 1.46.

11–32 Determine the exchange capacity for one of the following resins (resin to be selected by instructor). How much resin would be required to treat a flowrate of 4000 m^3/d to reduce the concentration of calcium (Ca^{2+}) from 125 to 45 mg/L? Assume the mass of resin used to obtain the data given in the table is 0.1 kg.

Throughput volume, L	Resin 1		Resin 2	
	Cl^-	Ca^{2+}	Cl^-	Ca^{2+}
0	0	0	0	0
5	2	0	2	0
10	8	0	13	0
15	44	0	29	0
20	65	0	45	0
25	70	0	60	1
30	71	0	69	8
35	71	6	71	17
40	71	20	71	27

(continued)

(*Continued*)

Throughput volume, L	Resin 1		Resin 2	
	Cl^-	Ca^{2+}	Cl^-	Ca^{2+}
45		34	71	35
50		39		39
55		40		40
60		40		40

11–33 Determine the exchange capacity for one of the resins given in Problem 11–32 (resin to be selected by instructor). How much resin would be required to treat a flowrate of 5500 m^3/d to reduce the concentration of magnesium, Mg^{2+}, from 115 to 15 mg/L?

11–34 Four different wastewaters have been reported to have the following ionic composition data. Estimate the selectivity coefficient and determine the amount of wastewater (1, 2, 3, or 4, to be selected by instructor) that can be treated by a strong-base ion exchange resin, per service cycle, for the removal of nitrate. Assume the resin has an ion exchange capacity of 1.8 eq/L.

			Concentration, mg/L			
			Wastewater sample number			
Cation	Conc., mg/L	Anion	1	2	3	4
Ca^{2+}	82.2	HCO_3^-	304.8	152	254	348
Mg^{2+}	17.9	SO_4^{2-}	0	0	0	0
Na^+	46.4	Cl^-	58.1	146.3	124	60
K^+	15.5	NO_3^-	82.5	90	21.5	42

11–35 Four different wastewaters have been reported to have the following ionic composition data. Estimate the selectivity coefficient and determine the amount of wastewater (1, 2, 3, or 4, to be selected by instructor) that can be treated by a strong-base ion exchange resin, per service cycle, for the removal of nitrate. Assume the resin has an ion exchange capacity of 2.5 eq/L.

			Concentration, mg/L			
			Wastewater sample number			
Cation	Conc., mg/L	Anion	1	2	3	4
Ca^{2+}	82.2	HCO_3^-	321	180	198.5	69
Mg^{2+}	17.9	SO_4^{2-}	65	36.5	124	136
Na^+	46.4	Cl^-	22	95	56	87
K^+	15.5	NO_3^-	46	93	34.5	97

11–36 For each compound in the following list, which of the treatment methods discussed in this chapter, if any, are suitable for use to reduce the concentration from 100 to 10 $\mu g/L$?

Benzene

Chloroform

Dieldrin

Heptachlor

N-Nitrosodimethylamine

Trichloroethylene (TCE)

Vinyl chloride

Disinfection Processes

WORKING TERMINOLOGY

Term	Definition
Absorbance	A measure of the amount of light of a specified wavelength that is absorbed by a solution and the constituents in the solution.
Breakpoint chlorination	A process whereby enough chlorine is added to react with all oxidizable substances in water such that if additional chlorine is added it will remain as free chlorine (see below, HOCl + OCl^-).
Chlorine residual, total	The concentration of free or combined chlorine in water, measured after a specified time period following addition. Combined chlorine residual is measured most commonly amperometrically.
Combined chlorine	Chlorine combined with other compounds [e.g., monochloramine (NH_2Cl), dichloramine ($NHCl_2$), and nitrogen trichloride (NCl_3), among others].
Combined chlorine residual	Chlorine residual comprised of combined chlorine compounds [e.g., monochloramine (NH_2Cl), dichloramine ($NHCl_2$), and nitrogen trichloride (NCl_3) and others].
CT	The product of disinfectant residual, C, expressed in mg/L and contact time, T, expressed in min. The term CT is used to assess the effectiveness of the disinfection process.
Dechlorination	The removal of residual chlorine from solution by a reducing agent such as sulfur dioxide or by reacting it with activated carbon.
Disinfection	The partial destruction and inactivation of disease-causing organisms from exposure to chemical agents (e.g., chlorine) or physical processes (e.g., UV radiation).
Disinfection byproducts (DBPs)	Chemicals that are formed with the residual organic matter found in treated wastewater as a result of the addition of a strong oxidant (e.g., chlorine or ozone) for the purpose of disinfection.
Dose response curve	The relationship between the degree of microorganism inactivation and the dose of the disinfectant.
Free chlorine	The total quantity of hypochlorous acid (HOCl) and hypochlorite ion (OCl^-) in solution.
Inactivation	Rendering microorganisms incapable of reproducing, and thus their ability to cause disease.
Irradiation	Exposure to penetrating UV radiation.
Natural organic matter (NOM)	Dissolved or particulate organic constituents that are typically derived from three sources: (1) the terrestrial environment (mostly humic materials), (2) the aquatic environment (algae and other aquatic species and their byproducts), and (3) the microorganisms in the biological treatment process.
Pasteurization	The process of heating food or water at a specified temperature and time for the purpose of killing microorganisms.
Pathogens	Microorganisms capable of causing diseases of varying severity.
Photoreactivation/dark repair	The ability of microorganisms to repair the damage caused by exposure to UV irradiation.
Radiation	Energy such as light, heat, and sound that can be transmitted over large distances without conductors or special conduits.
Reduction equivalent dose (RED)	The inactivation observed through the UV disinfection system as compared to the UV dose response derived from a collimated beam dose response study.
Sterilization	The total destruction of disease-causing and other organisms.
Total chlorine	The sum of the free and combined chlorine.
Transmittance	The ability of a solution to transmit light. Transmittance is related to absorbance.
Ultraviolet (UV) light	Electromagnetic radiation with a wavelength less than that of visible light in the range from 100 to 400 nm.
Ultraviolet (UV) irradiation	A disinfection process in which the exposure to UV radiation (or light) is used to inactivate microorganisms.

Because of the critical importance of the disinfection process in wastewater treatment and/or reuse applications, the purpose of this chapter is to introduce the reader to the important issues that must be considered in the disinfection of treated water with various disinfectants to render it safe for dispersal to the environment or for reuse in a variety of applications. The four categories of human enteric organisms found in wastewater that are of the greatest consequence in producing disease are (1) bacteria, (2) protozoan oocysts and cysts, (3) viruses, and (4) helminth ova. Diseases caused by these waterborne microorganisms have been discussed previously in Chap. 2. Disinfection, the subject of this chapter, is the process used to achieve a given level of destruction or inactivation of pathogenic organisms. Because not all the organisms present are destroyed during the process, the term *disinfection* is differentiated from the term *sterilization*, which is the destruction of all organisms.

To delineate the issues involved in disinfection the following topics are considered: (1) an introduction to the disinfectants used in wastewater, (2) general considerations in wastewater disinfection, (3) disinfection with chlorine and related compounds, (4) disinfection with chlorine dioxide, (5) dechlorination, (6) design considerations for chlorination and dechlorination facilities, (7) disinfection with ozone, (8) disinfection with other chemicals and combination of chemicals, (9) disinfection with UV irradiation, and (10) disinfection by pasteurization.

12–1 INTRODUCTION TO DISINFECTANTS USED IN WASTEWATER

Before discussing the details of the individual disinfection technologies and the practical aspects of disinfection that follow, it is appropriate to consider the characteristics of an ideal disinfectant, the major types of disinfection agents used for wastewater, and to provide a general comparison between disinfectants.

Characteristics for an Ideal Disinfectant

To provide a perspective on the disinfection of wastewater, it is useful to consider the characteristics of an ideal disinfectant as given in Table 12–1. As reported, an ideal disinfectant would have to possess a wide range of characteristics such as safe to handle and apply, stable in storage, toxic to microorganisms, nontoxic to higher forms of life, and soluble in water or cell tissue. It is also important that the strength or concentration of the disinfectant be measurable. The latter consideration is an issue with the use of ozone, where little or no residual may remain after disinfection, and UV and pasteurization disinfection where no residual is measurable.

Disinfection Agents and Methods

Disinfection is most commonly accomplished by the use of (1) chemical agents and (2) nonionizing radiation. Each of these techniques is considered briefly in the following discussion. Other methods of disinfection and or inactivation are mentioned for completeness.

Chemical Agents. Chlorine and its compounds, and ozone, are the principal chemical compounds employed for the disinfection of wastewater. Other chemical agents that have been used as disinfectants in different applications include (1) bromine, (2) iodine, (3) phenol and phenolic compounds, (4) alcohols, (5) heavy metals and related compounds,

Table 12–1

Characteristics of an ideal disinfectant[a]

Characteristic	Properties/response
Alteration of solution characteristics	Should be effective with minimum alteration of the solution characteristics such as increasing the total dissolved solids (TDS)
Availability	Should be available in large quantities and reasonably priced
Deodorizing ability	Should deodorize while disinfecting
Homogeneity	Solution must be uniform in composition
Interaction with extraneous material	Should not be absorbed by organic matter other than bacterial cells
Noncorrosive and nonstaining	Should not disfigure metals or stain clothing
Nontoxic to higher forms of life	Should be toxic to microorganisms and nontoxic to humans and other animals
Penetration	Should have the capacity to penetrate through particle surfaces
Safety	Should be safe to transport, store, handle, and use
Solubility	Must be soluble in water or cell tissue
Stability	Should have low loss of germicidal action with time on standing
Toxicity to microorganisms	Should be effective at high dilutions
Toxicity at ambient temperatures	Should be effective in ambient temperature range

[a] Adapted from Tchobanoglous et al. (2003).

(6) dyes, (7) soaps and synthetic detergents, (8) quaternary ammonium compounds, (9) hydrogen peroxide, (10) peracetic acid, (11) various alkalies, and (12) various acids. Highly acidic or alkaline water will destroy pathogenic bacteria, because water with a pH greater than 11 or less than 3 is relatively toxic to most microorganisms.

Non-Ionizing Radiation. In general, energy in the form of electromagnetic waves, heat, and acoustic waves that can be transmitted over large distances without conductors or special conduits is termed *radiation*. Electromagnetic waves include visible light, infrared light, microwaves, and radio waves. Ultraviolet light (UV) is the most common form of electromagnetic radiation used for the disinfection of treated wastewater. Heating water to the boiling point, for example, will destroy the major disease producing non-spore forming bacteria. Commonly used in the food processing industry, pasteurization in the wastewater field has received greater interest recently because of the availability of new equipment, the opportunity to utilize waste heat, and energy concerns with other disinfectants. Pasteurization of sludge is used extensively in Europe.

Ionizing Radiation. Radiation with sufficient energy to ionize atoms is termed *ionizing radiation*. Alpha particles, beta particles, gamma rays, X-ray radiation, and neutrons are generally considered to be forms of ionizing radiation. For example, gamma rays emitted from radioisotopes, such as cobalt 60, have been used to disinfect (sterilize) both water and wastewater. Although the use of a high-energy electron-beam device for the irradiation of wastewater or sludge has been studied extensively, there are no commercial devices or full-scale installations in operation.

Removal by Mechanical Means. Incidental removal of bacteria and other organisms also occurs by mechanical means during wastewater treatment. The removals accomplished are byproducts of the primary function of the treatment process (e.g., screening, sedimentation, filtration, etc.). The use of membrane filtration (e.g., microfiltration and ultrafiltration) has been recognized as a means to reduce pathogenic organisms for water reuse applications. The level of reduction is assessed by spiking a known concentration of an indicator organism and measuring the inactivation achieved. In a full-scale operation, surrogate parameters, such as pressure decay across the membrane and turbidity, are used to monitor the integrity of the membrane. Pathogen removal by membrane processes is discussed further in Chap. 11.

Mechanisms Used to Explain Action of Disinfectants

The five principal mechanisms that have been proposed to explain the action of disinfectants are (1) damage to the cell wall, (2) alteration of cell permeability, (3) alteration of the colloidal nature of the protoplasm within the cell, (4) alteration of the organism's DNA or RNA, and (5) inhibition of enzyme activity within the protoplasm. A comparison of the mechanisms of disinfection using chlorine, ozone, UV irradiation, and pasteurization is presented in Table 12–2. To a large extent, observed performance differences for the various disinfectants can be explained on the basis of the operative inactivation mechanisms.

Damage, destruction, or alteration of the cell wall by oxidizing chemicals, such as chlorine and ozone, results in cell lysis and death. Oxidizing chemicals can also alter the chemical arrangement of enzymes and inactivate the enzymes. Some oxidants can inhibit the synthesis of the bacterial cell wall. Exposure to UV irradiation can cause the formation of double bonds in the DNA of microorganisms as well as rupturing some DNA strands. When UV photons are absorbed by the DNA in bacteria and protozoa and the DNA and RNA in viruses, covalent dimers can be formed from adjacent thymines in DNA or uracils in RNA. The formation of double bonds disrupts the replication process so that the organism can no longer reproduce and is thus inactivated. When heat is applied, both the

Table 12–2

Mechanisms of disinfection using chlorine, ozone, UV, and pasteurization

Chlorine	Ozone	UV radiation	Pasteurization
1. Direct oxidation of cell wall allowing cellular constituents to flow out of the cell 2. Modification of cell wall permeability 3. Alteration of the cell protoplasm 4. Inhibition of enzyme activity 5. Damage to the cell DNA and RNA	1. Direct oxidation of cell wall allowing cellular constituents to flow out of the cell 2. Reactions with radical byproducts of ozone decomposition 3. Damage to the constituents of the nucleic acids (purines and pyrimidines) 4. Breakage of carbon-nitrogen bonds leading to depolymerization	1. Photochemical damage to RNA and DNA (e.g., formation of double bonds) within the cells of an organism 2. The nucleic acids in microorganisms are the most important absorbers of the energy of light in the wavelength range of 240–280 nm 3. Because DNA and RNA carry genetic information for reproduction, damage of these substances can effectively inactivate the cell	1. The structure of the enzymes within the cell is altered by heat (e.g. denatured), rendering them inoperative 2. The structure of the proteins and fatty acids that make up the cell wall are damaged by heat, allowing contents of cell to escape 3. The fluids within the cell can expand and rupture the cell wall, releasing the contents of the cell

nature of the enzymes in the cell protoplasm and the structure of the cell wall are altered, rendering the microorganism incapable of reproducing.

Comparison of Disinfectants

Using the criteria defined in Table 12–1 as a frame of reference and the issues discussed above, the disinfectants that have been used in wastewater applications are compared in Table 12–3. Additional details on the relative performance of the various disinfection technologies are presented in the following sections. In reviewing Table 12–3, important comparisons that should be noted include safety (e.g., chlorine gas versus sodium hypochlorite) and the increase in TDS (e.g., chlorine gas versus UV irradiation). These issues are also addressed in the subsequent sections.

12–2 DISINFECTION PROCESS CONSIDERATIONS

The purpose of this section is to present background material that will serve as a basis for the discussion of individual disinfectants considered in the following sections. Topics to be discussed include (1) an introduction to the physical facilities used for disinfection, (2) the factors that affect the performance of the disinfection process, (3) development of CT values (residual disinfectant concentration times time) for predicting disinfection performance, (4) application of CT values, (5) a comparison of the performance of alternative disinfection technologies, and (6) a review of the advantages and disadvantages of each disinfection technology. Costs, both capital and operation and maintenance, have not been provided other than in a general context. Costs are influenced by many site-specific factors and must be evaluated on a case-by-case basis.

Physical Facilities Used for Disinfection

In general, the disinfection is accomplished as a separate unit process in specially designed reactors. The purpose of the reactors is to maximize contact between the disinfecting agent and the liquid to be disinfected. The specific design of the reactor depends on the nature and action of the disinfecting agent. The types of reactors used are illustrated on Figs. 12–1 and 12–2 and described below briefly.

Chlorine and Related Compounds. As shown on Figs. 12–1(a) and 12–1(b) baffled serpentine contact chambers or long pipelines are used for the application of diluted chlorine and related compounds. Both of these contact chambers are designed to perform as ideal plug-flow reactors. As will be discussed later, the efficacy of disinfection is affected by the degree to which the flow in these chambers is less than ideal. Views of full scale chlorine contact basins are shown on Figs. 12–2(a) and 12–2(b).

Ozone. Ozone is typically applied by bubbling ozone gas through the liquid to be disinfected in a contact chamber [see Fig. 12–1(c)] or in a sidestream [see Fig. 12–1(d)] and then injected into an ozone contactor [see Fig. 12–2(d)]. Fine bubble diffusers are used to improve ozone transfer to the liquid. Eductors and Venturi injectors are used in sidestream designs. To limit the amount of short circuiting that can occur in a single contact chamber a series of baffled chambers are used [see Fig. 12–1(c)].

Ultraviolet Light (UV). Both open [see Figs. 12–1(e) and (f)] and closed [see Fig. 12–1(g)] contact chambers (reactors) are used for UV disinfection. Open channel reactors are used commonly for low-pressure, low-intensity and low-pressure, high-intensity

Table12–3

Comparison of technologies used for the disinfection of treated wastewater[a]

Characteristic[b]	Chlorine gas[c]	Sodium hypochlorite[c]	Combined chlorine	Chlorine dioxide	Ozone	UV radiation	Pasteurization
Availability/cost	Low	Moderately low	Moderately low	Moderately low	Moderately high	Moderately high	Moderate
Deodorizing ability	High	Moderate	Moderate	High	High	na[d]	na
Interaction with organic matter	Oxidizes organic matter	Oxidizes organic matter	Oxidizes organic matter	Oxidizes organic matter	Oxidizes organic matter	Absorbance of UV radiation	na
Corrosiveness	Highly corrosive	Corrosive	Corrosive	Highly corrosive	Highly corrosive	na	na
Toxic to higher forms of life	Highly toxic	Highly toxic	Toxic	Toxic	Toxic	Toxic	Toxic
Penetration into particles	High	High	Moderate	High	High	Moderate	High
Safety concern	High	Moderate to low	High to moderate[e]	High	Moderate	Low	Low
Solubility	Moderate	High	High	High	Moderate	na	na
Stability	Stable	Slightly unstable	Slightly unstable	Unstable[f]	Unstable[f]	na	na
Effectiveness for							
Bacteria	Excellent	Excellent	Good	Excellent	Excellent	Good	Excellent
Protozoa	Fair to poor	Fair to poor	Poor	Good	Good	Excellent	Excellent
Viruses	Excellent	Excellent	Fair	Excellent	Excellent	Good	Good
Byproduct formation	THMs and HAAs[g]	THMs and HAAs[g]	Traces of THMs and HAAs, cyanogens, NDMA	Chlorite and chlorate	Bromate	None known in measurable concentrations	None known in measurable concentrations
Increases TDS	Yes	Yes	Yes	Yes	No	No	No
Use as a disinfectant	Common	Common	Common	Increasing slowly	Increasing slowly	Increasing rapidly	Increasing slowly

[b] See Table 12–1 for a description of the characteristics of an ideal disinfectant.

[c] Free chlorine (HOCl and OCl^-).

[d] na = not applicable.

[e] Depends on whether chlorine gas or sodium hypchlorite is used to combine with nitrogenous compounds.

[f] Must be generated as used.

[g] THMs = trihalomethanes and HAAs = haloacetic acids.

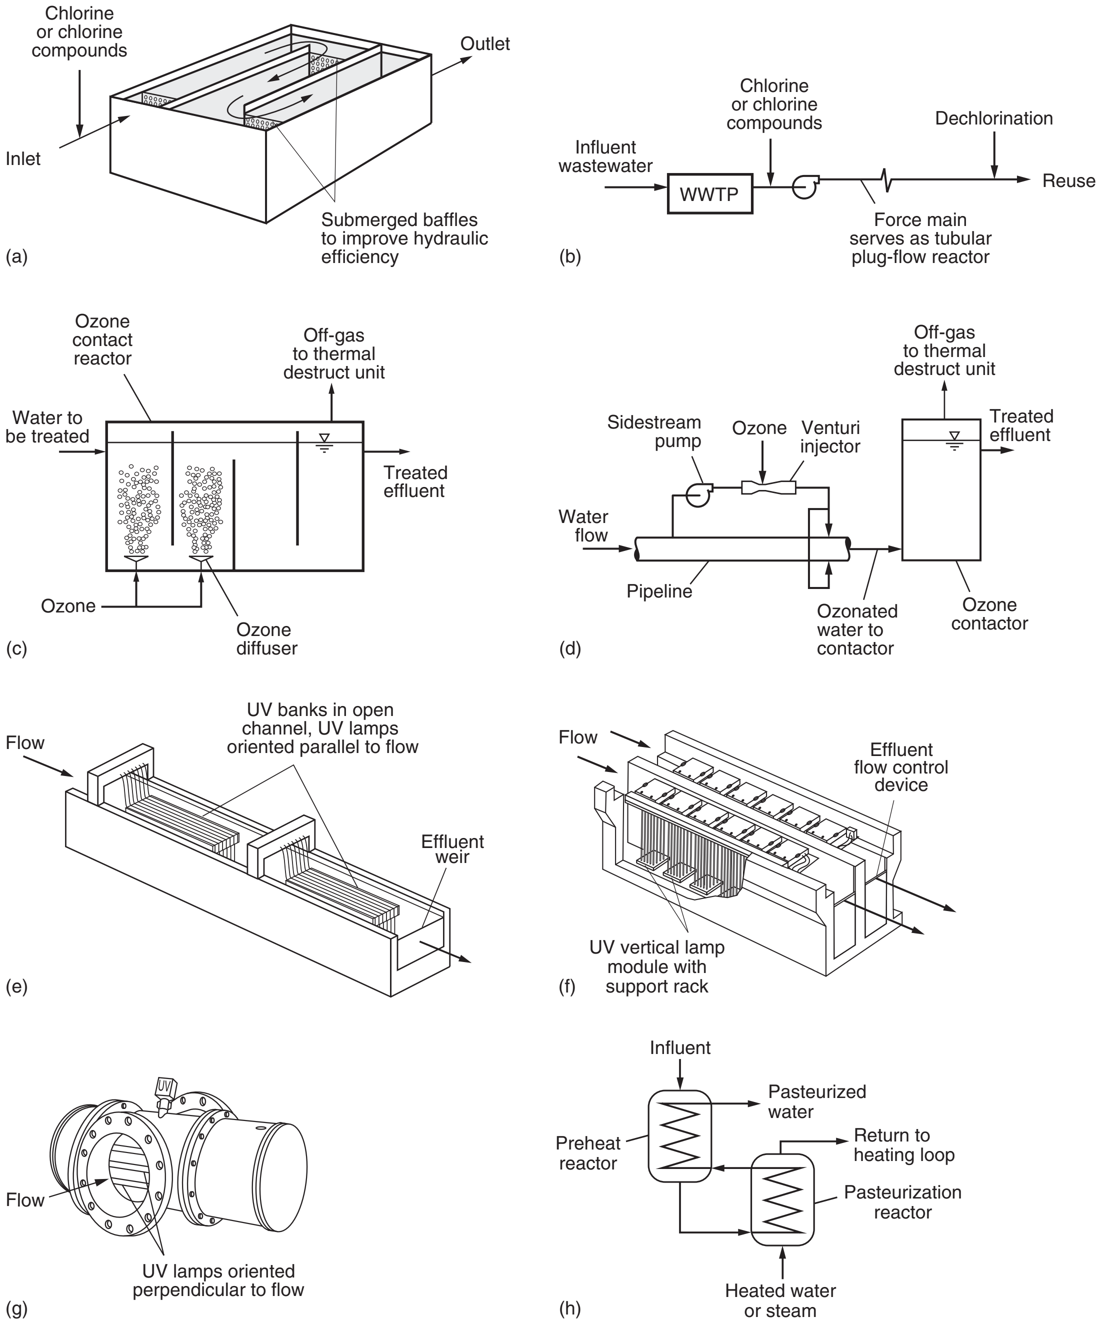

Figure 12–1

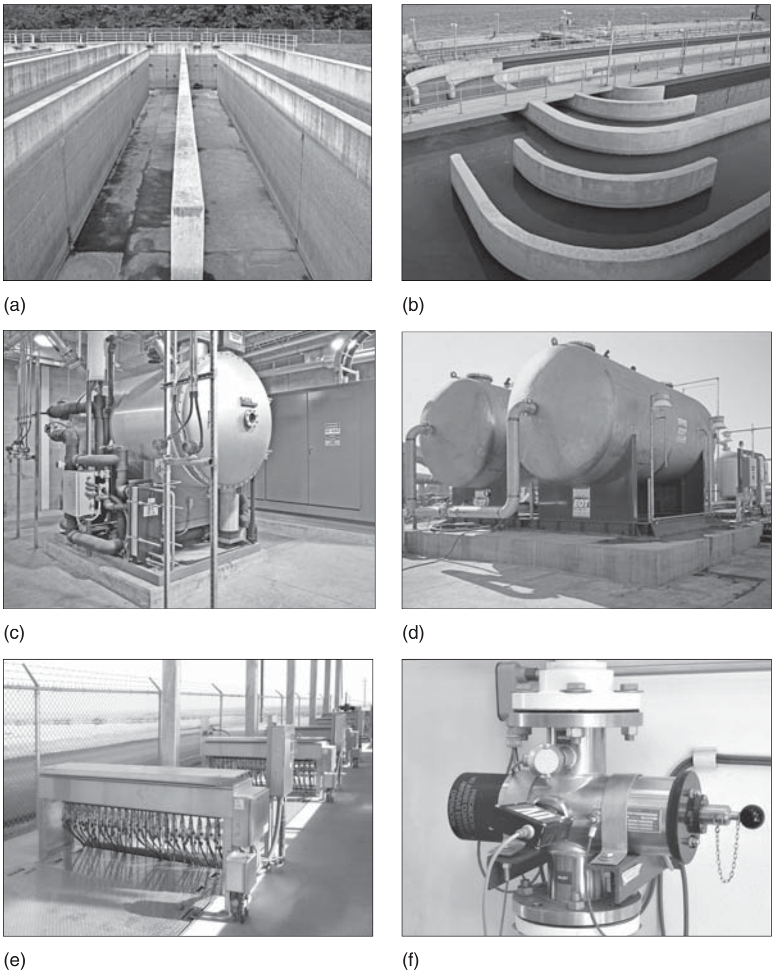
Types of reactors used to accomplish disinfection process: (a) plug-flow reactor in back-and-forth configuration, (b) force main which serves as a tubular plug-flow reactor, (c) multiple chamber inline ozone contactor, (d) sidestream ozone injection system, (e) UV irradiation in an open channel with two UV banks with flow parallel to UV lamps, (f) UV irradiation in an open channel with six UV banks with flow perpendicular to UV lamps, (g) UV irradiation in an closed reactor, and (h) reactors for pasteurization system.

Figure 12–2

Views of reactors used for disinfection: (a) serpentine plug-flow chlorine contact basin, (b) serpentine plug-flow chlorine contact basin with rounded corners and flow deflection baffles, (c) typical ozone generator, (d) view of ozone contactor used in conjunction with sidestream ozone injection, (e) view of open channel plug-flow UV reactor, and (f) view of closed channel UV reactor with manual lamp wiping device.



UV lamps. Closed proprietary reactors are used for low-pressure, high-intensity and medium pressure, high-intensity UV lamps. Because the contact time is short in UV reactors (seconds), the design of the open channel and closed reactors is of critical importance. Open plug-flow and closed channel UV reactors are shown on Figs. 12–2(e) and (f), respectively.

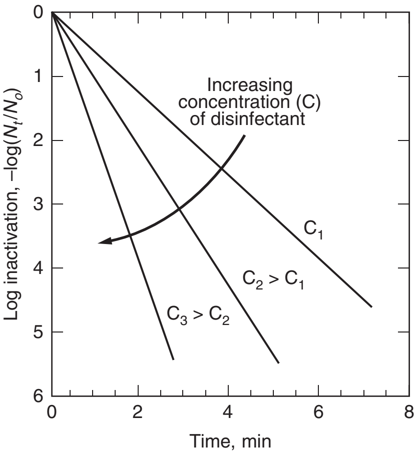
Pasteurization. The pasteurization process occurs in two reactors [see Fig. 12–1(h)]. In the first reactor, the liquid to be disinfected is preheated. Pasteurization occurs in the second reactor where the liquid to be disinfected is held for a specified period of time and temperature.

Factors Affecting Performance

In applying disinfection agents or physical processes, the following factors must be considered: (1) contact time and hydraulic efficiency of contact chambers, (2) concentration of the disinfectant, (3) intensity and nature of physical agent or means, (4) temperature, (5) types of organisms, (6) nature of suspending liquid (e.g., unfiltered or filtered secondary effluent), and (7) the upstream treatment processes. The subjects introduced in this

Figure 12–3

Log inactivation of dispersed microorganisms as a function of time in a batch reactor using increasing disinfectant dosages.



section are considered further in the subsequent sections dealing with the individual disinfectants.

Contact Time. Perhaps one of the most important factors in the disinfection process is contact time. Once the disinfectant has been added, the time of contact before the effluent is to be discharged or reused is of paramount importance. As shown on Fig. 12–1, disinfection reactors are designed to ensure that an adequate contact time is provided. The hydraulic efficiency of disinfection reactors is considered in Sec. 12–6.

Working in England in the early 1900s, Harriet Chick observed that for a given concentration of disinfectant, the longer the contact time, the greater the kill (see Fig. 12–3). This observation was first reported in the literature in 1908 (Chick, 1908). In differential form, Chick's law is

$$\frac{dN_t}{dt} = -KN_t \tag{12–1}$$

where dN_t/dt = the rate of change in the number (concentration) of organisms with time
K = inactivation rate constant, T^{-1}
N_t = number of organisms at time t
t = time

If N_o is the number of organisms when t equals 0, Eq. (12–1) can be integrated to

$$\ln\frac{N_t}{N_o} = -Kt \tag{12–2}$$

The value of the inactivation rate constant, K, in Eq. (12–2) can be obtained by plotting $-\ln(N_t/N_o)$ versus the contact time t, where K is the slope of the resulting line of best fit.

Concentration of Chemical Disinfectant. Also working in England in the early 1900s, Herbert Watson reported that the inactivation rate constant was related to the concentration as follows (Watson, 1908):

$$K = \Lambda C^n \tag{12–3}$$

where K = inactivation rate constant, T^{-1}, base e
Λ = coefficient of specific lethality, units vary with the value of n
C = concentration of disinfectant, mg/L
n = empirical constant related to dilution, dimensionless

The following explanation has been offered for various values of the dilution constant n:

$n = 1$, both the concentration and time are equally important
$n > 1$, concentration is more important than time
$n < 1$, time is more important than concentration

The value of n can be obtained by plotting C versus t on log-log paper for a given level of inactivation. When n is equal to one, the data are plotted on log-arithmetic paper.

Combining the expressions proposed by Chick and Watson in differential form yields (Haas and Karra, 1984a, b, c):

$$\frac{dN_t}{dt} = -\Lambda C^n N_t \tag{12–4}$$

The integrated form of Eq. (12–4) is:

$$\ln \frac{N_t}{N_o} = -\Lambda_{\text{base}\,e} C^n t \text{ or } \log \frac{N_t}{N_o} = -\Lambda_{\text{base}\,10} C^n t \tag{12–5}$$

If n is equal to one, a reasonable assumption based on past experience (Hall, 1973), Eq. (12–5) can be written as follows:

$$\log \frac{N_t}{N_o} = -\Lambda_{\text{base}\,10}(\mathrm{CT}) = -\Lambda_{\text{base}\,10}(D) \tag{12–6}$$

Where C = residual concentration of disinfectant, mg/L
T = contact time in the reactor, min
D = *germicidal dose* for a given degree of inactivation, mg·min/L

The concept of dose (concentration times time) is significant as the performance of the disinfectants, as discussed subsequently, is based on the concept (Morris, 1975). This concept has also been adopted by the U.S. EPA in establishing guidelines for the disinfection of public water supplies (see "Development of the CT Concept for Predicting Disinfection Performance" later in the chapter).

EXAMPLE 12–1 **Determination of the Coefficient of Specific Lethality Based on the Chick-Watson Expression** Using the microorganism inactivation data given below, determine the coefficient of specific lethality of the chemical disinfecting agent using Eq. (12–6).

C, mg/L	Time, min	Number of organisms, Number/100 mL
0	0	1.00×10^8
4.0	2	1.59×10^7
4.0	4.5	1.58×10^6
4.0	8	2.01×10^4
4.0	11.5	3.16×10^3

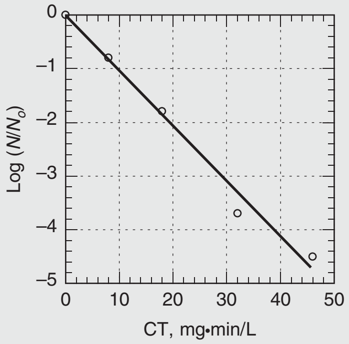
Solution

1. To determine the coefficient of lethality prepare a plot of $\log[N/N_o]$ as a function of CT and fit a linear trend line through the data.

a. Determine the values of log[N/N_o] and CT. The required data table is shown below.

C, mg/L	Time, min	Number of organisms, N/100 mL	CT, mg·min/L	log(N/N_o)
0	0	1.00×10^8	0	0
4.0	2	1.59×10^7	8	−0.8
4.0	4.5	1.58×10^6	18	−1.8
4.0	8	2.01×10^4	32	−3.7
4.0	11.5	3.16×10^3	46	−4.5

b. Prepare a plot of log(N/N_o) as a function of CT. The required plot is shown below.



2. Determine the coefficient of specific lethality. The slope of the line in the above plot corresponds to the coefficient of specific lethality, $-\Lambda_{CW}$ (base 10). From the plot

$$-\Lambda_{CW}\text{ (base 10)} = \frac{-5 - 0}{49 - 0}$$

$$\Lambda_{CW}\text{(base 10)} = 0.102\,\text{L/mg·min}$$

Check, when CT = 46,

$$\log\frac{N_t}{N_o} = -\Lambda_{\text{base }10}\text{CT} = -0.102(46) = -4.69\text{ versus } -4.5\text{ OK}$$

Temperature. The effect of temperature on the rate of kill with chemical disinfectants can be represented by a form of the van't Hoff-Arrhenius relationship. Increasing the temperature results in a more rapid kill. In terms of the coefficient of specific lethality, Λ, the effect of temperature is given by the following relationship, repeated here from Chap. 1.

$$\ln\frac{\Lambda_1}{\Lambda_2} = \frac{E(T_2 - T_1)}{RT_1T_2} \tag{12–7}$$

where Λ_1, Λ_2 = coefficient of specific lethality at temperatures T_1 and T_2, respectively
E = activation energy, J/mole
R = universal gas constant, 8.3144 J/mole·K

Typical values for the activation energy for various chlorine compounds at different pH values are given in Sec. 12–3. The effect of temperature is considered in Example 12–2.

EXAMPLE 12–2 **Effect of Temperature on Disinfection Times** Estimate the time required for a 99 percent kill for a chlorine dosage of 0.05 mg/L at a temperature of 20°C. Assume the activation energy is equal to 26,800 J/mole (from Table 12–12 in Sec. 12–3). The following coefficients were developed for Eq. (12–5) at 5°C using a batch reactor.

$\Lambda = 10.5\ \text{L/mg·min}$

$n = 1$

Solution

1. Estimate the time required at 5°C for a 99 percent kill using Eq. 12–5.

$$\log \frac{N_t}{N_o} = -10.5\,\text{CT}$$

$$\log \frac{10}{100} = -(10.5\ \text{L/mg·min})(0.05\ \text{mg/L})T$$

$$T = \frac{-6.91}{(-10.5)(0.05)} = 13.2\ \text{min at } 5°\text{C}$$

2. Estimate the time required at 20°C using the van't Hoff-Arrhenius equation [Eq. (12–7)].

$$\ln\frac{\Lambda_1}{\Lambda_2} = \frac{E(T_2 - T_1)}{RT_1T_2}$$

$$\ln\frac{10.5}{\Lambda_2} = \frac{(26{,}800\ \text{J/mole})(278 - 293)\text{K}}{(8.3144\ \text{J/mole·K})(293)(298)}$$

$$\ln\frac{10.5}{\Lambda_2} = -0.594$$

$$\ln\frac{10.5}{\Lambda_2} = e^{-0.594} = -0.552$$

$$\Lambda_2 = 19.0\ \text{L/mg·min}$$

$$T = \frac{-6.91}{(-19.0)(0.05)} = 7.27\ \text{min at } 20°\text{C}$$

Intensity and Nature of Non-Ionizing Radiation. As noted earlier, irradiation with ultraviolet light (UV) is used commonly for the disinfection of water. It has been found that the effectiveness of UV disinfection is a function of the average UV intensity, expressed as milliwatts per square centimeter (mW/cm^2). When the exposure time is considered, the dose of UV to which the microorganisms in the liquid are exposed to is given by the following expression.

$$D = I_{\text{avg}} \times t \tag{12–8}$$

Where D = UV dose, mJ/cm^2 (Note: $\text{mJ/cm}^2 = \text{mW·s/cm}^2$)
I_{avg} = average UV intensity, mW/cm^2
t = time, s

The UV dose is expressed in mJ/cm^2 (millijoule per square centimeter) which is equivalent to mW·s/cm^2. Thus, the concept of dose can also be used to define the effectiveness of UV light in a manner analogous to that used for chemical disinfectants, as well as when heat is used as in pasteurization.

Types of Organisms. The effectiveness of various disinfectants is influenced by the type, nature, and condition of the microorganisms. For example, viable growing (vegetative) bacteria cells are often killed or inactivated more easily than older cells that have developed a slime (polymer) coating. Bacteria that are able to form spores enter this protective state when stressors, such as increased temperature or a toxic agent, is applied. Bacterial spores are extremely resistant, and many of the chemical disinfectants normally used have little or no effect on them. Similarly, many of the viruses and protozoa of concern respond differently to each of the chemical disinfectants. In some cases, other disinfecting agents, such as heat or UV irradiation, may have to be used for effective disinfection. The inactivation of different types of microorganism groups is considered in the following sections.

Nature of Suspending Liquid. In reviewing the development of the relationships developed by Chick and Watson for the inactivation of microorganisms, as cited above, it is important to note that most of the tests were conducted in batch reactors using distilled or buffered water, under laboratory conditions. In practice, the nature of the suspending liquid must be evaluated carefully. Three constituents found in wastewater are significant: (1) inorganic constituents that can react with the disinfectant, (2) organic matter including both natural organic material (NOM) and other organic compounds, and (3) suspended material. The NOM found in treated wastewater will react with most oxidizing disinfectants and reduce their effectiveness or result in greater dosages to effect disinfection. The NOM is derived from three sources: (1) the terrestrial environment (mostly humic materials), (2) the aquatic environment (algae and other aquatic species and their byproducts), and (3) the microorganisms in the biological treatment process. The source of the other organic compounds is from the constituents discharged to the collection system. The presence of suspended matter will also reduce the effectiveness of disinfectants by absorption of the disinfectant and by shielding the entrapped bacteria.

Because of the interactions that can occur between the disinfecting agent and the wastewater constituents, departures from the Chick-Watson rate law [Eqs.(12–5) and (12–6)] are common as shown on Fig. 12–4. As shown on Fig. 12–4(a), there can be a lag or shoulder effect in which constituents in the suspending liquid react initially with the disinfectant rendering the disinfectant ineffective followed by a log-linear portion. The tailing effect in which large particles shield the organisms to be disinfected is shown on Fig. 12–4(b). The combined effects of lag and tailing are illustrated on Fig. 12–4(c). In general, Eq. (12–5) as applied to wastewater fails to account for the variable, heterogeneous characteristics of wastewater.

Effect of Upstream Treatment Processes. The extent to which upstream processes remove NOM, other organic matter, and suspended matter will greatly influence the disinfection process. Incidental removals of bacteria and other organisms are also achieved by mechanical and biological means during wastewater treatment. Typical removal efficiencies for various treatment operations and processes are reported in Table 12–4. The first and last four operations listed are essentially physical. The actual removal accomplished is a byproduct of the primary function of the process.

Another factor that impacts the performance of both chlorine and UV disinfection for unfiltered effluents (especially when coliform bacteria are used as the regulatory indicator) is the number of particles with associated coliform bacteria. It has been observed that for

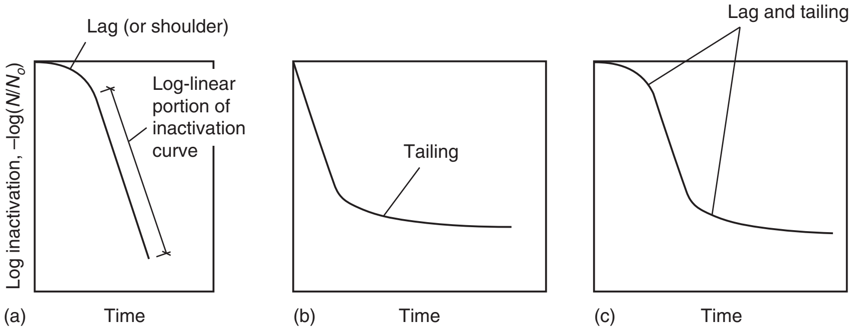


Figure 12–4

Departures observed from the Chicks' law: (a) lag or shoulder effect in which the disinfectant reacts first with constituents in the suspending liquid after which the response is log-linear (i.e., first order kinetics), (b) log-linear response followed by tailing effect in which large particles shield the organisms to be disinfected following the inactivation of dispersed organisms, and (c) combined lag, log-linear, and tailing effects.

activated sludge plants the number of particles with associated coliform organisms is a function of the solids retention time (SRT). The relationship between the fraction of wastewater particles with one or more associated coliform organisms and the SRT is illustrated on Fig. 12–5. As illustrated, longer SRTs result in a decrease in the fraction of particles containing coliform bacteria. The use of deep final clarifiers (or other filtration methods) reduces the number of large particles that may shield bacteria [see Fig. 7–7(b) in Chap. 7]. In general, without some form of filtration, it is difficult to achieve extremely low coliform concentrations in the settled effluent from activated sludge plants operated at low SRT values (e.g., 1 to 2 d).

Development of the CT Concept for Predicting Disinfection Performance

Although the disinfection models discussed above are useful for analyzing disinfection data, they are difficult to use to predict disinfection performance over a wide range of operating conditions. In the water treatment field, before the adoption of the Surface Water Treatment Rule (SWTR) (circa 1989) and before the importance of *Cryptosporidium* as a

Table 12–4

Removal or destruction of total coliform by different treatment processes

Process	Removal	
	Percent	log[a]
Coarse screens	0–5	~0
Fine screens	10–20	0–0.1
Grit chambers	10–25	0–0.1
Plain sedimentation	25–75	0.1–0.6
Chemical precipitation	40–80	0.2–0.7
Trickling filters	90–95	1–1.3
Activated sludge	90–98	1–1.7
Depth filtration	—	0.25–1
Microfiltration	—	2–4[b]
Ultrafiltration	—	2–5[b]
Reverse osmosis	—	2–6[b]

[a] The log-reduction credit allowed by regulatory agencies for these processes will vary from state to state.

[b] Depends on the characteristics and configuration of the membrane.

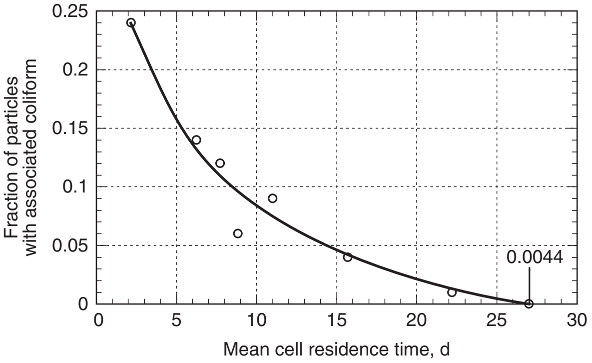

Figure 12–5

Fraction of particles in settled wastewater with one or more associated coliform organisms as function of the solids retention time. (From Emerick et al., 1999.)

causative agent in waterborne disease outbreaks was recognized, meeting water quality requirements was quite straightforward. Chlorine and its compounds were generally used to inactivate coliform bacteria to meet the drinking water standards in effect at that time.

In developing the rationale for the first SWTR, the U.S. EPA needed some way to ensure the safety of public water supplies that were unfiltered (e.g., New York City, San Francisco, Seattle). Based on ongoing research, the U.S. EPA determined that four logs of virus and three logs of *Giardia* reduction would be required by means of disinfection. Recognizing that guidance was required on how to achieve adequate disinfection, the U.S. EPA undertook an evaluation of the most commonly used disinfectants for the disinfection of viruses and *Giardia* cysts. In conducting their evaluation, the U.S. EPA adopted the CT concept (the product of the residual disinfectant concentration, C, in mg/L times and the contact time, T, in min), derived from the simplified Chick-Watson model [see Eq. (12–6)], as a measure of performance. The CT values obtained, typically in laboratory bench scale studies, are used as a surrogate measure of disinfection effectiveness. Thus, if a given CT value is achieved it could be assumed generally that disinfection requirements had been met. Bauman and Ludwig (1962) were among the first, if not the first, to suggest use of the CT concept in a paper published in 1962. The CT concept was not picked up again in a meaningful way until 1980 when it was used by the Safe Drinking Water Committee of the National Research Council in its evaluation of the disinfection literature (NRC, 1980; Hoff, 1986).

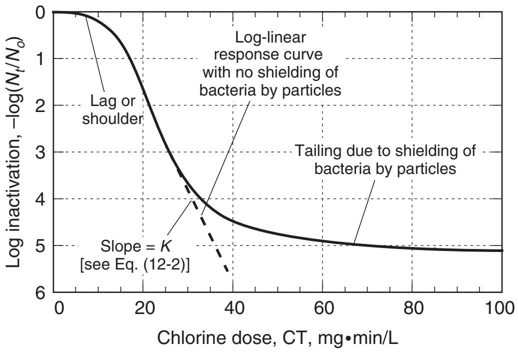
Although *Cryptosporidium* had been identified at the time the SWTR was adopted in 1989, CT values for *Cryptosporidium* were not included because it would have delayed adoption of the SWTR. It has since been found that many pathogens, including *Cryptosporidium,* remain intact and viable while in the presence of various disinfectants at concentrations that are sufficient to inactivate most other pathogens. Based on ongoing work, the U.S. EPA has now published extensive tables of CT values for a variety of disinfectants, microorganisms, and operating conditions (U.S. EPA, 2003a, 2006). In addition, corresponding UV dose values have also been published for *Cryptosporidium*, *Giardia,* and viruses. From a practical standpoint, the utility of the CT or UV dose approach can be appreciated as it is relatively easy to measure the residual concentration of the disinfectant or the UV intensity and the exposure contact time. With respect to the contact time, the t_{10} value (the contact time during which no more than 10 percent in the influent water has passed through the process–see discussion in Sec. 12–3) is used commonly in the field of water treatment for disinfectants other than UV irradiation.

Application of the CT Concept to Wastewater Disinfection

Use of the CT concept to control the disinfection process is now becoming more common in the wastewater field. In some states, the CT value and the chlorine contact time are

Figure 12–6

Typical disinfection dose-response curve obtained with wastewater containing oxidizable constituents and suspended solids. Both lag and tailing effects are evident.



specified in regulatory requirements. For example, the California Department of Public Health (CDPH) California requires a minimum CT value of 450 mg·min/L (based on combined chlorine residual) and a modal contact time of 90 min at peak flow for certain water reclamation applications. It is assumed, based on past testing, that a minimum CT value of 450 mg·min/L will produce a four-log inactivation of poliovirus. As the use of the CT concept becomes more common in the wastewater field, a number of past limitations must be considered in the application of this concept for regulatory purposes. In the past, most of the CT values reported in the literature are obtained using (1) complete-mix batch reactors (i.e., ideal plug flow conditions) in a laboratory setting under controlled conditions, (2) discrete organisms grown in the laboratory in pure culture, (3) a buffered fluid for the suspension of the discrete organisms, and (4) an absence of particulate matter.

Further, many of the CT values reported in the literature were based on older analytical techniques. As a consequence, CT values used for regulatory purposes often do not match what is observed in the field. Referring to Fig. 12–6, it can be seen that in the tailing region, the residual concentration of microorganisms is essentially independent of the CT value. In addition, some compounds present in treated wastewater will (1) react with the chlorine and its compounds, (2) be measured as combined residual, and (3) have no disinfection properties (see Sec. 12–3). In a similar manner, dissolved constituents, such as metals and humic acids, will reduce the effectiveness of UV disinfection. Thus, it is difficult to develop standardized CT or UV dose values suitable for all conditions encountered in wastewater treatment. Clearly, as discussed subsequently, site-specific testing is required to establish the appropriate disinfectant dose.

Performance Comparison of Disinfection Technologies

A general comparison of the germicidal effectiveness of the disinfection technologies based on Eq. (12–6) by classes of organisms is presented in Table 12–5. Additional information is presented in the sections dealing with the individual technologies. It is important to note that the values given in these tables are only meant to serve as a guide in assessing the effectiveness of these technologies. The CT values also vary with both temperature and pH. Because the characteristics of each wastewater and the degree of treatment will significantly impact the effectiveness of the various disinfection technologies, site-specific testing must be conducted to evaluate the effectiveness of alternative disinfection technologies and to establish appropriate dosing ranges.

Advantages and Disadvantages of Alternative Disinfection Technologies. The general advantages and disadvantages of using chlorine, chlorine dioxide, ozone, and UV for the disinfection of wastewater are summarized in Table 12–6. In most wastewater

Table 12–5

Relative CT values for various levels of inactivation of bacteria, viruses, *Cryptosporidium,* and *Giardia lamblia* cysts in filtered secondary effluent (pH ~7.5, ~20°C)[a,b]

		Inactivation			
Disinfectant	**Unit**	**1–log**	**2–log**	**3–log**	**4–log[c]**
Bacteria[d]					
Chlorine (free)	mg·min/L	0.4–0.6	0.8–1.2	1.2–1.8	1.6–2.4

UV radiation[e]	mJ/cm^2		40–50	60–75	80–100
Protozoa (*Cryptosporidium*)[f]					
Chlorine (free)	mg·min/L	2000–2600	4000–5000		
Chloramine	mg·min/L	4000–5000	8000–10,000		
Chlorine dioxide	mg·min/L	120–150	235–260	350–400	
Ozone	mg·min/L	4–4.5	8–8.5	12–13	
UV radiation	mJ/cm^2	2.5–3	6–7	12–13	
Protozoa (*Giardia lamblia* cysts)[g]					
Chlorine (free)	mg·min/L	20–30	45–55	70–80	
Chloramine	mg·min/L	400–450	800–900	1100–1300	
Chlorine dioxide	mg·min/L	5–5.5	9–11	15–16	
Ozone	mg·min/L	0.25–0.3	0.45–0.5	0.75–0.8	
UV radiation	mJ/cm^2	2–2.5	5.5–6.6	11–13	

[a] Adapted in part from AWWA (1991), Baumann and Ludwig (1962), Crittenden et al. (2012), Hoff (1986), Code of Federal Regulations – Title 40 (40 CFR 141.2), Maguin et al. (2009), Montgomery (1985), Roberts et al. (1980), Sung (1974), U.S. EPA (1999b).

[b] Reported CT values are highly temperature and pH sensitive. Disinfection rates will increase by a factor of 2 to 3 for each 10°C increase in temperature.

[c] The range of CT values for 4-log removal is for the linear portion of the dose-response curve (see Fig. 12–6). Depending on the particle size distribution resulting from the filtration of secondary effluent, much higher CT values may be needed to achieve a 4-log removal.

[d] The reported CT values are for total coliform. Significantly lower CT values have been reported for fecal coliform and *E coli*.

[e] With the exception of adenovirus which requires a much higher UV dose (as high as 160–200 mJ/cm^2 for 4-log inactivation).

[f] The data for *Cryptosporidium* inactivation with free or combined chlorine are extremely variable. Values of CT greater than 10,000 mg·min/L have been reported for 99 percent inactivation with chloramines. Clearly, free or combined chlorine is not an effective disinfectant for *Cryptosporidium*. Further, *Cryptosporidium* oocysts will, in general, require even higher CT values.

[g] Based primarily on the results of infectivity studies.

Note: Because there is such a wide variability in the susceptibility of different microorganism groups as well as within a microorganism group to the different disinfection technologies, a wide range of dosage values has been reported in the literature. Thus, the data presented in this table are only meant to serve as general guide to the relative effectiveness of the different disinfection technologies and are not for a specific microorganism.

Table 12–6

Advantages and disadvantages of chlorine, chlorine dioxide, ozone, and UV for the disinfection of treated wastewater[a]

Advantages	Disadvantages
Free and combined chlorine species	
1. Well established technology 2. Effective disinfectant 3. Chlorine residual can be monitored and maintained 4. Combined chlorine residual can also be provided by adding ammonia 5. Germicidal chlorine residual can be maintained in long transmission lines 6. Availability of chemical system for auxiliary uses such as odor control, dosing RAS, and disinfecting plant water systems 7. Oxidizes sulfides 8. Capital cost is relatively inexpensive, but cost increases considerably if conformance to Uniform Fire Code regulations is required 9. Available as calcium and sodium hypochlorite that are considered to be safer than chlorine gas 10. Hypochlorite can be generated onsite	1. Hazardous chemical that can be a threat to plant workers and the public; thus, strict safety measures must be employed especially in light of the Uniform Fire Code 2. Relatively long contact time required as compared to other disinfectants 3. Combined chlorine is less effective in inactivating some viruses, spores, and cysts at low dosages used for coliform organisms 4. Residual toxicity of treated effluent must be reduced through dechlorination 5. Forms trihalomethanes and other DBPs including NDMA[b] (see Table 12–16) 6. Releases volatile organic compounds from chlorine contact basins 7. Oxidizes iron, magnesium, and other inorganic compounds (consumes disinfectant) 8. Oxidizes a variety of organic compounds (consumes disinfectant) 9. Increases TDS level of treated effluent 10. Increases chloride content of treated effluent 11. Acid generation; pH of the wastewater can be reduced if alkalinity is insufficient 12. Chemical scrubbing facilities may be required to meet Uniform Fire Code regulations 13. Formal risk management plan may be required 14. Not effective disinfectant for *Cryptosporidium*
Chlorine dioxide	
1. Effective disinfectant for bacteria, *Giardia* and viruses 2. More effective than chlorine in inactivating most viruses, spores, cysts and oocysts 3. Biocidal properties not influenced by pH 4. Under proper generation conditions, halogen-substituted DBPs are not formed 5. Oxidizes sulfides 6. Provides residuals	1. Unstable, must be produced onsite 2. Oxidizes iron, magnesium, and other inorganic compounds (consumes disinfectant) 3. Oxidizes a variety of organic compounds 4. Forms DBPs (i.e., chlorite and chlorate), limiting applied dose 5. Potential for the formation of halogen-substituted DBPs 6. Decomposes in sunlight 7. Can lead to the formation of odors 8. Increases TDS level of treated effluent 9. Operating costs can be high (e.g., must test for chlorite and chlorate)

(*continued*)

Table 12–6 (*Continued*)

Advantages	Disadvantages
Ozone	
1. Effective disinfectant	1. Ozone residual monitoring and recording requires more operator time than chlorine residual monitoring and recording
2. More effective than chlorine in inactivating most viruses, spores, cysts and oocysts	2. No residual effect
3. Biocidal properties not influenced by pH	3. Less effective in inactivating some viruses, spores, cysts at low dosages used for coliform organisms
4. Shorter contact time than chlorine	4 Forms DBPs (see Table 12–15)
5. Oxidizes sulfides	5. Oxidizes iron, magnesium, and other inorganic compounds (consumes disinfectant)
6. Requires less space	6. Oxidizes a variety of organic compounds (consumes disinfectant)
7. Contributes dissolved oxygen	7. Off-gas requires treatment
8. At higher dosages than required for disinfection, ozone reduces the concentration of trace organic constituents	8. Safety concerns
	9. Highly corrosive and toxic
	10. Energy intensive
	11. Relatively expensive
	12. Highly operational and maintenance sensitive
	13. Has been shown to control the growth of filamentous microorganisms, but more expensive than chlorine
UV	
1. Effective disinfectant	1. No immediate measure of whether disinfection was successful
2. Requires no hazardous chemicals	2. No residual disinfectant
3. No residual toxicity	3. Less effective in inactivating some viruses, spores, and cysts at low dosages used for coliform organisms
4. More effective than chlorine in inactivating most viruses, spores, and cysts	4. Energy intensive
5. No formation of DBPs at dosages used for disinfection	5. Hydraulic design of UV system is critical
6. Does not increase TDS level of treated effluent	6. Capital cost is relatively expensive, but price is coming down as new and improved technology is brought to the market
7. At very high dosages, effective in the destruction of resistant organic constituents such as NDMA	7. Large number of UV lamps required where low-pressure, low-intensity systems are used
8. Improved safety as compared to use of chemical disinfectants	8. Acid washing to remove scale from quartz sleeves may be required for any technology
9. Requires less space than chlorine disinfection	9. Lacks a chemical system that can be adapted for auxiliary uses such as odor control, dosing RAS, and disinfecting plant water systems
10. At higher UV dosages than required for disinfection, UV radiation can be used to reduce the concentration of trace organic constituents of concern such as NDMA (see Sec. 10–8 in Chap. 10)	10. Fouling of UV lamps
	11. Lamps require routine periodic replacement
	12. Lamp disposal is problematic due to presence of mercury

[a] Adapted in part from Crites and Tchobanoglous (1998), U.S. EPA (1999b), and Hanzon et al. (2006).

[b] DBPs = disinfection byproducts.

treatment applications, the choice of disinfectant has usually between chlorine and UV. Recently, however, with concerns regarding trace constituents of concern, a renewed interest has developed in the use of ozone. Deciding factors in the selection of a disinfectant are commonly (1) economic evaluation, (2) public and operator safety, (3) environmental effects, and (4) ease of operation (Hanzon et al., 2006). Other treatment objectives are also important in the selection of a disinfectant. Potential concerns with pesticides, trace constituents of concern, endocrine disruptors, and similar compounds may influence the choice of disinfectants. Each disinfectant offers varying treatment performance with regard to these potential concerns.

12–3 DISINFECTION WITH CHLORINE

Chlorine, of all the chemical disinfectants, is the one used most commonly throughout the world. Specific topics considered in this section include a brief description of the characteristics of the various chlorine compounds, a review of chlorine chemistry and breakpoint chlorination, an analysis of the performance of chlorine as a disinfectant and the factors that may influence the effectiveness of the chlorination process, a discussion of the formation of disinfection byproducts (DBPs), and a consideration of the potential impacts of the discharge of DBPs to the environment. Disinfection with chlorine dioxide and dechlorination are considered in the following two sections, respectively. Chlorination facilities are considered in Sec. 12–6.

Characteristics of Chlorine Compounds

The principal chlorine compounds used at water reclamation plants are chlorine (Cl_2), sodium hypochlorite (NaOCl), and chlorine dioxide (ClO_2). Calcium hypochlorite [$Ca(OCl)_2$], another chlorine compound, is used in very small treatment plants due to its ease of operation. Many large cities have switched from chlorine gas to sodium hypochlorite because of the safety concerns and regulatory requirements related to the handling and storage of pressurized liquid chlorine (see Table 12–3). The characteristics of Cl_2, NaOCl, and $Ca(OCl)_2$ are considered below. The characteristics of chlorine dioxide and its use as a disinfectant are discussed in the following section.

Chlorine. The general properties of chlorine (Cl_2) are summarized in Table 12–7. Chlorine can be present as a gas or a pressurized liquid. Chlorine gas is greenish yellow in color and about 2.48 times as heavy as air. Liquid chlorine is amber colored and about 1.44 times as heavy as water. Unconfined liquid chlorine vaporizes rapidly to a gas at standard temperature and pressure with one liter of liquid yielding about 450 liters of gas. Chlorine is moderately soluble in water, with a maximum solubility of about 1 percent at 10°C (50°F).

Although the use of chlorine for the disinfection has been of great significance from a public health perspective in both potable water supplies and treated wastewater, serious concerns have been raised about its continued use. Important concerns include the following:

1. Chlorine is a highly toxic substance that is transported by rail and truck, both of which are prone to accidents.
2. Chlorine is a highly toxic substance that potentially poses health risks to treatment plant operators, and the general public, if released by accident.
3. Because chlorine is a highly toxic substance, stringent requirements for containment and neutralization must be implemented as specified in the Uniform Fire Code (UFC).

Table 12–7

Properties of chlorine, chlorine dioxide, and sulfur dioxide[a]

Property	Unit	Chlorine (Cl_2)	Chlorine dioxide (ClO_2)	Sulfur dioxide (SO_2)
Molecular weight	g	70.91	67.45	64.06
Boiling point (liquid)	°C	−33.97	11	−10
Melting point	°C	−100.98	−59	−72.7
Latent heat of vaporization	kJ/kg	253.6	27.28	376.0
Liquid density at 15.5°C	kg/m^3	1422.4	1640[b]	1396.8
Solubility in water at 15.5°C	g/L	7.0	70.0[b]	120
Specific gravity of liquid at 0°C (water = 1)	s.g.	1.468		1.486
Vapor density at 0°C and 1 atm	kg/m^3	3.213	2.4	2.927
Vapor density compared to dry air at 0°C and 1 atm	unitless	2.486	1.856	2.927
Specific volume of vapor at 0°C and 1 atm	m^3/kg	0.3112	0.417	0.342
Critical temperature	°C	143.9	153	157.0
Critical pressure	kPa	7811.8		7973.1

[a] Adapted in part from U.S. EPA (1986), White (1999).

[b] At 20°C.

4. Chlorine reacts with the organic constituents in wastewater to produce odorous compounds.
5. Chlorine reacts with the organic constituents in wastewater to produce byproducts, many of which are known to be carcinogenic and/or mutagenic.
6. Residual chlorine in treated effluent is toxic to aquatic life.
7. The discharge of chloro-organic compounds has long-term effects on the environment that are not known.

Sodium Hypochlorite. Sodium hypochlorite (NaOCl) (i.e., liquid bleach), is only available as an aqueous solution and usually contains 12.5 to 17 percent available chlorine at the time it is manufactured. Sodium hypochlorite can be purchased in bulk or manufactured onsite; however, the solution decomposes more readily at high concentrations and is affected by exposure to light and heat. A 16.7 percent solution stored at 26.7°C (80°F) will lose 10 percent of its strength in 10 d, 20 percent in 25 d, and 30 percent in 43 d. It must, therefore, be stored in a cool location in a corrosion resistant tank. Another disadvantage of sodium hypochlorite is the chemical cost. The purchase price may range from 150 to 200 percent of the cost of liquid chlorine. The handling of sodium hypochlorite requires special design considerations because of its corrosiveness, the presence of chlorine fumes, and gas binding and caking in chemical feed lines. Several proprietary systems are available for the generation of sodium hypochlorite from sodium chloride (NaCl) or seawater. These systems are electric power intensive and result in a very dilute solution, a maximum of 0.8 percent as chlorine. Onsite generation systems have been used only on a limited basis, typically at relatively large plants, due to their complexity and high power cost.

Calcium Hypochlorite. Calcium hypochlorite [$Ca(OCl)_2$], is available commercially in either a dry or a wet form. In dry form it is available as an off-white powder or as granules, compressed tablets, or pellets. Calcium hypochlorite granules or pellets are readily soluble in water, varying from about 21.5 g/100 mL at 0°C (32°F) to 23.4 g/100 mL at 40°C (104°F). Because of its oxidizing potential, calcium hypochlorite should be stored in a cool, dry location away from other chemicals in corrosion resistant containers. With proper storage conditions the granules are relatively stable. Calcium hypochlorite is more expensive than liquid chlorine, loses its available strength when stored, and because it must be dissolved before being used, it is difficult to handle for large installations. In addition, calcium hypochlorite can clog metering pumps, piping, and valves as it tends to crystallize readily. Calcium hypochlorite is used most commonly at small installations in a dry form as tablets, where handling is relatively easy for plant operators.

Chemistry of Chlorine Compounds

The reactions of chlorine in water and the reaction of chlorine with ammonia are presented below.

Chlorine Reactions in Water. When chlorine in the form of Cl_2 gas is added to water, two reactions take place: *hydrolysis* and *ionization*.

Hydrolysis may be defined as the reaction in which chlorine gas combines with water to form hypochlorous acid (HOCl).

$$Cl_2 + H_2O \rightarrow HOCl + H^+ + Cl^- \tag{12–9}$$

The equilibrium constant, K_H, for this reaction is

$$K_H = \frac{[HOCl][H^+][Cl^-]}{[Cl_2]} = 4.5 \times 10^{-4} \text{ at } 25°C \tag{12–10}$$

Because of the magnitude of the equilibrium constant, large quantities of chlorine can be dissolved in water.

Ionization of hypochlorous acid to hypochlorite ion (OCl^-) may be defined as

$$HOCl \rightleftarrows H^+ + OCl^- \tag{12–11}$$

The ionization constant, K_i, for this reaction is

$$K_i = \frac{[H^+][OCl^-]}{[HOCl]} = 3 \times 10^{-8} \text{ at } 25°C \tag{12–12}$$

The variation in the value of K_i with temperature is reported in Table 12–8.

The total quantity of HOCl and OCl^- present in water is called the *free chlorine*. The relative distribution of these two species (see Fig. 12–7) is very important because the killing efficiency of HOCl is many times that of OCl^-. The percentage distribution of HOCl at various temperatures can be computed using Eq. (12–13) and the data in Table 12–8.

$$\frac{[HOCl]}{[HOCl] + [OCl^-]} = \frac{1}{1 + [OCl^-]/[HOCl]} = \frac{1}{1 + [K_i]/[H^+]} = \frac{1}{1 + K_i 10^{pH}} \tag{12–13}$$

Hypochlorite Reactions in Water. Free chlorine can also be added to water in the form of hypochlorite salts. Both sodium and calcium hypochlorite hydrolyze to form hypochlorous acid (HOCl) as follows:

$$NaOCl + H_2O \rightarrow HOCl + NaOH \tag{12–14}$$

Table 12–8

Values of the ionization constant of hypochlorous acid at different temperatures[a]

Temperature, °C	$K_i \times 10^8$, mole/L
0	1.50
5	1.76
10	2.04
15	2.23
20	2.62
25	2.90
30	3.18

[a] Computed using equation from Morris (1966).

$$\mathrm{Ca(OCl)_2 + 2H_2O \rightarrow 2HOCl + Ca(OH)_2} \tag{12–15}$$

The ionization of hypochlorous acid was discussed previously [see Eq. (12–11)].

Chlorine Reactions with Ammonia. Untreated wastewater contains nitrogen in the form of ammonia, ammonium, and various combined organic forms (see Table 2–6 in Chap. 2). The effluent from most treatment plants also contains significant amounts of nitrogen, usually in the form of ammonia, ammonium, or nitrate, if the plant is designed to achieve nitrification. As noted in Chap. 2 the relative distribution between ammonia and ammonium will depend on the pH. Because hypochlorous acid is a very active oxidizing agent, it will react readily with ammonia (used here for the purpose of illustration) in water to form three types of chloramines in successive reactions:

$$\mathrm{NH_3 + HOCl \rightarrow NH_2Cl\ (monochloramine) + H_2O}\ \text{[see also Eq. (12–19)]} \tag{12–16}$$

$$\mathrm{NH_2Cl + HOCl \rightarrow NHCl_2\ (dichloramine) + H_2O} \tag{12–17}$$

$$\mathrm{NHCl_2 + HOCl \rightarrow NCl_3\ (nitrogen\ trichloride) + H_2O} \tag{12–18}$$

These reactions are very dependent on the pH, temperature, and contact time, and on the ratio of chlorine to ammonia (White, 1999). The two species that predominate, in most cases, are monochloramine (NH_2Cl) and dichloramine ($NHCl_2$). The ratio of dichloramine to monochloramine as a function of the ratio of chlorine to ammonia at various pH values is presented in Table 12–9. The amount of nitrogen trichloride present is negligible up to chlorine-to-nitrogen ratios of 2.0. As will be discussed subsequently, chloramines also

[a] From U.S. EPA (1986).

serve as disinfectants, although they are slow-reacting. When chloramines are the only disinfectants, the measured residual chlorine is defined as *combined chlorine residual* as opposed to free chlorine in the form of hypochlorous acid and hypochorite ion.

Breakpoint Reaction with Chlorine

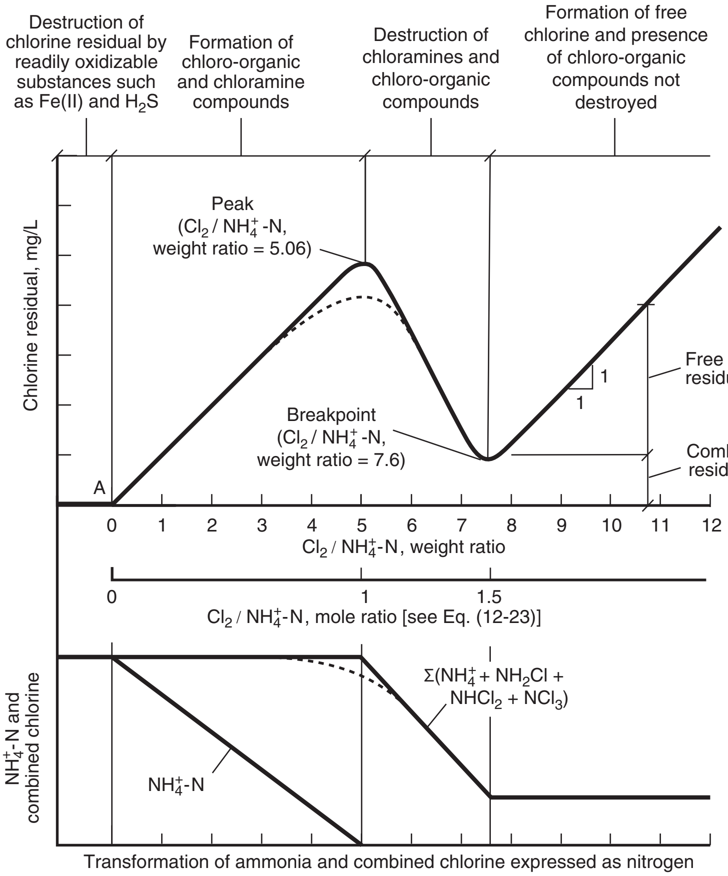
The maintenance of a residual (free or combined) for the purpose of disinfection is complicated because free chlorine not only reacts with ammonium, as noted previously, but also is a strong oxidizing agent. The term *breakpoint chlorination* is the term applied to the process whereby enough chlorine is added to react with all oxidizable substances such that if additional chlorine is added it will remain as free chlorine. The main reason for adding enough chlorine to obtain a free chlorine residual is that effective disinfection can usually then be assured. The amount of chlorine that must be added to reach a desired level of residual is called the *chlorine demand*. Breakpoint chlorination chemistry, acid generation, and the buildup of dissolved solids are considered in the following discussion.

Breakpoint Chlorination Chemistry. The stepwise phenomena that result when chlorine is added to water containing oxidizable substances and ammonium can be explained by referring to Fig. 12–8. As chlorine is added, readily oxidizable substances, such as Fe^{2+}, Mn^{2+}, H_2S, and organic matter, react with the chlorine and reduce most of it to the chloride ion (point A on Fig. 12–8). After meeting this immediate demand, the added chlorine continues to react with the ammonium to form chloramines between point A and the peak of the curve, as discussed above. For mole ratios of chlorine to ammonium less than 1, monochloramine and dichloramine are formed. At the peak of the curve, the mole ratio of chlorine (Cl_2) to ammonium (NH_4^+ as N) is equal to one [see Eq. (12–16)]. The corresponding Cl_2/NH_4^+ weight ratio is 5.06.

The distribution of the two chloramine forms is governed by their rates of formation, which are dependent on the pH and temperature. Between the peak and the breakpoint, some chloramines are converted to nitrogen trichloride [see Eq. (12–18)], the remaining chloramines are oxidized to nitrous oxide (N_2O) and nitrogen (N_2), and the chlorine is reduced to chloride ion. Most of the chloramines will be oxidized at the breakpoint. Continued addition of chlorine past the breakpoint, as shown on Fig. 12–8, will result in a directly proportional increase in the free chlorine. Theoretically, the weight ratio of

Figure 12–8

Generalized breakpoint chlorination curve. The upper portion of the diagram represents residual chlorine as a function of the amount of chlorine added to wastewater containing ammonium. The lower portion represents the fate of ammonium and chloramines during the breakpoint chlorination process. The dashed line reflects the fact that along with the formation of chloramines, some destruction of the chloramines occurs simultaneously before the peak is reached.



chlorine to ammonium nitrogen at the breakpoint is 7.6 to 1 (see Example 12–3) and the mole ratio is equal to 1.5 to 1 [see Eq. (12–23)].

Possible reactions to account for the appearance of N_2 and N_2O and the disappearance of chloramines during breakpoint chlorination are as follows (Saunier, 1976; Saunier and Selleck, 1976):

$$NH_4^+ + HOCl \rightarrow NH_2Cl + H_2O + H^+ \qquad (12\text{–}19)$$

$$NH_2Cl + HOCl \rightarrow NHCl_2 + H_2O \qquad (12\text{–}20)$$

$$NHCl_2 + H_2O \rightarrow NOH + 2HCl \qquad (12\text{–}21)$$

$$NHCl_2 + NOH \rightarrow N_2 + HOCl + HCl \qquad (12\text{–}22)$$

The overall reaction, obtained by summing Eqs. 12–19 through 12–22, is given as:

$$2NH_4^+ + 3HOCl \rightarrow N_2 + 3H_2O + 3HCl + 2H^+ \qquad (12\text{–}23)$$

Occasionally, serious odor problems have developed during breakpoint-chlorination operations because of the formation of nitrogen trichloride and related compounds. The presence of additional compounds that will react with chlorine, such as organic nitrogen, may greatly alter the shape of the breakpoint curve, as shown on Fig. 12–9. The formation of disinfection byproducts is considered later in this section.

Acid Generation. The addition of chlorine gas produces acid. When chlorine is added to water the hydrolysis reaction results in the formation of a strong acid (HCl) as given

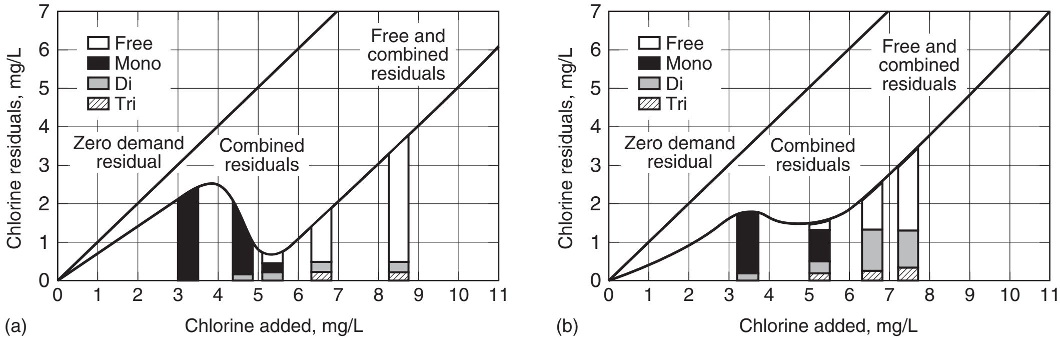


Figure 12–9

Curves of chlorine residual versus chlorine dosage for wastewater: (a) for wastewater containing ammonia nitrogen and (b) for wastewater containing nitrogen in the form of ammonia and organic nitrogen. (Adapted from White, 1999.)

by Eq. (12–9). The reaction of HOCl with ammonium also results in the formation of acid as given by Eq. (12–23). The total moles of hydrogen that must be neutralized can be determined by combining Eq. (12–9) with Eq. (12–23), which results in the following expression:

$$2NH_4^+ + 3Cl_2 \rightarrow N_2 + 6HCl + 2H^+ \qquad (12\text{–}24)$$

In practice, the hydrochloric acid formed during chlorination [see Eq. (12–16)] reacts with the alkalinity of the wastewater, and under most circumstances, there is a slight pH drop. Stoichiometrically, 14.3 mg/L of alkalinity, expressed as $CaCO_3$, are required for each 1.0 mg/L of ammonium nitrogen that is oxidized in the breakpoint-chlorination process (see Example 12–3).

Buildup of Total Dissolved Solids (TDS). In addition to the formation of hydrochloric acid, the chemicals added to achieve the breakpoint reaction also contribute an incremental increase in the TDS. As shown in Eq. (12–24), 6 moles of HCl and 2 moles of H^+ are formed, while 2 moles of NH_4^+ are removed from solution. In situations where the level of total dissolved solids may be critical with respect to water reuse applications, this incremental buildup from breakpoint chlorination should always be checked. The TDS contribution for each of several chemicals that may be used in the breakpoint reaction is summarized in Table 12–10. The magnitude of the possible buildup of TDS is illustrated

Table 12–10

Effects of chemical addition on total dissolved solids in breakpoint chlorination[a]

Chemical addition	Increase in total dissolved solids per unit of NH_4^+ consumed
Breakpoint with chlorine gas	6.2 : 1
Breakpoint with sodium hypochlorite	7.1 : 1
Breakpoint with chlorine gas—neutralization of all acidity with lime (CaO)	12.2 : 1
Breakpoint with chlorine gas—neutralization of all acidity with sodium hydroxide (NaOH)	14.8 : 1

[a] From U.S. EPA (1986).

in Example 12–3 in which the use of breakpoint chlorination is considered for the seasonal control of nitrogen.

EXAMPLE 12–3 **Analysis of Disinfection Process for Nitrified Secondary Effluent with Free Chlorine** Estimate the daily required chlorine dosage, the required alkalinity, if alkalinity needs to be added, and the resulting buildup of TDS when breakpoint chlorination is used achieve disinfection with free chlorine. Assume that the following data apply to this problem:

1. Plant flowrate = 3800 m^3/d
2. Secondary effluent characteristics
   a. BOD = 20 mg/L
   b. Total suspended solids = 25 mg/L
   c. Residual NH_3–N = 2 mg/L
   d. Alkalinity = 150 mg/L as $CaCO_3$
3. Required free chlorine residual concentration for disinfection = 0.5 mg/L
4. Any alkalinity added is in the form of lime (CaO)

Solution

1. Determine the molecular weight ratio of hypochlorous acid (HOCl), expressed as Cl_2, to ammonium (NH_4^+), expressed as N, using the overall reaction for the breakpoint reactions given by Eq. (12–23).

$$\underset{\substack{2(18)\\2(14)}}{2NH_4^+} + \underset{\substack{3(52.45)\\3(2\times35.45)}}{3HOCl} \rightarrow N_2 + 3H_2O + 3HCl + 2H^+$$

Molecular weight ratio is:

$$\frac{Cl_2}{NH_4^+\text{-N}} = \frac{3(2 \times 35.45)}{2(14)} = 7.60$$

2. Estimate the required Cl_2 dosage.
   a. Determine the Cl_2 dosage needed to reach the breakpoint using the molecular ratio developed in Step 1.

$$Cl_2 = (2\ g/m^3)(7.6\ g/g) = 15.2\ g/m^3$$

   b. Determine the required Cl_2 dosage including the free residual.

$$Cl_2/d = (3800\ m^3/d)[(15.2 + 0.5)\ g/m^3](1\ kg/10^3\ g) = 59.9\ kg/d$$

3. Determine the alkalinity required.
   a. The total number of moles of H^+ that must be neutralized per mole of NH_4^+ oxidized is given by Eq. (12–24), which has been divided by 2.

$$NH_4^+ + 1.5Cl_2 \rightarrow 0.5N_2 + 3HCl + H^+$$

   b. When using lime to neutralize the acidity, the required alkalinity ratio is computed as follows:

$$2CaO + 2H_2O \rightarrow 2Ca^{2+} + 4OH^-$$

$$\text{Required alkalinity ratio} = \frac{2(100\ \text{g/mole of } CaCO_3)}{(14\ \text{g/mole of } NH_4^+ \text{ as N})} = 14.3$$

c. The required alkalinity is

$$\text{Alk} = \frac{[(14.3\,\text{mg/L alk})/(\text{mg/L NH}_4^+)](2\,\text{mg/L NH}_4^+)(3800\,\text{m}^3/\text{d})}{(10^3\,\text{g/kg})}$$

$$= 108.7\ \text{mg/L as CaCO}_3$$

4. Determine whether sufficient alkalinity is available to neutralize the acid during breakpoint chlorination.
   Because the available alkalinity (150 mg/L) is greater than the required alkalinity (108.7 mg/L), alkalinity will not have to be added to complete the reaction.
5. Determine the increment of TDS added to the secondary effluent. Using the data reported in Table 12–10, the TDS increase per mg/L of ammonia consumed when CaO is used to neutralize the acid formed is equal to 12.2 to 1.

   TDS increment added = 12.2(2) mg/L = 24.4 mg/L

Comment The ratio computed in Step 1 will vary somewhat, depending on the actual reactions involved. In practice, the actual ratio typically has been found to vary from 8 : 1 to 10 : 1. Similarly, in Step 3, the stoichiometric coefficients will also depend on the actual reactions involved. In practice, it has been found that about 15 mg/L of alkalinity are required because of the hydrolysis of chlorine. In Step 5, it should be noted that although breakpoint chlorination can be used to control nitrogen, it may be counter productive if in the process the treated effluent is rendered unusable for other applications because of the buildup of total dissolved solids, and the potential formation of disinfection byproducts.

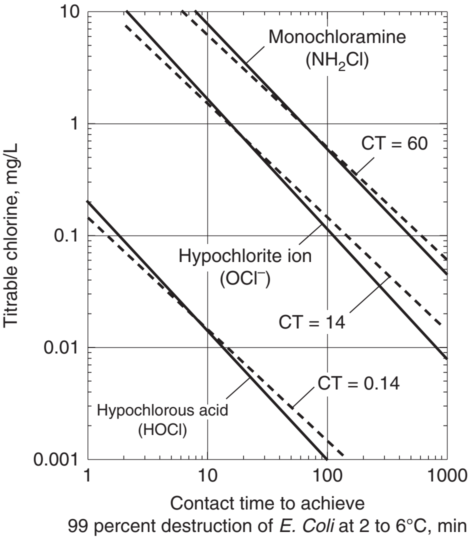
Effectiveness of Free and Combined Chlorine as Disinfectants

In view of the renewed interest in public health, environmental water quality, and water reclamation, the effectiveness of the chlorination process is of great concern. Numerous tests have shown that when all the physical parameters controlling the chlorination process are held constant, the germicidal efficiency of disinfection, as measured by the survival of "discrete bacteria," depends primarily on the form of the chlorine residual and time (i.e., CT).

Relative Effectiveness of Free and Combined Chlorine. Generalized data on the relative germicidal effectiveness of combined and free chlorine for the disinfection of different microorganisms were presented previously in Table 12–5 in terms of the required CT values to achieve various levels of inactivation. A comparison of the relative germicidal efficiency of hypochlorous acid (HOCl), hypochlorite ion (OCl^-), and monochloramine (NH_2Cl), based on the work of Butterfield et al. (1943), is presented on Fig. 12–10. As shown on Fig. 12–10, for a given contact time or chlorine residual, the germicidal efficiency of HOCl is 100 times that of OCl^- and more than 400 times that of NH_2Cl. However, because of the equilibrium relationship that exists between HOCl and OCl^- ion (see Fig. 12–7), maintenance of the proper pH is extremely important in achieving effective disinfection. It should be noted, however, that given an adequate contact time, monochloramine is nearly as effective as free chlorine in achieving disinfection. In addition to the data for the chlorine compounds given on Fig. 12–10, corresponding CT values have been added for the purpose of comparison. As shown, the

Figure 12–10

Comparison of the germicidal efficiency of hypochlorous (HOCl) acid and hypochlorite ion (OCl^-), and monochloramine for 99 percent destruction of *E. coli* at 2 to 6°C with CT values added for the purpose of comparison. (From Butterfield et al., 1943.)



disinfection data presented on Fig. 12–10 can be represented quite well with the CT relationship.

Coefficient of Specific Lethality. Another parameter that can be used to assess the relative effectiveness of the various forms of chorine is the coefficient of specific lethality, Λ. Utilizing the data from Table 12–5 and Fig. 12–10 as well as numerous literature sources, coefficients of specific lethality, computed for various microorganism groups and disinfecting agents, are summarized in Table 12–11. It is important to note that the data presented in Table 12–11 were derived primarily using batch reactors operated under

Table 12–11

Relative coefficients of specific lethality, Λ, for the inactivation of bacteria, viruses, *Cryptosporidium*, and *Giardia lamblia* cysts in filtered secondary effluent with various disinfectants (pH ~7.5, ~20°C)[a]

		Coefficient of specific lethality[b], $\Lambda_{(\text{base } 10)}$			
Disinfectant	**Unit**	**Total coliform[c]**	**Virus**	**Protozoa *Cryptosporidium***	**Protozoa *Giardia lamblia* cysts**
Chlorine (free)	L/mg·min	2	1.2	0.00044	0.04
Chloramine	L/mg·min	0.016	0.0052	0.00022	0.0024
Chlorine dioxide	L/mg·min	2	0.38	0.008	0.2
Ozone	L/mg·min	44	7.27	0.24	4.21
UV radiation	cm^2/mJ	5.7	0.0215	0.31	0.33

[a] Based on Eq. (12–6).

[b] The coefficient of specific lethality values are for the linear portion of the dose (CT) response curve.

[c] The reported coefficient of specific lethality values for fecal coliform and *E coli* are quit different.

Table 12–12

Activation energies for aqueous chlorine and chloramines at normal temperatures[a]

Compound	**pH**	***E*, Cal/mole**	***E*, J/mole**
Aqueous chlorine	8.5	6400	26,800
	9.8	12,000	50,250
	10.7	15,000	62,810
Chloramines	7.0	12,000	50,250
	8.5	14,000	58,630
	9.5	20,000	83,750

[a] Adapted from Fair et al. (1948) who developed the reported values using the data developed by Butterfield et al. (1943).

controlled conditions, and, as such, are of limited use other than for the purpose of illustrating the relative differences in the effectiveness of the different disinfectants for different organism groups. As shown, there are significant differences in the effectiveness of the various disinfectants for each organism group. For example, free chlorine is very effective for the inactivation of bacteria and viruses, but less so for *cryptosporidium* and *Giardia* cysts.

Effect of pH. The importance of pH and temperature on the disinfection process with chlorine and chloramines was investigated by Butterfield and his associates in 1943 (Butterfield et al., 1943; Wattie and Butterfield, 1944). Based on the results published by Butterfield et al. (1943), Fair and Geyer (1954) determined the activation energy values reported in Table 12–12 for the disinfection of *E. coli* in clean water. Reviewing the data in Table 12–12, it is important to note the magnitude of the activation energy as a function of pH. As the pH increases, the value of the activation energy increases which corresponds to a reduced effectiveness which is consistent with the data presented on Fig. 12–10.

Effect of Temperature. Temperature also has a significant impact on the coefficient of specific lethality, Λ. As a rule of thumb, it has been found that for each 10°C increase in temperature (identified as the Q_{10} temperature coefficient in biological and chemical engineering literature) there is a 2 to 2.5 times increase in the coefficient of specific lethality. Thus, when referring to the CT values given in Table 12–5 and the coefficient of specific lethality values in Table 12–11, it is important to note that the given values are for a pH and temperature of approximately 7.5 and 20°C, respectively.

Measurement and Reporting of Disinfection Process Performance

To provide a framework in which to consider the effectiveness of disinfection and the factors that affect the disinfection of treated wastewater, it is appropriate to consider how the effectiveness of the chlorination process is now assessed and how the results are analyzed. When using chlorine for the disinfection, the principal parameters that can be measured, apart from environmental variables such as pH and temperature, are the number of organisms and the form of the chlorine residual (i.e., combined or free or both) remaining after a specified period of time.

Number of Organisms Remaining. The coliform group of bacteria can be determined using a number of different techniques (Standard Methods, 2012). The membrane filter technique or the most probable number (MPN) procedure as discussed in

Chap. 2 are used commonly. The organisms remaining can also be determined by the plate-count procedure using an agar mixture as the plating medium. Either the standard "pour-plate" method or the "spread-plate" method can be used. The plates should be incubated at 37°C (98.6°F) because this temperature results in the optimum growth of *E. coli*, and the colonies should be counted after a 24-h incubation period.

Measurement of Chlorine Residual. The principal methods used to measure the free and combined chlorine residual include (1) the DPD (N,N-diethyl-p-phenylenediamine) colorimetric method, (2) DPD titration method, (3) the Iodometric titration method, and (4) the amperometric titration method. Of these methods, the DPD colorimetric method is currently the most widely used because it can be used to differentiate between free and combined chlorine species. Both field hand-held and continuous online residual analyzers are available. In the DPD method, appropriate chemicals, typically preformed in packets, are added to a sample containing chlorine. The red color resulting from the presence of chlorine is measured with a spectrophotometer or filter photometer. The initial color is due to free chlorine. Additional chemicals are added to obtain total residual chlorine (free and combined). Additional details on these chlorine analysis methods may be found in Harp (2002) and Standard Methods (2012).

Reporting of Results. Disinfection process results are reported in terms of the number of organisms and the chlorine residual remaining after a specified period of time. When the results are plotted it is common practice to plot the logs of removal versus the corresponding CT value as shown previously on Fig. 12–6.

Factors that Affect Disinfection of Wastewater with Chlorine Compounds

The purpose of the following discussion is to explore the important factors that affect the disinfection efficiency of chlorine compounds in actual wastewater applications. These include the following:

1. Initial mixing
2. Chemical characteristics of the water to be disinfected
3. NOM content
4. Impact of particles and particle associated microorganisms
5. Characteristics of the microorganisms
6. Contact time

Each of these factors are discussed in more detail below.

Issues related to the design of chlorine contact basins not included in this chapter include (1) basin configuration, (2) the use of baffles and guide vanes, (3) number of chlorine contact basins, (4) precipitation of solids in chlorine contact basins, (5) solids transport velocity, and (6) a procedure for predicting disinfection performance. These subjects are considered in detail elsewhere (Tchobanoglous et al., 2003).

Initial Mixing. The importance of initial mixing on the disinfection process cannot be overstressed. It has been shown that the application of chlorine in a highly turbulent regime ($N_R \geq 10^4$) results in kills two orders of magnitude greater than when chlorine is added separately to a conventional rapid-mix reactor under similar conditions. Although the importance of initial mixing is well delineated, the optimum level of turbulence is not known. Examples of mixing facilities designed to achieve the rapid mixing of chlorine with the water are presented later in Sec. 12–6 (see Fig. 12–22).

Based on recent findings, questions have now been raised about the form in which the chlorine compounds are added. In some plants where chlorine injectors are used, there is concern over the practice of using chlorinated wastewater for the chlorine injection water as opposed to clean water. The concern is that if nitrogenous compounds are present in the wastewater, a portion of the chlorine that is added reacts with these compounds, and by the time chlorine solution is injected, it is in the form of monochloramine or dichloramine. The formation of chloramines can be a problem if adequate retention time is not available in the chlorine contact basin as combined chlorine requires a longer contact time. Again, it should be remembered that although both HOCl and NH_2Cl are both effective as disinfecting compounds, the contact time required is significantly different for the same residual concentration (see Fig. 12–10).

The formation of disinfection byproducts (DBPs) is another major concern with the use of free chlorine. When wastewater is exposed to free chlorine, competing reactions, such as the formation of chloramines (free chlorine and ammonia), and DBPs can occur. The predominant reaction depends on the applicable kinetic rates for the various reactions. The formation and control of DBPs is discussed later in this section.

Chemical Characteristics of Wastewater. It has often been observed that, for treatment plants of similar design with exactly the same effluent characteristics measured in terms of BOD, COD, and nitrogen, the effectiveness of the chlorination process varies significantly from plant to plant. To investigate the reasons for this observed phenomenon and to assess the effects of the compounds present in the chlorination process, Sung (1974) studied the characteristics of the compounds in untreated and treated wastewater. Among the more important conclusions derived from Sung's study are the following:

1. In the presence of interfering organic compounds, the total chlorine residual cannot be used as a reliable measure for assessing the bactericidal efficiency of chlorine.
2. The degree of interference of the compounds studied depended on their functional groups and their chemical structure.
3. Saturated compounds and carbohydrates exert little or no chlorine demand and do not appear to interfere with the chlorination process.
4. Organic compounds with unsaturated bonds may exert an immediate chlorine demand, depending on their functional groups. In some cases, the resulting compounds may titrate as chlorine residual and yet may possess little or no disinfection potential.
5. Compounds with polycyclic rings containing hydroxyl groups and compounds containing sulfur groups react readily with chlorine to form compounds which have little or no bactericidal potential, but which still titrate as chlorine residual.
6. To achieve low bacterial counts in the presence of interfering organic compounds, additional chlorine and longer contact times are required.

From the results of Sung's work, it is easy to see why the efficiency of chlorination at plants with the same general effluent characteristics can be quite different. Clearly, it is not the value of the BOD or COD that is significant, but the nature of the organic compounds that make up the measured values. Thus, the nature of the treatment process used in any plant also has an effect on the chlorination process. The impact of wastewater characteristics on chlorine disinfection is presented in Table 12–13. The presence of oxidizable compounds such as humics and iron causes the inactivation curve to have a lag or shoulder affect as shown on Fig. 12–6. In effect, the added chlorine is being utilized in the oxidization of these substances and is not available for the inactivation of microorganisms.

Because more wastewater treatment plants are now removing nitrogen, operational problems with chlorine disinfection are now reported more frequently. In treatment plants

Table 12–13

Impact of wastewater constituents on the use of chlorine for wastewater disinfection

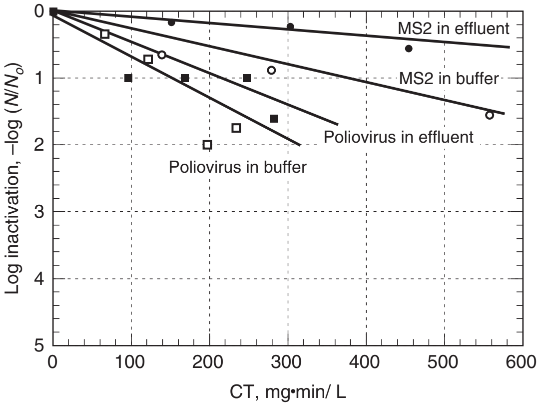
Constituent	Effect
BOD, COD, TOC, etc.	Organic compounds that comprise the BOD and COD can exert a chlorine demand. The degree of interference depends on their functional groups and their chemical structure
NOM (natural organic matter)	Reduces effectiveness of chlorine by forming chlorinated organic compounds that are measured as chlorine residual, but are not effective for disinfection
Oil and grease	Can exert a chlorine demand
TSS	Shields embedded bacteria
Alkalinity	No or minor effect
Hardness	No or minor effect
Ammonia	Combines with chlorine to form chloramines
Nitrite	Oxidized by chlorine, formation of N-nitrosodimethylamine (NDMA)
Nitrate	Chlorine dose is reduced because chloramines are not formed. Complete nitrification may lead to the formation of NDMA due the presence of free chlorine. Partial nitrification, especially diurnal swings in nitrification, may lead to difficulties in establishing the proper chlorine dose
Iron	Oxidized by chlorine
Manganese	Oxidized by chlorine
pH	Affects distribution between hypochlorous acid and hypochlorite ion
Industrial discharges	Depending on the constituents, may lead to a diurnal and seasonal variations in the chlorine demand

where the effluent is nitrified completely, the chlorine added to the water is present as free chlorine, after satisfying any immediate and nitrogenous (see Example 12–3) chlorine demand. In general, the presence of free chlorine will reduce significantly the required chlorine dosage. However, the presence of free chlorine may lead to the formation of disinfection byproducts including N-nitrosodimethylamine (NDMA). In treatment plants that do not nitrify completely, partially nitrify, or move in and out of nitrification diurnally, control of the chlorination process is especially difficult because of the variation in the effectiveness of the chlorine compounds. Some of the chlorine is used to satisfy the demand of the residual nitrite and/or ammonia. Because of the uncertainties involved in knowing to what degree the plant is nitrifying at any point in time, the chlorine dosage that is added is based on the dosage required if the disinfection is to be accomplished by combined chlorine compounds, resulting in excessive chlorine use.

Impact of Particles Found in Treated Wastewater. Another factor that must be considered is the presence of suspended solids in the water to be disinfected. As shown previously on Fig. 12–6, when suspended solids are present, the disinfection process is controlled by two different mechanisms. The log-linear bacterial inactivation that is observed initially, after the shoulder effect, is of individual free swimming bacteria and bacteria in small clumps. The straight line portion of the bacterial inactivation can be described using Eq. (12–2). In the curved portion of the curve the bacterial kill is controlled by the presence of suspended solids. The slope of the curved portion of the curve is a function of (1) the particle size distribution and (2) the number of particles with associated coliform organisms. Further, as noted previously, if particles contain

Figure 12–11

Inactivation of MS2 coliphage and polivirus in buffer and treated wastewater effluent with combined chlorine. (From BioVir Laboratories, 2001.)



significant numbers of organisms, the organisms can provide protection to other organisms embedded within the particle by limiting the penetration of chlorine through diffusion. Unfortunately, the observed variability caused by the presence of particles often is masked by the addition of excess chlorine to overcome both chemical and particle effects.

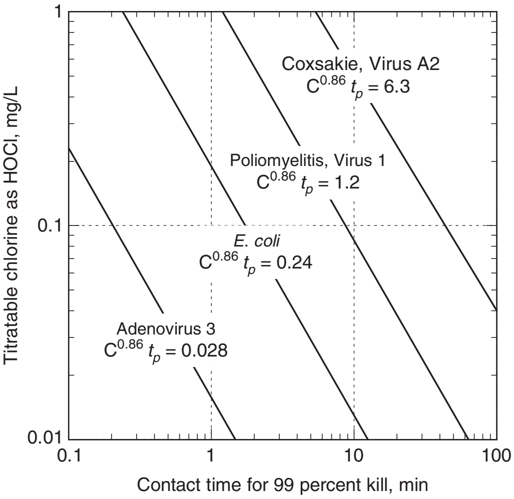
Characteristics of the Microorganisms. Other important variables in the chlorination process are the type, characteristics, and age of the microorganisms. For a young bacterial culture (1 d old or less) with a free chlorine dosage of 2 mg/L, only 1 min was needed to reach a low bacterial number. When the bacterial culture was 10 d old or more, approximately 30 min was required to achieve a comparable reduction for the same applied chlorine dosage. It is likely that the resistance offered by the polysaccharide sheath, which microorganisms develop as they age, accounts for this observation. In the activated sludge treatment process, the operating solids retention time (SRT), which to some extent is related to the age of the bacterial cells in the system, will, as discussed previously, affect the performance of the chlorination process. Some recent data on the disinfection of bacteriophage MS2 and poliovirus are shown on Fig. 12–11. As shown on Fig. 12–11, it is clear that a CT value of 450 mg·min/L, as used by the State of California, does not result in a four-log reduction of virus, when the measured residual chlorine is combined chlorine (i.e., mono- and dichloramine). Clearly, site-specific testing is required to establish the appropriate chlorine dose.

Some representative data on the effectiveness of chlorine for the inactivation of *E. coli* and three enteric viruses are reported on Fig. 12–12. Because of newer analytical techniques that have been developed, the data presented on Fig 12–12 are only meant to illustrate the differences in the resistances of different organisms. From the available evidence on the viricidal effectiveness of the chlorination process, it appears that chlorination beyond the breakpoint to obtain free chlorine is required to kill many of the viruses of concern. Where breakpoint chlorination is used, it is necessary to dechlorinate the treated water before discharge to the environment or reuse in sensitive applications to reduce any residual toxicity that may remain after chlorination. Based on the use of integrated cell culture-PCR techniques (see Chap. 2), it has been reported that the inactivation of poliovirus may require five times more chlorine than thought previously (Blackmer et al., 2000).

Contact Time. Along with the residual concentration of the disinfectant, contact time is of critical importance in the design and operation of chlorination facilities.

Figure 12–12

Concentration of chlorine as HOCl required for 99 percent kill of *E. coli* and three enteric viruses at 0 to 6°C (Butterfield et al., 1943).



The principal design objective for chlorine contact basins is to ensure that some defined percentage of the flow remains in the chlorine contact basin for the design contact time to ensure effective disinfection. The mean contact time is usually specified by the regulatory agency and may range from 30 to 120 min; contact times of 15 to 90 min at peak flow are common. To be assured that a given percentage of the flow remains in the chlorine contact basin for a given period of time, the most common approach is to use long plug-flow, around-the-end type of contact basins (see Fig. 12–13). For example, for water reuse applications the CDPH requires a CT value of 450 mg·min/L based on a modal contact time of 90 min at peak flow. In other states, the t_{10} is used in the

CT relationship (see subsequent discussion on assessing the performance of chlorine contact basins).

Modeling the Chlorine Disinfection Process

When considering the disinfection of both secondary and filtered secondary effluent, both the lag or shoulder effect and the effect of the residual particles (see Fig. 12–6) must be considered. As noted previously, depending on the constituents in the wastewater, a shoulder region may be observed in which there is no reduction in the number of organisms as the result of the addition of a disinfectant. As additional chlorine is added beyond some limiting value, a log linear reduction in the number of organisms is observed with increased chlorine dosages. If particles (typically greater than 20 μm) are present, the disinfection curve starts to diverge from the log linear form and a tailing region is observed due to particle shielding of the microorganisms. The tailing region is of importance as more restrictive standards are to be achieved (e.g., 23 MPN/100 mL). It is interesting that the tailing region was identified in an early report on the chlorination of treated wastewater (Enslow, 1938). Further, because large particles have little effect on turbidity (see Chap. 2), effluents with low measured turbidity values can still be difficult to disinfect, due the presence of undetected large particles (Ekster, 2001; see also discussion of turbidity in Chap. 8).

The Collins-Selleck Model. In the early 1970s, Collins conducted extensive experiments on the disinfection of various wastewaters (Collins, 1970; Collins and Selleck, 1972). Using the batch reactor whose contents were well stirred, Collins and Selleck found that the reduction of coliform organisms in a chlorinated primary treated effluent followed a linear relationship when plotted on log-log paper (see Fig. 12–14). The equation developed to describe the observed results is

$$\frac{N}{N_o} = \frac{1}{(1 + 0.23\,\mathrm{CT})^3} \tag{12–25}$$

Note that the form of the equation developed by Collins accounts for the shoulder effect and for tailing. A number of other models have been proposed including an empirical model proposed by Gard (1957), Hom (1972), which was subsequently rationalized by Haas and Joffe (1994) and Rennecker et al. (1999).

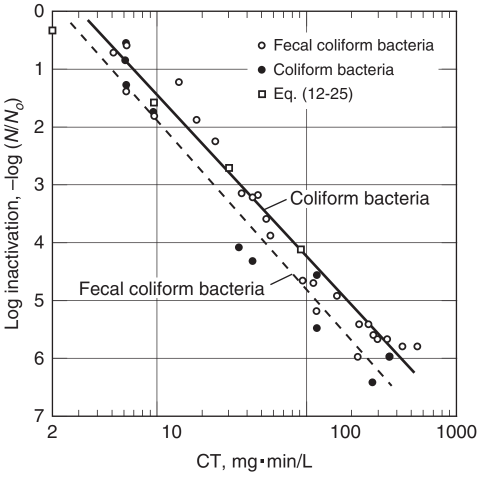

Figure 12–14

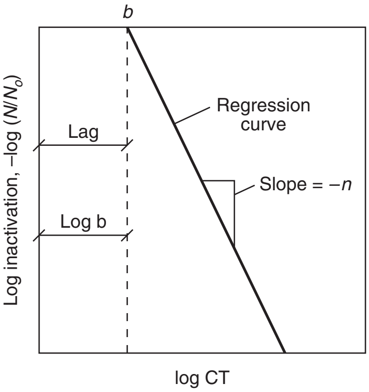
Coliform survival in a batch reactor as a function of amperometric chlorine residual and contact time (temperature range 11.5 to 18°C). (From Collins, 1970; Collins and Selleck, 1972.)

Figure 12–15

Definition sketch for the application of Eq. (12–27).



The Refined Collins-Selleck Model. A refinement of the original Collins model for the disinfection of secondary effluent in which a shoulder effect and tailing is observed, as proposed by White (1999), is

$$N/N_o = 1 \text{ for CT} < b \tag{12–26}$$

$$N/N_o = [(\text{CT})/b]^{-n} \text{ for CT} > b \tag{12–27}$$

Where C = residual concentration of chemical agent at the end of time t, mg/L
T = contact time, min
n = slope of inactivation curve
b = value of x-intercept when $N/N_o = 1$ or $\log (N/N_o) = 0$ (see Fig. 12–15)

Typical values for the coefficients n and b for secondary non-nitrified effluent for coliform and fecal coliform organisms are 2.8 and 4.0 and 2.8 and 3.0, respectively (Roberts et al., 1980; White, 1999; Black & Veatch Corporation, 2010). However, because of the variability of the chemical composition of wastewater and the variable particle size distribution, it is recommended that the constants be determined for the wastewater in question.

Effluent from Membrane Processes. The most important characteristic of these effluents is that they do not contain particles that can shield microorganisms. Depending on the type of membrane process used (microfiltration, ultrafiltration, nanofiltration, or reverse osmosis), moderate to significant reductions in the number of microorganisms present will also be observed (see discussion in Chaps. 8, 9, and 11). For these effluents, the Chick-Watson model, as given by Eq. (12–6), or, if a shoulder exists, the Collins-Selleck relationship, can be used to model the disinfection process with chlorine. Typically, the shoulder effect is reduced considerably, especially with reverse osmosis effluent.

Required Chorine Dosages for Disinfection

The required chemical dosage for disinfection can be estimated by considering (1) the initial chlorine demand of the treated wastewater, (2) the allowance needed for decay during the chlorine contact time, and (3) the required chlorine residual concentration determined using Eq. (12–27) for the organism under consideration (e.g., bacteria, virus, or protozoan oocysts and cysts).

Initial Chlorine Demand. The chlorine dosage required to meet the initial demand depends on the constituents in the water (see Fig. 12–15). It is important to remember that the chlorine added to meet the initial demand, due to inorganic compounds, is reduced to the chloride ion and will not be measured as chlorine residual. Also, chlorine that combines with humic and other organic material that may be present is not effective as a disinfectant, but is nevertheless measured as a chlorine residual contributing to the lag term, *b*, in Eq. (12–27).

Chlorine Decay. Two different cases of chlorine decay have to be considered: (1) chlorine decay, which occurs in chlorine contact basins and (2) chlorine decay, which occurs in long effluent transmission lines and in water reuse distribution systems.

In Chlorine Contact Basins. In chlorine contact basins the principal factors affecting chlorine decay are

1. Chemical reactions that occur in the bulk liquid.
2. Reactions that occur with the biofilm on the walls of the chlorine contact basin.
3. Photooxidation that occurs in uncovered chlorine contact basins.

In addition to the rapid reactions that occur initially, slower addition and substitution type reactions can occur with the residual organic matter in the bulk of the treated effluent as it moves through the chlorine contact basin (Gang et al., 2003). Similarly, addition and substitution chemical reactions can occur with the biofilms attached to the wall of the chlorine contact basin. The nature of the reactions is site specific, but biofilms are almost always present, especially in uncovered chlorine contact basins. To reduce the decay due to UV oxidation observed in open uncovered chlorine contact basins, a variety of floating and fixed covers have been added to existing contact basins (see Fig. 12–16). Typical decay values for chlorine residual are on the order of 2 to 4 mg/L for a contact time of about one hour.

In Transmission and Distribution Piping. The principal factors affecting chlorine decay in transmission and distribution piping are

1. Chemical reactions that occur in the bulk liquid flowing within the pipe.
2. Reactions that occur with the biofilm on the walls of the piping system.
3. Chemical reactions due to the release of constituents under anaerobic conditions that will react with chlorine.

The reactions that occur in the bulk fluid and in the biofilm on the pipe wall are as described above for the chlorine contact basin. Under anaerobic conditions that often occur in long transmission lines, bacteria on the pipe walls will convert the sulfate present in the treated effluent to form sulfide, which in turn forms hydrogen sulfide, which readily reacts with any chlorine that may be present. There are many articles in the literature that deal with the modeling of chlorine decay in pipelines. In general, the decay process is modeled

(a) (b)

Figure 12–16

Typical examples of covered back-and-forth chlorine contact basins: (a) basins covered with inexpensive floating tarp, and (b) basins covered with specially designed polypropylene cover.

Table 12–14

Typical chlorine dosages, based on combined chlorine unless otherwise indicated, required to achieve different total coliform disinfection standards for various wastewaters based on a 30 min contact time with a decay factor of 0.6[a]

Type of wastewater	Initial total coliform count, MPN/100 mL	Chlorine dose, mg/L			
		Effluent standard, MPN/100 mL			
		1000	200	23	≤2.2
Raw wastewater	10^7–10^9	16–30			
Primary effluent	10^7–10^9	8–12	18–24		
Trickling filter effluent	10^5–10^6	6–7.5	12–15	18–22	
Activated sludge effluent	10^5–10^6	5.5–7.5	10–13	13–17	
Filtered activated sludge effluent	10^4–10^6	2.5–3.5	5.5–7.5	10–13	13–17
Nitrified effluent[b]	10^4–10^6		0.02–0.03	0.03–0.04	0.04–0.05
Filtered nitified effluent[b]	10^4–10^6		0.02–0.03	0.03–0.04	0.04–0.05
Microfiltration effluent[b]	10^1–10^3			0.02–0.03	0.03–0.04
Reverse osmosis[b]	~ 0				0.01–0.02
Septic tank effluent	10^7–10^9	16–30	30–60		
Intermittent sand filter effluent	10^2–10^4	1–2	2–4	3–6	4–8

[a] The combined chlorine values are based on the assumption that the added chlorine only combines with ammonia to form monochloramine. The reported values are independent of the chlorine dose required to meet the immediate chlorine demand.

[b] Based on free chlorine. The reported values are independent of the chlorine dose required to reach the breakpoint (see Example 12–3).

using either first or second-order decay models. The computer model EPANET 2, developed by the U.S. EPA to simulate the hydraulic and water quality behavior within pressurized pipe networks, has also been used to study the decay of chlorine in pipelines (Rossman, 2000). It is critical that decay be considered in long transmission and distribution piping in determining the required residual that may be needed.

Required Chlorine Residual. Typical chlorine dosage values for various for residual total coliform concentrations, based on a contact time of 30 min, are reported in Table 12–14. It should be noted that the dosage values given in Table 12–14 are only meant to serve as a guide for the initial estimation of the required chlorine dose. As noted above, site-specific testing is required to establish the appropriate chlorine dose. Estimation of the required chlorine dose is illustrated in Example 12–4.

EXAMPLE 12–4 **Estimate the Required Chlorine Dose for a Typical Non-nitrified Secondary Effluent** Estimate the chlorine dose needed to disinfect a filtered non-nitrified secondary activated sludge effluent using the refined Collins-Selleck model assuming a shoulder effect exists and that the following conditions apply. Check the computed summer combined residual using Eq. (12–6).

1. Effluent total coliform count before disinfection = 10^7/100 mL
2. Required summer effluent total coliform count = 23/100 mL
3. Required winter effluent total coliform count = 240/100 mL
4. Immediate summer or winter effluent chlorine demand, not including the shoulder effect = 2 mg/L
5. Chlorine demand due to decay in chlorine contact tanks during the summer months (May–October) = 2.5 mg/L
6. Chlorine demand due to decay in chlorine contact tanks during the winter months (November–April) = 1.5 mg/L
7. Required chlorine contact time = 30 min
8. Use the typical values given in the above discussion for the coefficients $n = 2.8$ and $b = 4.0$
9. The coefficient of specific lethality for summer conditions = 0.024 L/mg·min (base 10)

Solution

1. Estimate the required combined chlorine residual using the refined Collins-Selleck Model, Eq. (12–27) and the given coefficients.

$$N/N_o = (\mathrm{CT}/b)^{-n}$$

   a. Summer

$$23/10^6 = (\mathrm{CT}/4.0)^{-2.8}$$

$$(23/10^6)^{-\frac{1}{2.8}} = (\mathrm{CT}/4.0)$$

$$(45.3)4 = \mathrm{C}(30)$$

$$\mathrm{C} = 6.0 \text{ mg/L}$$

   b. Winter

$$240/10^6 = (\mathrm{CT}/4.0)^{-2.8}$$

$$(19.6)4 = \mathrm{C}(30)$$

$$\mathrm{C} = 2.6 \text{ mg/L}$$

2. The required chlorine dosage is

   a. Summer

   Chlorine dosage = 2.0 mg/L + 2.5 mg/L + 6.0 mg/L = 10.5 mg/L

   b. Winter

   Chlorine dosage = 2.0 mg/L + 1.5 mg/L + 2.6 mg/L = 6.1 mg/L

3. Determine the required chlorine summer dose using Eq. (12–6).

   a. Solve Eq. (12–6) for the combined residual.

$$\log \frac{N_t}{N_o} = -\Lambda_{\text{base }10}\mathrm{CT} = \log \frac{23}{10^6} = (-0.024)(\mathrm{C})(30)$$

$$\mathrm{C} = \frac{-4.64}{-(0.024\,\mathrm{L/mg \cdot min})(30\,\mathrm{min})} = 6.4 \text{ mg/L}$$

   b. The required chlorine doses computed with the two methods are similar.

Comment The chlorine dosage increases significantly as the effluent standards become more stringent. In the above computation, it was assumed that the filtered effluent to be disinfected remained in the chlorine contact tank for the full 30 minutes. Thus, it is clear that the proper design of a plug-flow chlorine contact basin is critical to the effective use of chlorine as disinfectant. The design of chlorine contact basins is considered in Sec. 12–6.

Formation and Control of Disinfection Byproducts (DBPs)

In the early 1970s, it was found that the use of oxidants, such as chlorine and ozone, in water treatment for disinfection; for the control of tastes, odors, and color removal; and other in-plant uses resulted in the production of undesirable DBPs (Rook, 1974; Bellar and Lichtenberg, 1974). The DBPs measured most frequently and with the highest concentration are trihalomethanes (THMs) and haloacetic acids (HAAs), resulting from chlorination. In addition to trihalomethanes and haloacetic acids, a variety of other DBPs are also produced. The principal DBPs that have been identified are reported in Table 12–15. Many of the compounds identified in Table 12–15 have also been identified in treated effluent that has been disinfected using chlorine, chloramines, chlorine dioxide, and ozone.

Concerns with DBPs. Formation of DBPs is of great concern in effluent dispersal to the environment and for indirect and direct potable reuse because of the potential long-term (chronic) impact of these compounds on public health and the environment. Chloroform, for example, is a well-known animal carcinogen and many of the haloforms are also thought to be animal carcinogens. In addition, many of these compounds have been classified as probable human carcinogens. Still others of these compounds are known to cause chromosomal aberrations and sperm abnormalities. Recognizing the many unknowns and the potential public health and environmental risks associated with these compounds, the U.S. EPA has moved aggressively to control their formation in drinking water.

Formation of DBPs Using Chlorine for Disinfection. Trihalomethanes (THMs) and other DBPs are formed as a result of a series of complex reactions between free chlorine and a group of organic acids known collectively as humic acids. The reactions lead to the formation of single carbon molecules that are often designated as CHX_3, where X is either a chlorine (Cl^-) or bromine (Br^-) atom. For example, the chemical formula for chloroform is $CHCl_3$.

The rate of formation of DBPs is dependent on a number of factors, including

1. Presence of organic precursors
2. Free chlorine concentration
3. Bromide concentration
4. pH
5. Temperature
6. Time

The type and concentration of the organic precursor affects both the rate of the reaction and extent to which the reaction is completed.

The presence of free chlorine was thought to be necessary for the THM formation reaction to proceed, but it appears that THMs can form in the presence of combined chlorine (chloramines), but at a much reduced rate. It is important to note that initial mixing can affect the formation of THMs because of the competing reactions between chlorine and ammonia,

Table 12–15

Selected, known disinfection byproducts formed during application of chlorine, chloramine, ozone, and chlorine dioxide in natural waters[a]

Class	Byproduct	Chemical agent	Molecular formula
Trihalomethanes	Chloroform	Chlorine	$CHCl_3$
	Bromodichloromethane	Chlorine	$CHBrCl_2$
	Dibromochloromethane	Chlorine	$CHBr_2Cl$
	Bromoform	Chlorine, ozone	$CHBr_3$
	Dichloroiodomethane	Chlorine	$CHICl_2$
	Chlorodiiodomethane	Chlorine	CHI_2Cl
	Bromochloroiodomethane	Chlorine	$CHBrICl$
	Dibromoiodomethane	Chlorine	$CHBr_2I$
	Bromodiiodomethane	Chlorine	$CHBrI_2$
	Triiodomethane	Chlorine	CHI_3
Haloacetic acids	Monochloroacetic acid	Chlorine	$CH_2ClCOOH$
	Dichloroacetic acid	Chlorine	$CHCl_2COOH$
	Trichloroacetic acid	Chlorine	CCl_3COOH
	Bromochloroacetic acid	Chlorine	$CHBrClCOOH$
	Bromodichloroacetic acid	Chlorine	$CBrCl_2COOH$
	Dibromochloroacetic acid	Chlorine	$CBr_2ClCOOH$
	Monobromoacetic acid	Chlorine	$CH_2BrCOOH$
	Dibromoacetic acid	Chlorine	$CHBr_2COOH$
	Tribromoacetic acid	Chlorine	CBr_3COOH
Haloacetonitriles	Trichloroacetonitrile	Chlorine	$CCl_3C{\equiv}N$
	Dichloroacetonitrile	Chlorine	$CHCl_2C{\equiv}N$
	Bromochloroacetonitrile	Chlorine	$CHBrClC{\equiv}N$
	Dibromoacetonitrile	Chlorine	$CHBr_2C{\equiv}N$
Haloketones	1,1-Dichloroacetone	Chlorine	$CHCl_2COCH_3$
	1,1,1-Trichloroacetone	Chlorine	CCl_3COCH_3
Aldehydes	Formaldehyde	Ozone, chlorine	$HCHO$
	Acetaldehyde	Ozone, chlorine	CH_3CHO
	Glyoxal	Ozone, chlorine	$OHCCHO$
	Methyl glyoxal	Ozone, chlorine	CH_3COCHO
Aldoketoacids	Glyoxylic acid	Ozone	$OHCCOOH$
	Pyruvic acid	Ozone	$CH_3COCOOH$
	Ketomalonic acid	Ozone	$HOOCCOCOOH$
Carboxylic acids	Formate	Ozone	$HCOO^-$
	Acetate	Ozone	CH_3COO^-
	Oxalate	Ozone	$OOCCOO^{2-}$

(*continued*)

Table 12–15 (*Continued*)

Class	Byproduct	Chemical agent	Molecular formula
Oxyhalides	Chlorite	Chlorine dioxide	ClO_2^-
	Chlorate	Chlorine dioxide	ClO_3^-
	Bromate	Ozone	BrO_3^-
Nitrosamines	N-nitrosodimethylamine	Chloramines	$(CH_3)_2NNO$
Cyanogen Halides	Cyanogen chloride	Chloramines	ClCN
	Cyanogen bromide	Chloramines	BrCN
Misc.	Chloral hydrate	Chlorine	$CCl_3CH(OH)_2$
Trihalonitromethanes	Trichloronitromethane (Chloropicrin)	Chlorine	CCl_3NO_2
	Bromodichloronitromethane	Chlorine	$CBrCl_2NO_2$
	Dibromochloronitromethane	Chlorine	CBr_2ClNO_2
	Tribromonitromethane	Chlorine	CBr_3NO_2

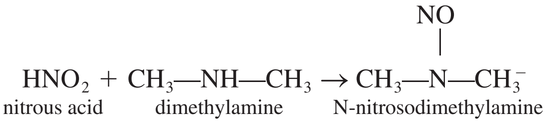
[a] Adapted from Krasner (1999), Krasner et al. (2001), and Thibaud et al. (1987).

and between chlorine and humic acids. If bromide is present, it can be oxidized to bromine by free chlorine. In turn the bromine ion can combine with the organic precursors to form THMs, including bromodichoromethane, dibromochoromethane, and bromoform. The rate of formation of THMs has been observed to increase with both pH and temperature. Additional details on the formation of THMs may be found in U.S. EPA (1999a).

Although chloramines, as discussed above, produce THMs at reduced rates, they can, nevertheless, produce other DBP compounds that are of concern. Other DBPs that are produced when treated wastewater is disinfected with chloramines include N-nitrosodimethylamine (NDMA), a member of a class of compounds known as nitrosoamines, cyanogen chloride, and cyanogen bromide (see Table 12–15). As a class of compounds nitrosoamines are among the most powerful carcinogens known (Snyder, 1995). The compounds in this class have been found to produce cancer in every species of laboratory animal tested.

One pathway leading to the formation of NDMA can be illustrated with the following two reactions:

$$\underset{\substack{\text{nitrite}\\\text{anion}}}{NO_2^-} + \underset{\substack{\text{hydrochloric}\\\text{acid}}}{HCl} \rightarrow \underset{\substack{\text{nitrous}\\\text{acid}}}{HNO_2} + \underset{\substack{\text{chloride}\\\text{ion}}}{Cl^-} \qquad (12\text{–}28)$$



$$\underset{\text{nitrous acid}}{HNO_2} + \underset{\text{dimethylamine}}{CH_3\text{—}NH\text{—}CH_3} \rightarrow \underset{\text{N-nitrosodimethylamine}}{CH_3\text{—}\overset{\overset{NO}{|}}{N}\text{—}CH_3^-} \qquad (12\text{–}29)$$

The concern in biological wastewater treatment facilities is that some nitrite may leak through the process. While the concentration of nitrite may be too low to measure by conventional means, concentrations of NDMA as low as 1 or 2 ng/L are being measured and the CDPH notification level for groundwater recharge is 10 ng/L. Based on a limited number of test locations, it has been observed that the concentrations of NDMA in the incoming wastewater can be quite variable, with concentrations as high as 6000 ng/L being measured.

In addition to the formation of NDMA as outlined above, it appears the addition of chloramines for disinfection can serve to amplify the concentration of any NDMA that may be present in the treated effluent before disinfection. In a series of studies conducted by the Los Angeles County Sanitation Districts (Jalali et al., 2005), it was found that chloramination increased the concentration of NDMA in treated effluent following disinfection by tenfold.

Other DBPs resulting from the use of chloramines as disinfectants in treated effluents include cyanogen chloride and cyanogen bromide, where bromides are present (see Table 12–15). In very large quantities, cyanogen chloride is used in tear gas, in fumigant gases, and as a reagent in the formation of other compounds. In the body, cyanogen chloride is metabolized rapidly to cyanide. Because there is limited information on the toxicity of low-level concentrations of cyanogen chloride, proposed guidelines are based on cyanide. The cyanogen compounds are of concern and they are now beginning to be regulated in effluent discharge permits. The current NPDES permit limit for cyanide is 5 mg/L.

Control of DBP Formation Using Chlorine for Disinfection. The principal means of controlling the formation of THMs and other related DBPs is to avoid the direct addition of free chlorine. Based on the evidence to date, it appears that the use of chloramines generally does not lead to the formation of THMs in amounts that would be of concern relative to current standards. As discussed previously, other DBPs may be produced that are of equal concern, but for other reasons (see following discussion). It is important to note that if chloramines are to be used for disinfection, the chloramine solution must be prepared with a potable water supply containing little or no ammonia (i.e., *treated plant effluent should not be used*). If the formation of DBPs is of concern due to the presence of specific organic precursors (i.e., humic materials), the practice of breakpoint chlorination cannot be used. Further, if humic materials are present consistently, it may be appropriate to investigate alternative means of disinfection such as UV irradiation.

The control of DBPs produced when chloramines are used (by reducing direct reactions of organics with residual free chlorine) can be more challenging as chloramination may form other DBPs. With respect to NDMA it appears that with proper control and operation of the biological treatment process, the potential for the formation or amplification of this compound can be reduced. Removals of 50 to 70 percent have been reported for NDMA when using reverse osmosis employing thin film composite membranes (see Chap. 11). The use of UV irradiation has also proven to be effective in the control of NDMA. Where the formation of NDMA and cyanogen chloride is a persistent concern, a number of wastewater agencies have switched to UV irradiation for disinfection. In the study cited above (Jalali et al., 2005), it was also found that there was no net change in the total cyanide (CN^-) concentration in the treated effluent due to UV irradiation. The use of sequential chlorination to control the formation of NDMA is considered in Sec. 12–8.

Environmental Impacts of Disinfection with Chlorine

The environmental impacts associated with the use of chlorine and chlorine compounds as a disinfectant in wastewater applications include the discharge of DBPs and the regrowth of microorganisms.

Discharge of DBPs. It has been shown that many of the DBPs can cause environmental impacts at very low concentrations. The occurrence of DBPs and compounds such as NDMA raises serious questions about the continued use of free chlorine for disinfection.

Regrowth of Microorganisms. In many locations, a regrowth of microorganisms has been observed in receiving water bodies and in long transmission pipelines following dechlorination of treated effluent disinfected with chlorine. The regrowth of microorganisms is not unexpected as it is well known that a number of microorganisms survive the disinfection process. It has been hypothesized that regrowth (also known as aftergrowth) results, in part, because (1) the amount of organic matter and available nutrients in treated wastewater is sufficient to sustain the limited number of organisms remaining after disinfection, (2) predators such as protozoa are absent, (3) there are favorable temperatures, and (4) disinfectant residuals are ineffective. Because regrowth is an especially important issue in transmission lines used for the transport of reclaimed water, a suitable chlorine residual (on the order of 1 to 2 mg/L, depending on local conditions) should be maintained in the pipeline to control regrowth (a common practice in water distribution systems). In very long pipelines, it may be necessary to add additional chlorine at intermediate points along the length of the pipeline.

12–4 DISINFECTION WITH CHLORINE DIOXIDE

Chloride dioxide (ClO_2), another bactericide, is equal to or greater than chlorine in disinfecting power. Chlorine dioxide has proven to be an effective virucide, being more effective in achieving inactivation of viruses than chlorine. A possible explanation is that because chlorine dioxide is absorbed by peptone (a protein), and that viruses have a protein coat, adsorption of ClO_2 onto this coating could cause inactivation of the virus. In the past, ClO_2 did not receive much consideration as a wastewater disinfectant due to its high costs; sodium chlorite feed stock is about ten times as expensive as chlorine on a weight basis.

Characteristics of Chlorine Dioxide

Chlorine dioxide (ClO_2) is, under atmospheric conditions, a yellow to red unpleasant smelling, irritating, unstable gas with a high specific gravity. Because chlorine dioxide is unstable and decomposes rapidly, it is usually generated onsite before its application. Chlorine dioxide is generated by mixing and reacting a chlorine solution in water with a solution of sodium chlorite ($NaClO_2$) according to the following reaction:

$$2NaClO_2 + Cl_2 \rightarrow 2ClO_2 + 2NaCl \tag{12–30}$$

Based on Eq. (12–30), 1.34 mg sodium chlorite reacts with 0.5 mg chlorine to yield 1.0 mg chlorine dioxide. Because technical grade sodium chlorite is only about 80 percent pure, about 1.68 mg of the technical grade sodium chlorite is required to produce 1.0 mg of chlorine dioxide. Sodium chlorite may be purchased and stored as a liquid (generally a 25 percent solution) in refrigerated storage facilities. The properties of chlorine dioxide were presented previously in Tables 12–3 and 12–7.

Chlorine Dioxide Chemistry

The active disinfecting agent in a chlorine dioxide system is free dissolved chlorine dioxide (ClO_2). At the present time, the complete chemistry of chlorine dioxide in an aqueous environment is not understood completely. Because ClO_2 does not hydrolyze in a manner similar to the chlorine compounds discussed in the previous section, the oxidizing power of ClO_2 is often referred to as *equivalent available chlorine*. The definition of the term equivalent available chlorine is based on a consideration of the following oxidation half reaction for ClO_2:

$$ClO_2 + 5e^- + 4H^+ \rightarrow Cl^- + 2H_2O \tag{12–31}$$

As shown in Eq. (12–31), the chlorine atom undergoes a 5 electron change in its conversion from chlorine dioxide to the chloride ion. Because the weight of chlorine in ClO_2 is 52.6 percent and there is a 5 election change, the equivalent available chlorine content is equal to 263 percent as compared to chlorine. Thus, ClO_2 has 2.63 times the oxidizing power of chlorine. The concentration of ClO_2 is usually expressed in g/m^3. On a molar basis, one mole of ClO_2 is equal to 67.45 g, which is equivalent to 177.25 g (5×35.45) of chlorine. Thus, 1 g/m^3 of ClO_2 is equivalent to 2.63 g/m^3 of chlorine.

Effectiveness of Chlorine Dioxide as a Disinfectant

Chlorine dioxide has an extremely high oxidation potential, which probably accounts for its potent germicidal powers. Because of its extremely high oxidizing potential, possible bactericidal mechanisms may include inactivation of critical enzyme systems or disruption of protein synthesis. It should be noted, however, that when ClO_2 is added to water it is often reduced to the chlorite ion (ClO_2^-), a weak disinfectant, according to the following reaction. The formation of ClO_2^- may help to explain the variability that is sometimes observed in the performance of ClO_2 as a disinfectant.

$$ClO_2 + e^- \rightarrow ClO_2^- \tag{12–32}$$

Based on the coefficient of specific lethality as reported in Table 12–11, the effectiveness of ClO_2 with respect to bacteria is similar to that of free chlorine. However, there are some differences, depending on the microorganism group and members within each group. Chlorine dioxide appears to be more effective than free chlorine in the inactivation of protozoan cysts.

Modeling the Chlorine Dioxide Disinfection Process

As discussed previously in Sec. 12–3, the models that have been developed to describe the disinfection process with chlorine can also be used, with appropriate caution, for chlorine dioxide. As with chlorine, the shoulder effect and the effect of the residual particles must be considered. Further, the differences between (1) secondary and filtered secondary effluent and (2) microfiltration and reverse osmosis effluent must also be considered.

Required Chlorine Dioxide Dosages for Disinfection

The required chlorine dioxide dosage will depend on the pH and the specific organism under investigation. Relative CT values for chlorine dioxide are given in Table 12–5, presented previously in Sec. 12–2, and values of the coefficient of specific lethality are given in Table 12–11. Because the data on chlorine dioxide in the literature are limited, site-specific testing is recommended to establish appropriate dosage ranges although the values given in Table 12–5 can be used as a starting point.

Byproduct Formation and Control

The formation of DBPs is of great concern with the use of chlorine dioxide. The formation and control of DBPs with chlorine dioxide is considered in the following discussion.

Formation of DBPs Using Chlorine Dioxide for Disinfection. The principal DBPs formed when chlorine dioxide is used as a disinfectant are chlorite (ClO_2^-) and chlorate (ClO_3^-), both of which are potentially toxic at low concentrations. The principal sources of the chlorite ion are from the process used to generate the chlorine dioxide and from the reduction of chlorine dioxide. As given by Eq. (12–30), all of the $NaClO_2$ reacts with chlorine to form ClO_2. Unfortunately, on occasion some unreacted chlorite ion can escape from the reactor where the chlorine dioxide is being generated and find its way into the water that is being treated. The second source of chlorite is from the reduction of chlorine dioxide as discussed above [see Eq. (12–32)]. The chlorate ion can be derived from the oxidation of chlorine dioxide, from the impurities in the sodium chlorite feed stock, and from the photolytic decomposition of chlorine dioxide.

The chlorine dioxide residuals and other end products are believed to degrade more quickly than chlorine residuals, and, therefore, may not pose as serious a threat to aquatic life as chlorine residuals. An advantage in using chlorine dioxide is that it does not react with ammonia to form the potentially toxic chlorinated DBPs. It has also been reported that halogenated organic compounds are not produced to any appreciable extent.

Control of DBP Formation Using Chlorine Dioxide for Disinfection. The formation of chlorite can be controlled by careful management of the feedstock or increasing the chlorine dose beyond the stoichiometric amount. Treatment methods for the removal of the chlorite ion involve reducing the chlorite ion to the chloride ion using either ferrous iron or sulfite. Granular activated carbon (GAC) can also be used to absorb trace amounts of chlorite. At the present time there are no cost-effective methods for the removal of the chlorate ion. The control of the chlorate ion depends primarily on the effective management of the facilities used for the production of chlorine dioxide (White, 1999; Black and Veatch Corporation, 2010).

Environmental Impacts

The environmental impacts associated with the use of chlorine dioxide as a wastewater disinfectant are not well known. It has been reported that the impacts are less adverse than those associated with chlorination. Chlorine dioxide does not dissociate or react with water as does chlorine. However, because chlorine dioxide is normally produced from chlorine and sodium chlorite, free chlorine may remain in the resultant chlorine dioxide solution (depending on the process) and impact the receiving aquatic environment, as does chlorine and its byproducts.

12–5 DECHLORINATION

Chlorination is one of the most commonly used methods for the destruction of pathogenic and other harmful organisms that may endanger human health. As noted in the previous sections, however, certain organic constituents in wastewater interfere with the chlorination process. Many of these organic compounds may react with the chlorine to form toxic compounds that can have long-term adverse effects on the beneficial uses of the waters to which they are discharged or reused. To minimize the effects of these potentially toxic chlorine residuals on the environment, dechlorination of treated effluent is necessary. Dechlorination may be accomplished by reacting the residual chlorine with a reducing agent such as sulfur dioxide or sodium bisulfite or by adsorption on and reaction with activated carbon.

Dechlorination of Treated Wastewater with Sulfur Dioxide

Where effluent toxicity requirements are applicable, or where dechlorination is used as a polishing step following the breakpoint chlorination process for the removal of ammonia nitrogen, sulfur dioxide (SO_2) is used most commonly for dechlorination. Sulfur dioxide is available commercially as a liquefied gas under pressure in steel containers. Sulfur dioxide is handled in equipment very similar to standard chlorine systems. When added to water, sulfur dioxide reacts to form sulfurous acid (H_2SO_3), a strong reducing agent. In turn, the sulfurous acid dissociates to form HSO_3^- that will react with free and combined chlorine, resulting in formation of chloride and sulfate ions. Sulfur dioxide gas successively removes free chlorine, monochloramine, dichloramine, nitrogen trichloride, and poly-n-chlor compounds as illustrated in Eqs. (12–33) through (12–38).

Reactions between sulfur dioxide and free chlorine:

$$SO_2 + H_2O \rightarrow H_2SO_3 \tag{12–33}$$

$$\underline{HOCl + H_2SO_3 \rightarrow HCl + H_2SO_4} \tag{12–34}$$

$$SO_2 + HOCl \rightarrow HCl + H_2SO_4 \tag{12–35}$$

Reactions between sulfur dioxide and monochloramine, dichloramine, and nitrogen trichloride are:

$$NH_2Cl + H_2SO_3 + H_2O \rightarrow NH_4Cl + H_2SO_4 \tag{12–36}$$

$$NHCl_2 + 2H_2SO_3 + 2H_2O \rightarrow NH_4Cl + 2H_2SO_4 + HCl \tag{12–37}$$

$$NCl_3 + 3H_2SO_3 + 3H_2O \rightarrow NH_4Cl + 3H_2SO_4 + 2HCl \tag{12–38}$$

For the overall reaction between SO_2 and chlorine [Eq. (12–35)], the stoichiometric amount of SO_2 required per mg/L of chlorine residual is 0.903 mg/L. In practice, as reported in Table 12–16, it has been found that about 1.0 to 1.2 mg/L of sulfur dioxide will be required for the dechlorination of 1.0 mg/L of chlorine residue (expressed as Cl_2). Because the reactions of sulfur dioxide with chlorine and chloramines are nearly instantaneous, contact time is not usually a factor and contact chambers are not used, but rapid and positive mixing at the point of application is an absolute requirement.

The ratio of free chlorine to the total combined chlorine residual before dechlorination will determine whether the dechlorination process is partial or proceeds to completion. If the ratio is less than 85 percent, it can be assumed that significant organic nitrogen is present and that it will interfere with the dechlorination of free residual chlorine.

Table 12–16

Typical information on the quantity of dechlorinating compound required for each mg/L of residual chlorine

Dechlorinating compound			Quantity, mg/(mg/L) residual	
Name	**Formula**	**Molecular weight**	**Stoichiometric amount**	**Range in use**
Hydrogen peroxide	H_2O_2	34.01	0.48	0.5–0.7
Sodium bisulfite	$NaHSO_3$	104.06	1.46	1.5–1.7
Sodium metabisulfite	$Na_2S_2O_5$	190.10	1.34	1.4–1.6
Sodium sulfite	Na_2SO_3	126.04	1.78	1.8–2.0
Sodium thiosulfate	$Na_2S_2O_3$	112.12	0.56	0.6–0.9
Sulfur dioxide	SO_2	64.09	0.903	1.0–1.2

In most situations, sulfur dioxide dechlorination is a very reliable unit process, provided that the precision of the combined chlorine residual monitoring service is adequate. Excess sulfur dioxide dosages should be avoided, not only because of the chemical wastage, but also because of the oxygen demand exerted by the excess sulfur dioxide. The relatively slow reaction between excess sulfur dioxide and dissolved oxygen is given by the following expression:

$$HSO_3^- + 0.5O_2 \rightarrow SO_4^{2-} + H^+ \qquad (12\text{–}39)$$

The result of this reaction is a reduction in the dissolved oxygen in the water, a corresponding increase in the measured BOD and COD, and a possible drop in the pH. All these effects can be eliminated by proper control of the dechlorination system.

Dechlorination of Treated Wastewater with Sodium Based Compounds

Sodium based chemicals that have been used for dechlorination include sodium sulfite (Na_2SO_3), sodium bisulfite ($NaHSO_3$), sodium metabisulfite ($Na_2S_2O_5$), sodium thiosulfate ($Na_2S_2O_3$), and hydrogen peroxide (H_2O_2). When these chemicals are used for dechlorination, the following reactions occur. The stoichiometric weight ratios of these compounds needed per mg/L of residual chlorine are given in Table 12–15, along with the range of values used in practice.

Sodium Sulfite. Reactions between sodium sulfite and free chlorine residual and combined chlorine residual, as represented by monochloramine:

$$Na_2SO_3 + Cl_2 + H_2O \rightarrow Na_2SO_4 + 2HCl \qquad (12\text{–}40)$$

$$Na_2SO_3 + NH_2Cl + H_2O \rightarrow Na_2SO_4 + Cl^- + NH_4^+ \qquad (12\text{–}41)$$

Sodium Bisulfite. Reaction between sodium bisulfite and free chlorine residual and combined chlorine residual, as represented by monochloramine:

$$NaHSO_3 + Cl_2 + H_2O \rightarrow NaHSO_4 + 2HCl \qquad (12\text{–}42)$$

$$NaHSO_3 + NH_2Cl + H_2O \rightarrow NaHSO_4 + Cl^- + NH_4^+ \qquad (12\text{–}43)$$

Sodium Metabisulfite. Reactions between sodium metabisulfite and free chlorine residual and combined chlorine residual, as represented by monochloramine:

$$Na_2S_2O_5 + Cl_2 + 3H_2O \rightarrow 2NaHSO_4 + 4HCl \qquad (12\text{–}44)$$

$$Na_2S_2O_5 + 2NH_2Cl + 3H_2O \rightarrow Na_2SO_4 + H_2SO_4 + 2Cl^- + 2NH_4^+ \qquad (12\text{–}45)$$

Sodium Thiosulfate and Related Compounds. Often used as a dechlorinating agent in analytical laboratories, the use of sodium thiosulfate ($Na_2S_2O_3$) in full scale water reclaimation treatment plants is limited for the following reasons. It appears the reaction of sodium thiosulfate with residual chlorine is stepwise, creating a problem with uniform mixing. The ability of sodium thiosulfate to remove residual chlorine is a function of the pH (White, 1999; Black and Veatch Corporation, 2010). The reaction with residual chlorine is only stoichiometric at a pH value of 2, making prediction of the required dose impossible in wastewater applications. As reported in Table 12–16, the stoichiometric weight ratio of sodium thiosulfate per mg/L of residual chlorine is 0.556. Although not in common use, calcium thiosulfate (CaS_2O_3) ascorbic acid ($C_6H_8O_6$), and sodium ascorbate ($C_6H_7NaO_6$) have all been used at full scale for dechlorination.

Dechlorination with Hydrogen Peroxide

Hydrogen peroxide (H_2O_2) has also been used for dechlorination. Unlike sulfur dioxide and the sodium-based compounds discussed above, hydrogen peroxide does not result in an increase in the total dissolved solids as it only adds oxygen to the water. When hydrogen peroxide is used for dechlorination, the following reaction occurs.

$$H_2O_2 + Cl_2 \rightarrow O_2 + 2HCl \tag{12–46}$$

The stoichiometric weight ratio of hydrogen peroxide needed per mg/L of residual chlorine is 0.48. Because the reaction between hydrogen peroxide and chlorine compounds is so rapid, other inorganic and organic compounds generally do not interfere with the reaction. The optimal pH range is about 8.5 at which the reaction occurs instantaneously, although there is no upper limit. In the past, hydrogen peroxide has not been used for dechlorination because it is difficult to handle.

Dechlorination with Activated Carbon

Both combined and free residual chlorine can be removed by means of adsorption on and reaction with activated carbon. When activated carbon is used for dechlorination, the following reactions occur once chlorine or chlorine compounds have been adsorbed.

Reactions with free chlorine residual:

$$C + 2Cl_2 + 2H_2O \rightarrow 4HCl + CO_2 \tag{12–47}$$

Reactions with combined residual as represented by mono- and dichloramine:

$$C + 2NH_2Cl + 2H_2O \rightarrow CO_2 + 2NH_4^+ + 2Cl^- \tag{12–48}$$

$$C + 4NHCl_2 + 2H_2O \rightarrow CO_2 + 2N_2 + 8H^+ + 8Cl^- \tag{12–49}$$

Granular activated carbon is used in either a gravity or pressure filter bed. If carbon is to be used solely for dechlorination, it must be preceded by an activated carbon process for the removal of other constituents susceptible to removal by activated carbon. In treatment plants where granular activated carbon is used to remove organics, either the same or separate beds can also be used for dechlorination.

Because granular carbon in column applications has proved to be very effective and reliable, activated carbon should be considered where dechlorination is required. However, this method is quite expensive. It is expected that the primary application of activated carbon for dechlorination will be in situations where high levels of organic removal are also required.

Dechlorination of Chlorine Dioxide with Sulfur Dioxide

Where treated wastewater is disinfected with chlorine dioxide, dechlorination can be achieved using sulfur dioxide. The reaction that takes place in the chlorine dioxide solution can be expressed as

$$SO_2 + H_2O \rightarrow H_2SO_3 \tag{12–50}$$

$$5H_2SO_3 + 2ClO_2 + H_2O \rightarrow 5H_2SO_4 + 2HCl \tag{12–51}$$

Based on Eq. (12–51), it can be seen that 2.5 mg of sulfur dioxide will be required for each mg of chlorine dioxide residual (expressed as ClO_2). In practice, 2.7 mg SO_2/mg ClO_2 would normally be used.

12–6 DESIGN OF CHLORINATION AND DECHLORINATION FACILITIES

The chemistry of chlorine in water and wastewater has been discussed in the previous sections, along with an analysis of how chlorine functions as a disinfectant. Important considerations in the implementation of chlorination and dechlorination facilities for a variety of purposes include (1) estimation of the chlorine dosage, (2) application flow diagrams, (3) dosage control, (4) injection and initial mixing, (5) chlorine contact basin design, (6) assessing the hydraulic performance of existing chlorine contact basins, (7) outlet control and chlorine residual measurement, (8) chlorine storage facilities, (9) chemical containment and neutralization facilities, and (10) dechlorination facilities. These topics are considered in the following discussion.

Sizing Chlorination Facilities

To aid in the design and selection of the required chlorination facilities and equipment, it is important to know the uses, including dosage ranges, to which chlorine and its compounds have been applied. Chlorination capacities for disinfection are generally selected to meet the specific design criteria of the state or other regulatory agencies controlling the receiving body of water. In any case, where the residual in the effluent is specified or the final number of coliform bacteria is limited, onsite testing is preferred to determine the dosage of chlorine required. Typical chlorine dosages for disinfection have been given previously in Table 12–14. Typical chlorine dosages for applications other than disinfection are given in Table 12–17. A range of dosage values is given because they will vary depending on the characteristics of the wastewater. In the absence of more specific data, the maximum values given in Tables 12–14 and 12–17 can be used as a guide in sizing chlorination equipment. The sizing of chlorination facilities is illustrated in Example 12–5.

Table 12–17

Typical dosages for various chlorination applications in wastewater collection and treatment

Application	Dosage range, mg/L
Collection:	
Corrosion control (H_2S)	2–9[a]
Odor control	2–9[a]
Slime growth control	1–10
Treatment:	
BOD reduction	0.5–2[b]
Digester and Imhoff tank foaming control	2–15
Digester supernatant oxidation	20–140
Ferrous sulfate oxidation	–[c]
Filter fly control	0.1–0.5
Filter ponding control	1–10
Grease removal	2–10
Sludge bulking control	1–10

[a] Per mg/L of H_2S.

[b] Per mg/L of BOD_5 destroyed.

[c] $6FeSO_4 \cdot 7H_2O + 3Cl_2 \rightarrow 2Fe_2(SO_4)_3 + 42H_2O$.

EXAMPLE 12–5 **Sizing of Chlorination Facilities** Determine the capacity of a chlorinator for a treatment plant with an average wastewater flowrate of 1000 m^3/d (0.26 Mgal/d). The peak daily factor for the treatment plant is 3.0 and the maximum required chlorine dosage (set by state regulations) is to be 20 mg/L.

Solution

1. Determine the capacity of the chlorinator at peak flow.

$$\begin{aligned} Cl_2, \text{kg/d} &= (20\ \text{g/m}^3)(1000\ \text{m}^3/\text{d})(3)(1\ \text{kg}/10^3\ \text{g}) \\ &= 60\ \text{kg/d} \end{aligned}$$

Use the next largest standard size chlorinator: two 90 kg/d (200 lb/d) units with one unit serving as a spare. Although the peak capacity will not be required during most of the day, it must be available to meet the chlorine requirements at peak flow. Best design practice calls for the availability of a standby chlorinator.

2. Estimate the daily consumption of chlorine. Assume an average dosage of 10 mg/L.

$$\begin{aligned} Cl_2, \text{kg/d} &= (10\ \text{g/m}^3)(1000\ \text{m}^3/\text{d})(1\ \text{kg}/10^3\ \text{g}) \\ &= 10\ \text{kg/d} \end{aligned}$$

Comment In sizing and designing chlorination systems, it is also important to consider the low flow/dosage requirements. The chlorination system should have sufficient turndown capability for these conditions so that excessive chlorine is not applied.

Disinfection Process Flow Diagrams

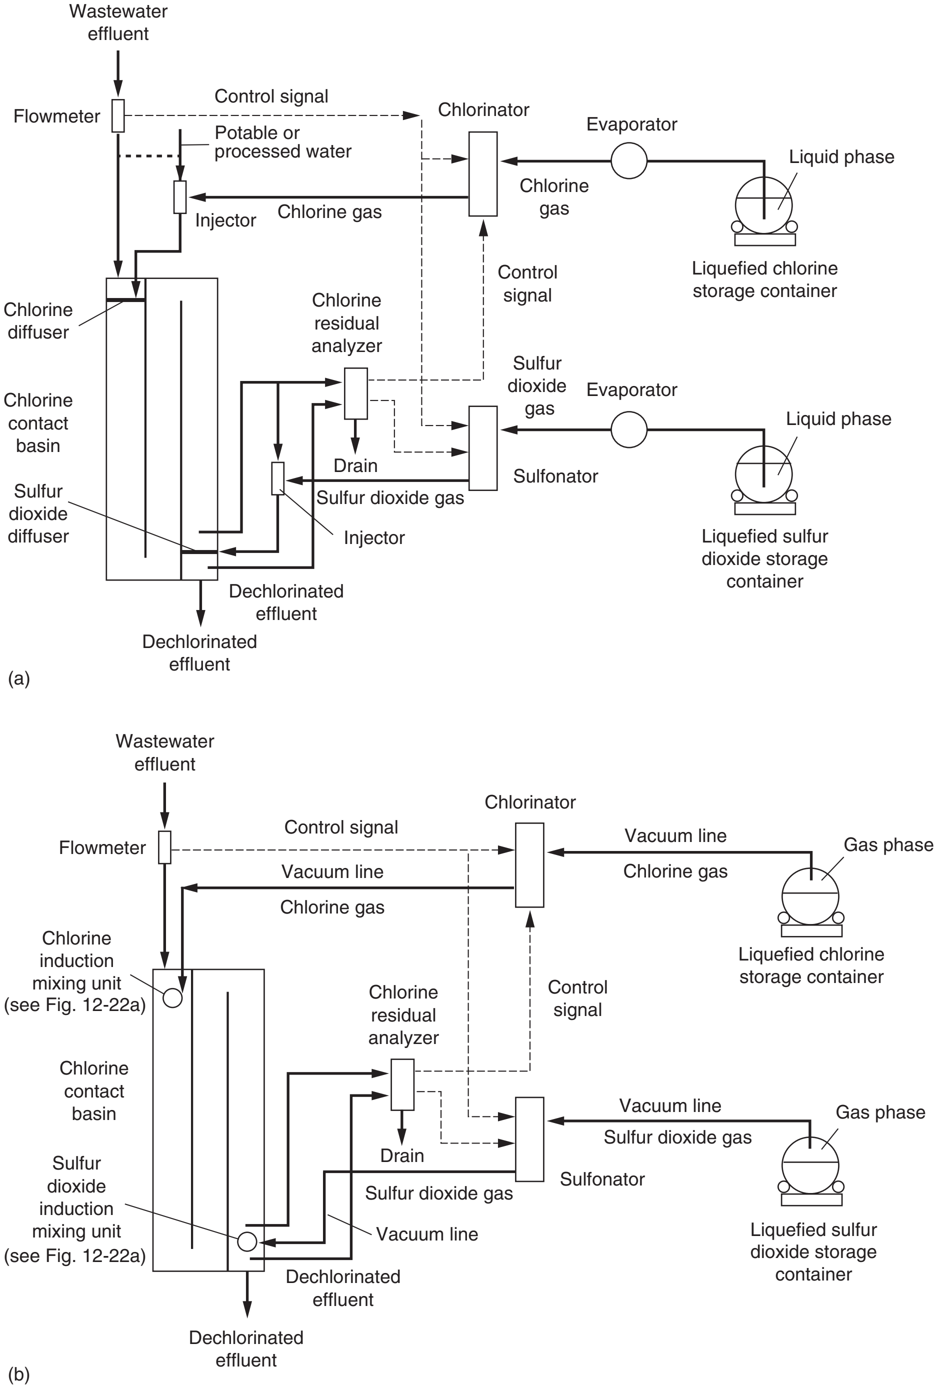
Process flow diagrams and equipment used to inject (feed) chlorine, hypochlorite, dry calcium hypochlorite, and chlorine dioxide into wastewater are illustrated and discussed below.

Flow Diagram for Chlorine. Chlorine may be applied directly as a gas or in an aqueous solution. Typical chlorine/sulfur dioxide chlorination/dechlorination process flow diagrams are shown on Fig. 12–17. The difference in the two diagrams shown on Fig. 12–17 is in the method of introducing and mixing the chlorine solution with the wastewater. Chlorine can be withdrawn from storage containers either in liquid or gas form. If withdrawn as a gas, the evaporation of the liquid in the container results in frost formation that restricts gas withdrawal rates to 18 kg/d (40 lb/d) for 68 kg (150 lb) cylinders and 205 kg/d (450 lb/d) for 0.9-tonne (1-ton) containers at 21°C (70°F). Evaporators are used normally where the maximum rate of chlorine gas withdrawal from a 0.9-tonne (1-ton) container must exceed approximately 180 kg/d (400 lb/d). Although multiple ton cylinders can be connected to provide more than 180 kg/d (400 lb/d), the use of an evaporator conserves space. Evaporators are almost always used when the total dosage exceeds 680 kg/d (1500 lb/d). Chlorine evaporators are available in sizes ranging from 1818 to 4545 kg/d (4000 to 10,000 lb/d) capacities; chlorinators are available normally in sizes ranging from 227 to 4545 kg/d (500 to 10,000 lb/d).

Flow Diagram for Liquid Hypochlorite Solutions. A typical sodium hypochlorite/sodium bisulfite chlorination/dechlorination process flow diagram is shown on Fig. 12–18. For small treatment plants, the most satisfactory means of feeding sodium or calcium hypochlorite is through the use of low capacity proportioning pumps. Generally, pumps are available in capacities up to 450 L/d (120 gal/d), with adjustable stroke for any reduced values. Large capacities or multiple units are available from some of

Figure 12–17

Schematic flow diagrams for chlorination/dechlorination: (a) using a chlorine injector system and (b) using a molecular chlorine vapor induction system.

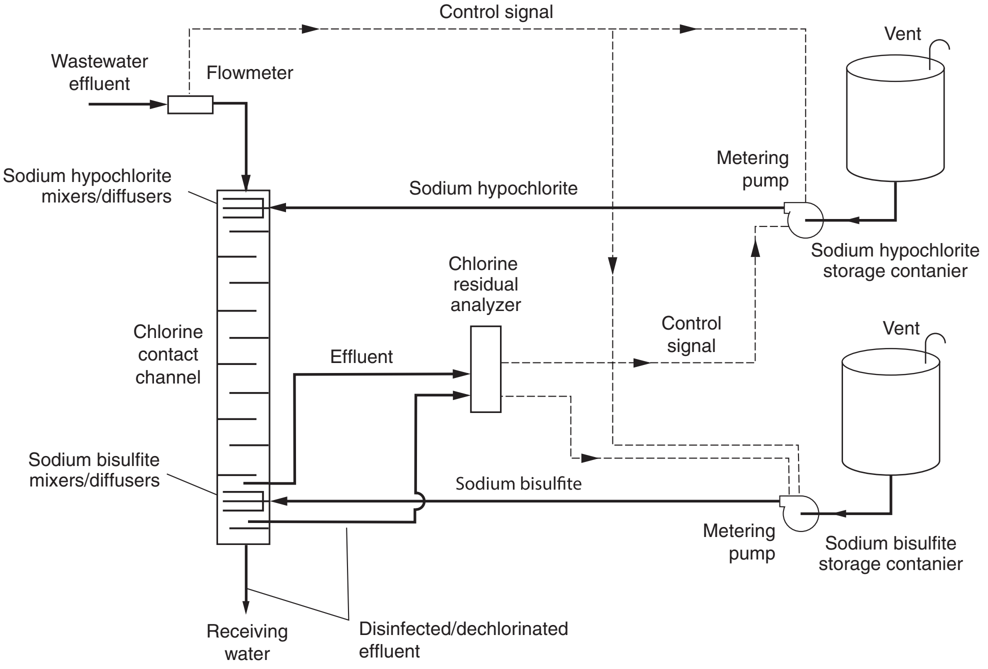


the manufacturers. The pumps can be arranged to feed at a constant rate, or they can be provided with variable speed and with analog signals for varying the feed rate. The stroke length can also be controlled.

Flow Diagram for Dry Calcium Hypochlorite Feed System. For small wastewater flowrates up to about 400 m^3/d (10^5 gal/d) chlorine in the form of dry calcium

Figure 12–18

Schematic flow diagrams for sodium hypochlorite chlorination with sodium bisulfite dechlorination.



hypochlorite tablets is used for disinfection. Two of the most common types of tablet chlorinators (nonpressurized and pressurized) are shown on Fig. 12–19. The schematic flow diagrams for the two tablet chlorinators are essentially the same; a sidestream of water is diverted from the main discharge line, chlorine at relatively high concentrations is added to the sidestream, and the chlorinated sidestream is discharged back into the main flow by means of a pump [see Fig. 12–19(a)] or by reducing the pressure in the main discharge line [see Fig. 12–19(b)]. As shown on Fig. 12–19(a), in the nonpressurized tablet chlorinator the sidestream contacts the bottom surface of the chlorine tablets that rest on a screen. The chlorine tablets have been designed to dissolve at a more or less

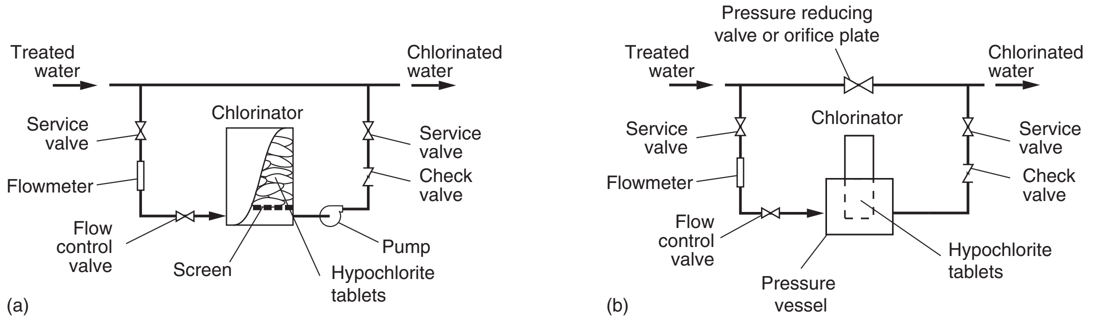


Figure 12–19

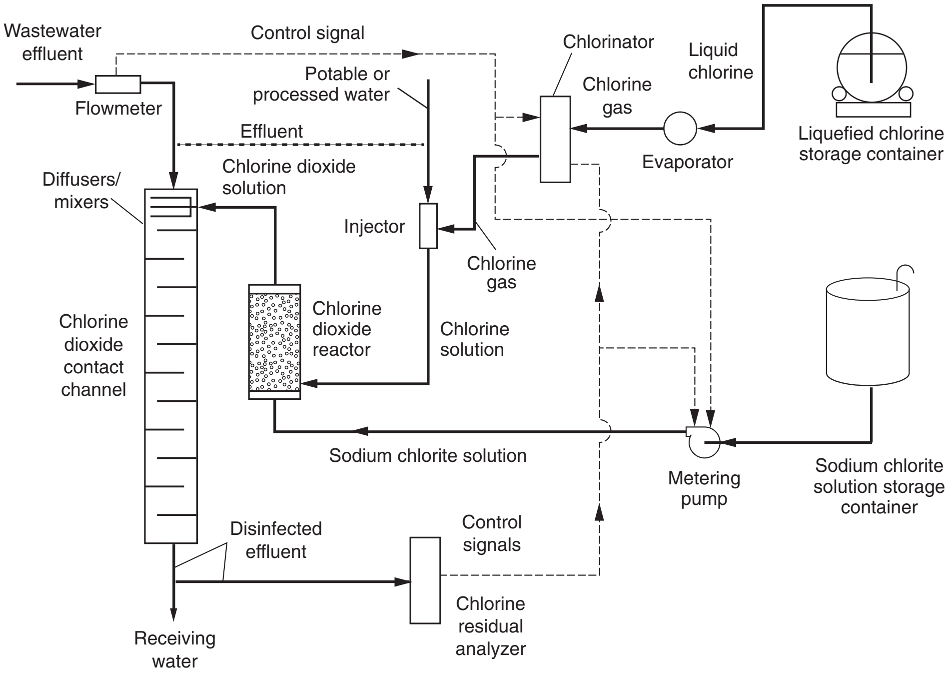
Figure 12–20

Typical flow diagram for the addition of chlorine dioxide.



constant rate, releasing a controlled amount of chlorine. The amount of chlorine added is dependent on the flowrate through the tablet chlorinator. The tablet chlorinator shown on Fig. 12–19(b) is pressurized and hypochlorite is released as water flows over the hypochlorite tablets. Dry calcium hypochlorite tablets, typically 75 mm (3 in.) in diameter, contain about 65 to 70 percent available chlorine. For small treatment plants, the use of chlorine tablets eliminates the hazards associated with handling chlorine cylinders. Further, because there are no moving parts, tablet chlorinators are simple to operate and maintain.

Flow Diagram for Chlorine Dioxide. The chlorine dioxide, generated onsite, is present in an aqueous solution which is applied in same manner as that used for typical chlorination systems. A schematic process flow diagram of a typical chlorine dioxide installation is shown on Fig. 12–20.

Dosage Control

The control of the chlorine dosage can be accomplished in a number of different ways depending on the disinfection objective. The principal control methods are summarized in Table 12–18. The specific control method to be used will depend on the variability of the influent flowrate, the presence of unoxidized constituents that can react with chlorine, the pH of the wastewater, and whether combined or free or a combination of the two forms of chlorine will be used for disinfection. Dosage control is easiest where combined chlorine is used as the disinfectant. Dosage control has also become more difficult due to the impact of climate change resulting in short duration, high intensity rainfall events. Because of the rapid increase in the influent flowrate observed at some treatment plants, due to increased stormwater runoff, the carryover (washout) of solids from the secondary sedimentation basins, especially where shallow basins are used, has further complicated dosage control

Table 12–18

Methods used to control the chlorine dosage for disinfection[a]

Control method	Description
Manual control	Manual control, where the operator changes the feed rate to suit conditions, is the simplest method for controlling the chlorine dose. The required dosage is usually determined by measuring the free and/or the combined chlorine residual at the end of the chlorine contact basin and adjusting the chlorine dosage to obtain a the desired residual. This method works best where combined chlorine is used for disinfection, and the flowrate does not vary too rapidly, but can also be used where free chlorine residual is used.
Manual control with online effluent residual chlorine monitoring	An online chlorine analyzer is used to monitor the chlorine residual in the effluent from the chlorine contact basin. The chlorine dose is adjusted manually based on the plant flowrate and the residual chlorine concentrations. This method works best where combined chlorine is used for disinfection, and the flowrate does not vary too rapidly.
Flow pacing	The chlorine flowrate is paced proportional to the wastewater flowrate as measured by a primary meter such as a magnetic meter, Parshall flume, or flow tube. This method works best where combined chlorine is used for disinfection.
Flow pacing with online effluent residual chlorine monitoring	The chlorine dosage is controlled by automatic measurement of the chlorine residual and the wastewater flowrate. An automatic analyzer with signal transmitter and recorder is required.
Flow pacing with online effluent residual chlorine monitoring and automatic control	The control signals obtained from the wastewater flowmeter and the residual monitor are fed to a programmable logic controller (PLC) to provide more precise control of chlorine dosage and residual. This method works best where combined chlorine is used for disinfection.
Flow pacing with online residual chlorine monitoring after initial demand and automatic control	In this method, the chlorine residual is measured a short distance downstream from the point of chlorine addition. The readings from the wastewater flowmeter and the residual chlorine monitor are fed to a PLC to provide more precise control of chlorine dosage and residual. This method works best where combined chlorine is used for disinfection.
Flow pacing with online free and combined residual chlorine monitoring and automatic control	This approach is used for the disinfection of nitrified effluents with free chlorine where a variable residual ammonia must be removed to reach the breakpoint. The free and combined chlorine residual concentrations along with the readings from the wastewater flowmeter are fed to a PLC to provide more precise control of chlorine dosage. This approach is complex as the PLC must be programmed to recognize the difference between free and combined chlorine residuals and be able to interpret the data with respect to the chemistry of the breakpoint reaction. Data from an online ammonia analyzer, now available for field use, can also be integrated with the other data fed to the PLC to optimize the disinfection process with free chlorine.

[a] Adapted in part from Kobylinski et al. (2006).

because of the increase in chlorine demand needed to disinfect microorganisms embedded in floc particles. With manual control it is difficult, if not impossible, to maintain a constant CT, system monitoring and control is resource intensive, manual system is resource intensive; and chemical usage is higher due to residual variability. With automated systems, the ability to maintain the online analyzers is of critical importance if the benefits of automation are to be realized (Hurst, 2012).

Where free chorine is to be used as the disinfectant, dosage control is more difficult, especially if the concentration of residual ammonia in the effluent to be disinfected is somewhat variable. As noted in Table 12–18, both free and combined chlorine residual monitors can be used in conjunction with readings from the influent wastewater flowmeter(s) to provide input to a programmable logic controller (PLC). More recently, online ammonia analyzers have been developed that can be used in conjunction with a PLC and inputs from chlorine residual monitors and flowrate measuring devices. Because the three online monitors must be maintained for complete automated control of the disinfection process, such systems are best employed at larger treatment plants with adequate staff.

Injection and Initial Mixing

As pointed out previously in Section 12–3, other things being equal, effective mixing of the chlorine solution with the wastewater, the contact time, and the chlorine residual are the principal factors involved in achieving effective bacterial kill. The addition of chlorine solution is often accomplished with a diffuser, which may be a plastic pipe with drilled holes through which the chlorine solution can be distributed into the path of wastewater flow (see Fig. 12–21). Unfortunately, the use of diffusers for adding chlorine is not very effective. To optimize the performance of disinfection systems, the chlorine should be introduced and mixed as rapidly as possible (ideally in less than a second). Techniques that can be used to mix chlorine in a fraction of a second were introduced and discussed in Chap. 5. Effective devices for mixing chlorine with the wastewater within a fraction of a second are illustrated on Fig. 12–22.

Chlorine Contact Basin Design

The principal design objective for chlorine contact basins is to ensure that some defined percentage of the flow remains in the chlorine contact basin for the design contact time to ensure effective disinfection. The contact time is usually specified by the regulatory agency and may range from 30 to 120 min; contact times of 15 to 90 min at peak flow are common. For example, for reuse applications the CDPH of the State of California requires a CT value of 450 mg·min/L with a modal contact time of 90 min at peak flow. Issues related to the design and analysis of chlorine contact basins considered in the following discussion include (1) basin configuration, (2) the use of baffles and guide vanes, (3) number of chlorine contact basins, (4) precipitation of solids in chlorine contact basins, (5) solids transport velocity and (6) a procedure for predicting disinfection performance.

Chlorine Contact Basin Configuration. To be assured that a given percentage of the flow will remain in the chlorine contact basin for a given period of time, the most common approach is to use long plug-flow, around-the-end type of contact basins (see Fig. 12–13) or a series of interconnected basins or compartments. Plug-flow chlorine contact basins that are built in a serpentine fashion (e.g., folded back and forth) to conserve space require special attention in their design to eliminate the formation of hydraulic dead zones that will reduce the hydraulic detention times. Length-to-width ratios (L/W) of at least 20 to 1 (preferably 40 to 1) and the use of baffles and guide vanes, as described below,

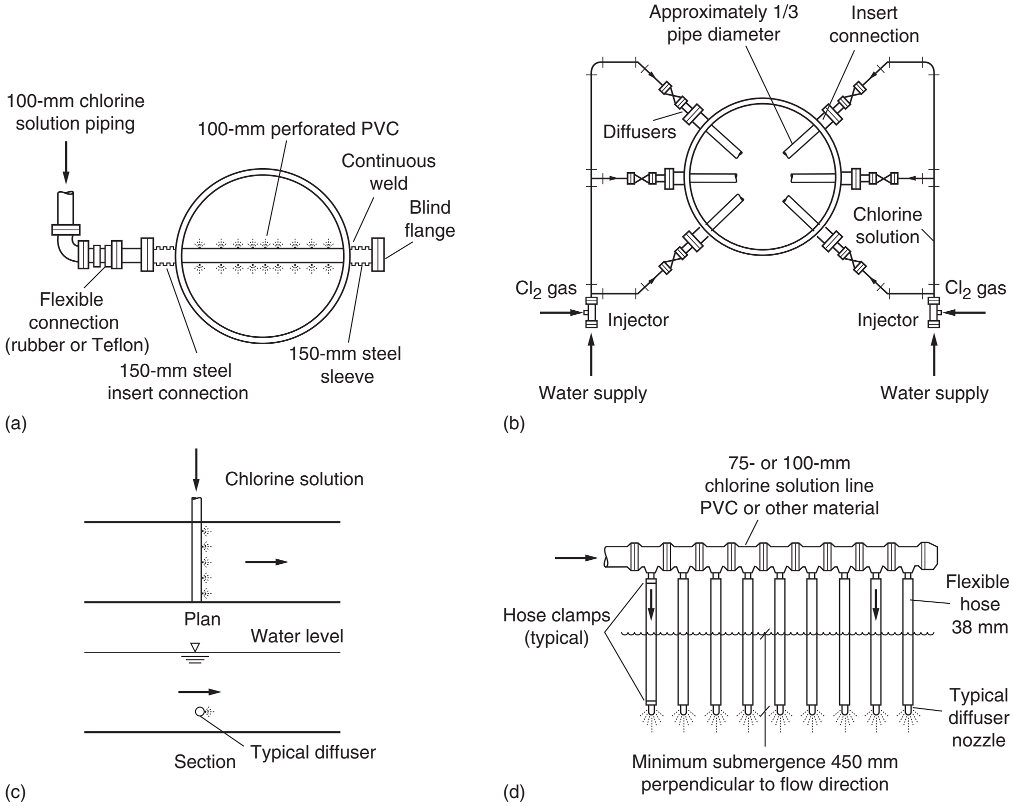


Figure 12–21

Typical diffusers used to inject chlorine solution: (a) across the pipe diffuser (b) diffuser system for large conduits, (c) single across the channel diffuser, and (d) typical hanging nozzle type chlorine diffuser for open channels. (Adapted from White, 1999.)

will help to minimize short circuiting. In some small plants, chlorine contact basins have been constructed of large diameter sewer pipe. The design of a chlorine contact basin based on dispersion is considered in Example 12–6.

Use of Baffles and Deflection Guide Vanes. To improve the hydraulic performance of chlorine contact basins, it has become common practice to use either submerged baffles, deflection guide vanes, or combinations of the two. Submerged baffles are used to break up density currents caused by temperature gradients, to limit short circuiting, and to minimize the effect of hydraulic dead spaces. The location of the baffles is critical in improving the performance of chlorine contact basins. A typical placement of baffles, and the effect on the corresponding tracer response curves, is illustrated on Fig. 12–23. As shown on Fig. 12–23, the addition of baffles improves the hydraulic performance of the chlorine contact basin significantly. The open area in submerged baffles will typically vary from 6 to 10 percent of the cross-sectional area of flow. The headloss through each baffle can be estimated using the following expression:

$$h = \frac{1}{2g}\left(\frac{Q}{Cna}\right)^2 \tag{12–52}$$

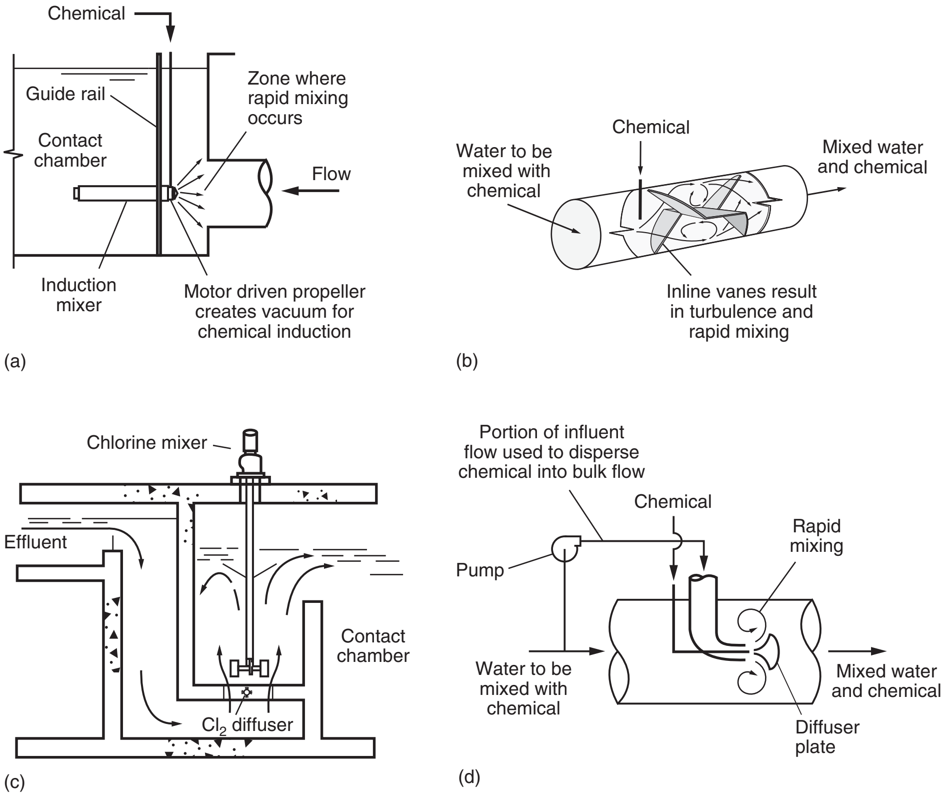

Figure 12–22

Typical mixers for the addition of chlorine: (a) Water Champ® induction mixer can be mounted horizontally, as shown, or vertically, depending on the basin configuration, (b) inline static mixer, (c) inline turbine mixer, and (d) inline injector pump type. For additional types of chlorine mixers see Fig. 5–12 in Chap. 5.

where h = headloss, m
g = acceleration due to gravity, 9.81 m/s^2
Q = discharge through chlorine contact basin channel, m^3/s
C = discharge coefficient, unitless (typically about 0.8)
n = number of openings
a = area of individual opening, m^2

An alternative approach that has been used to improve the performance of chlorine contact basins is through the addition of deflection guide vanes, as shown on Fig. 12–24. The placement and number of vanes will depend on the layout of the chlorine contact basin. Two or three guide vanes are used most commonly. The beneficial effect of adding guide vanes was studied extensively by Louie and Fohrman (1968).

Number of Chlorine Contact Basins. For most treatment plants, two or more contact basins should be used to meet reliability and redundancy requirements to facilitate maintenance and cleaning. Provisions should also be included for draining and scum removal. Vacuum type cleaning equipment may be used as an alternative to draining the basin for removal of accumulated solids. Bypassing the contact basin for maintenance should only be practiced on rare occasions, with the approval of regulatory agencies. If the time of travel in the outfall sewer at the maximum design flowrate is sufficient to equal or exceed the required contact time, it may be possible to eliminate the chlorine contact chambers, provided regulatory authorities agree.

Precipitation in Chlorine Contact Basins. A problem often encountered in the operation of chlorine contact basins is the formation and precipitation of a light flocculent

(b)

material. The principal cause of the formation and precipitation of floc is the lowering of the pH that results from the addition of chlorine. The problem occurs most frequently where alum is used for phosphorus removal in separate precipitation facilities or is added before the effluent filters. For a variety of reasons including high pH and inadequate initial mixing, not all of the alum added will react completely to form a floc that can be removed by precipitation or filtration. However, when the pH is lowered in the chlorine contact basin due to the addition of chlorine, some of the unreacted alum may form a floc. Oxidation of organic material in the treated effluent can also result in the formation of precipitates. Thus, in addition to meeting reliability and redundancy requirements, a minimum of two chlorine contact basins is necessary to allow one basin to be removed from service so that the accumulated solids can be removed from the basins.

Solids Transport Velocity. The horizontal velocity at minimum flow in a chlorine contact basin should, in theory, be sufficient to scour the bottom or to limit the deposition of sludge solids that may have passed through the settling tank. To limit excessive deposition, horizontal velocities should be at least 2 to 4.5 m/min (6.5 to 15 ft/min). In general, it will be difficult to achieve such velocities and simultaneously meet stringent dispersion requirements (see Example 12–6). If floc particles form, it will generally be impossible to avoid the accumulation of a sludge layer in the chlorine contact basins, another reason at least two chlorine contact basins should be used.

EXAMPLE 12–6 **Design of a Chlorine Contact Basin Based on Dispersion** Design a chlorine contact basin for secondary effluent with an average flowrate of 4000 m^3/d. The estimated peaking factor is 2.0. The detention time at peak flow is to be 90 min. A minimum of two parallel channels must be used for redundancy requirements. The dimensions of the chlorine contact basin should be such to achieve a dispersion number equal to or less 0.015 at peak flow. Also check the dispersion number at average flow. What will happen if the low flow drops to 33 percent of the average flow in the early morning hours? Based on the resulting calculations will solids deposition occur, requiring periodic draining and cleaning of the chlorine contact basin?

Solution

1. Assume some trial cross-sectional dimensions for the chlorine contact basin and determine the corresponding length and flow velocity.
   a. Assumed dimensions

      Width = 2 m (6.6 ft)

      Depth = 3 m (9.8 ft)

      Number of parallel channels = 2

   b. Determine required length

$$L = \frac{(2 \times 4000\ \text{m}^3/\text{d})}{(2)(1440\ \text{min/d})} \times (90\ \text{min}) \times \frac{1}{(2\ \text{m} \times 3\ \text{m})} = 41.7\ \text{m}$$

   c. Check velocity at peak flow

$$v = \frac{(2 \times 4000\ \text{m}^3/\text{d})}{(2)(1440\ \text{min/d})(60\ \text{s/min})} \times \frac{1}{(2\ \text{m} \times 3\ \text{m})} = 0.0077\ \text{m/s}$$

2. Determine the coefficient of dispersion using Eq. (I–14) from Appendix I and the dispersion number using Eq. (I–9) from Appendix I for the chlorine contact basin.

a. Compute the coefficient of dispersion

$D = 1.01\nu N_R^{0.875}$

i. Compute the Reynolds number

$N_R = 4vR/\nu$

v = velocity in open channel, LT^{-1}, (m/s)

R = hydraulic radius = area/wetted perimeter, L, (m)

$v = 0.0077$ m/s

$\nu = 1.003 \times 10^{-6}$ m²/s (at 20°C)

$$N_R = \frac{(4)(0.0077 \text{ m/s})[(2.0 \text{ m} \times 3.0 \text{ m})/(2 \times 3.0 \text{ m} + 2.0 \text{ m})]}{(1.003 \times 10^{-6} \text{ m}^2/\text{s})} = 23{,}031$$

ii. Determine the coefficient of dispersion

$$D = 1.01(1.003 \times 10^{-6} \text{ m}^2/\text{s})(23{,}031)^{0.875} = 6.648 \times 10^{-3} \text{ m}^2/\text{s}$$

b. Determine the dispersion number

$$d = \frac{D}{vL} = \frac{Dt}{L^2} = \frac{(0.006648 \text{ m}^2/\text{s})(90 \text{ min} \times 60 \text{ s/min})}{(41.4 \text{ m}^2)} = 0.0206$$

Because the computed dispersion number (0.0206) is greater than the desired value (0.015), an alternative design must be evaluated. For the alternative design, assume three parallel channels will be used.

3. Assume new trial cross-sectional dimensions for the chlorine contact basin and determine the new length and flow velocity.

a. Assumed dimensions

Width = 1.25 m (5.0 ft)

Depth = 3 m (9.8 ft)

Number of parallel channels = 3

b. Determine required length

$$L = \frac{(2 \times 4000 \text{ m}^3/\text{d})}{(3)(1440 \text{ min/d})} \times (90 \text{ min}) \times \frac{1}{(1.25 \text{ m} \times 3 \text{ m})} = 44.4 \text{ m}$$

c. Check velocity at peak flow

$$v = \frac{(2 \times 4000 \text{ m}^3/\text{d})}{(3)(1440 \text{ min/d})(60 \text{ s/min})} \times \frac{1}{(1.25 \text{ m} \times 3 \text{ m})} = 0.0082 \text{ m/s}$$

4. Check the dispersion number for the chlorine contact basin.

a. Compute the Reynolds number

$N_R = 4vR/\nu$

$v = 0.0082$ m/s

$\nu = 1.003 \times 10^{-6}$ m²/s (at 20°C)

$$N_R = \frac{(4)(0.0082 \text{ m/s})[(1.25 \text{ m} \times 3.0 \text{ m})/(2 \times 3.0 \text{ m} + 1.25 \text{ m})]}{(1.003 \times 10^{-6} \text{ m}^2/\text{s})} = 16{,}915$$

b. Compute the coefficient of dispersion

$$D = 1.01\nu N_R^{0.875}$$

$$D = 1.01 \times 1.003 \times 10^{-6}\ \text{m}^2\text{/s}\ (16{,}915)^{0.875} = 5.07 \times 10^{-3}\ \text{m}^2\text{/s}$$

c. Determine the dispersion number

$$d = \frac{D}{vL} = \frac{Dt}{L^2} = \frac{(0.00507\ \text{m}^2\text{/s})(90\ \text{min} \times 60\ \text{s/min})}{(44.4\ \text{m})^2} = 0.0139$$

Because the computed dispersion number (0.0139) is smaller than the desired value (0.015), the proposed design is acceptable.

5. Check the dispersion number for the chlorine contact basin at average flow.

a. Compute the Reynolds number

$$N_R = 4vR/\nu$$

$$v = 0.0082/2 = 0.0041\ \text{m/s}$$

$$\nu = 1.003 \times 10^{-6}\ \text{m}^2\text{/s}$$

$$N_R = \frac{(4)(0.0041\ \text{m/s})[(1.25\ \text{m} \times 3.0\ \text{m})/(2 \times 3.0\ \text{m} + 1.25\ \text{m})]}{(1.003 \times 10^{-6}\ \text{m}^2\text{/s})} = 8{,}457$$

b. Determine the coefficient of dispersion

$$D = 1.01\ \nu N_R^{0.875}$$

$$D = 1.01(1.003 \times 10^{-6}\ \text{m}^2\text{/s})(8{,}457)^{0.875} = 2.77 \times 10^{-3}\ \text{m}^2\text{/s}$$

c. Determine the dispersion number

$$d = \frac{D}{vL} = \frac{Dt}{L^2} = \frac{(0.00277\ \text{m}^2\text{/s})(90\ \text{min} \times 60\ \text{s/min})}{(44.4\ \text{m})^2} = 0.0076$$

d. Because the velocity is reduced at average flow, the computed dispersion number is equivalent to about 66 complete-mix reactors in series.

Comment Under all flow conditions, deposition of residual suspended solids would be expected in the chlorine contact basin, especially so at low flow.

Predicting Disinfection Performance. An extremely important issue in the design of chlorine contact basins is being able to predict the performance of the proposed design. To predict performance, the actual residence time that a given molecule of the fluid spends in the reactor must be known. The residence time in the reactor can be determined using some of the analytical techniques presented previously in Chap. 1 and Appendix I. The pertinent equations from Appendix I are repeated here for convenience. In Appendix I, it was noted that the Peclet number divided by 2 is equal to the number of reactors in series. The relationship of the Peclet number to the dispersion number is

$$P_e = \frac{vL}{D} = \frac{1}{d} \tag{12–53}$$

For complete mix-reactors in series, the normalized residence time distribution curve, $E(\theta)$, where θ is equal to t/τ for n reactors in series, as derived in Appendix I, is given by

$$E(\theta) = \frac{n}{(n-1)!}(n\theta)^{n-1}e^{-n\theta} \tag{12–54}$$

Further, the fraction of tracer, $F(\theta)$, that has been in the reactor for less than time t is defined as follows:

$$F(\theta) = \int_0^t E(\theta)d\theta \approx \sum_0^n E(\theta)\Delta\theta \tag{12–55}$$

Thus, for a given dispersion number, the Peclet number can be used to determine the corresponding number of complete-mix reactors in series needed to achieve that dispersion number. Knowing the number of reactors in series, the value of $E(\theta)$ can be computed for various values of θ. The value of $F(\theta)$ can then be determined by summing the area under the $E(\theta)$ curve. The amount of flow that has been in the reactor for less than time θ can now be determined. Coupling normalized microorganism inactivation dose response data, obtained using a batch reactor, with the normalized detention time data, the actual performance for the chlorine contact basin can be estimated using what is known as a segregated flow model (SFM).

In the SFM approach, it is assumed that each block of fluid that enters a chlorine contact basin does not interact with other blocks of water. Thus, each block of water corresponds to an ideal plug flow reactor, each having a different residence time as defined by the value of $E(\theta)$, as given above. The reduction in organisms that would occur in each block of water can then be estimated for the period of time the block of water has remained in the chlorine contact basin. The overall performance is obtained by summing the results for each block of water. The SFM approach can be described as follows (Fogler, 1999):

Word statement

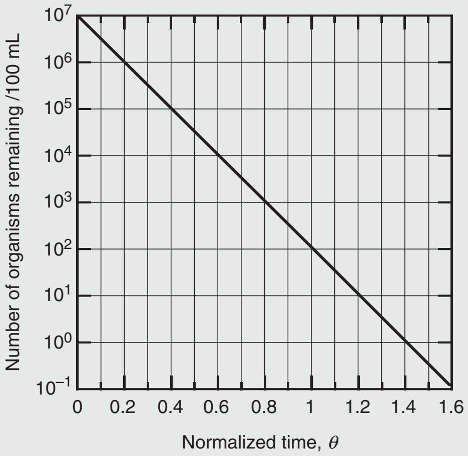
$$\begin{pmatrix}\text{Mean reduction in}\\\text{number of}\\\text{microorganisms}\\\text{spending between}\\\text{time } t \text{ and } t + dt \text{ in the}\\\text{chlorine contact basin}\end{pmatrix} = \begin{pmatrix}\text{number of}\\\text{microorganisms}\\\text{remaining after spending}\\\text{time } t \text{ in the chlorine}\\\text{contact basin based on}\\\text{batch test results}\end{pmatrix} \times \begin{pmatrix}\text{fraction of flow}\\\text{that remained}\\\text{in the chlorine}\\\text{contact basin}\\\text{between time } t\\\text{and } t + dt\end{pmatrix} \tag{12–56}$$

In equation form,

$$d\overline{N} = N(\theta) \times E(\theta)dt \tag{12–57}$$

The values of $N(\theta)$ and $E(\theta)$ are obtained from batch disinfection and tracer or dispersion prediction studies. Application of the above equations for predicting the hydraulic performance and the effluent microorganism concentration using the SFM are illustrated in Example 12–7 using the data from Example 12–6.

EXAMPLE 12–7 **Estimation of Performance of a Chlorine Contact Basin** Using the design information from Example 12–6, determine the fraction of flow that has not remained in the chlorine contact basin for the full hydraulic detention time. Determine how much larger the chlorine contact basin must be to be assured that 90 percent of the flow remains in the chlorine contact basin for the full design hydraulic detention time. Using the following normalized dose response data for an enteric virus, based on a τ value of 90 min and combined chlorine residual of 6 mg/L, estimate the performance of the chlorine contact basin in terms of the residual number of organisms remaining in the effluent.



Solution

1. Determine the number of complete mix reactors in series.
   a. From Example 12–6, the dispersion number at peak flow is

   $$d = 0.0139$$

   b. Using Eq. (12–53), the number of complete-mix reactors in series is

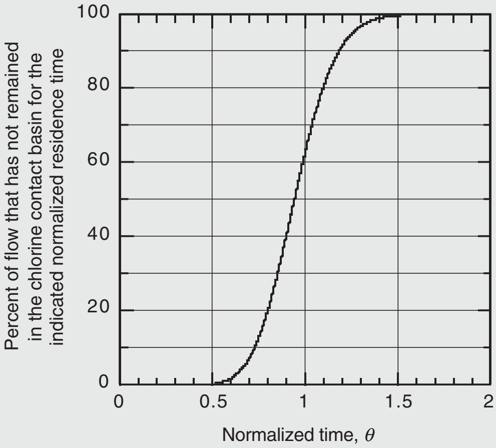
   $$\text{Number of reactors in series} = \frac{P_e}{2} = \frac{1}{2d} = \frac{1}{(2)\,0.0139} = 36$$

2. Determine the percentage of the flow that has been in the chlorine contact basin for less than the hydraulic detention time.
   a. Set up a computation table and compute $E(\theta)$ using Eq. (12–54) and the data given above.

   $$E(\theta) = \frac{n}{(n-1)!}(n\theta)^{n-1}e^{-n\theta}$$

Normalized time, θ	$E(\theta)$	$E(\theta) \times \Delta\theta \times 100$	Cumulative percent, $F(\theta)$
0.30	0.0000	0.000	0.000
0.40	0.0000	0.000	0.001
0.50	0.0046	0.046	0.046
0.60	0.0737	0.737	0.783
0.70	0.4435	4.435	5.218
0.80	1.2976	12.976	18.193
0.90	2.1878	21.878	40.071
1.00	2.3881	23.881	63.952
1.10	1.8337	18.337	82.290
1.20	1.0531	10.531	92.821
1.30	0.4739	4.739	97.560
1.40	0.1733	1.733	99.293
1.50	0.0530	0.530	99.822
1.60	0.0139	0.139	99.961
1.70	0.0031	0.032	99.992
1.80	0.0006	0.006	99.999
1.90	0.0001	0.001	100.00
2.00	0.0000	0.000	100.00

b. Plot the cumulative percent values from the above table.



c. From the computation table and graph given above, the percentage of the flow that has been in the chlorine contact basin for less than the hydraulic residence time is 64 percent. In fact, about 18 percent of the flow has left the chlorine contact basin before 80 percent of the nominal hydraulic detention time has elapsed.

3. Estimate how much larger the chlorine contact basin must be to be assured that 90 percent of the flow remains in the chlorine contact basin for the full hydraulic detention time. From the above graph, the size of the chlorine contact basin would have to be increased by a factor of 1.2.

4. Estimate the performance of the chlorine contact basin.

a. Set up a computation table to determine the number of organisms remaining in the effluent from the chlorine contact basin. The SFM approach, described above, will be used for this analysis. In effect, flow in each time period is treated as a batch reactor for the time interval it has remained in the reactor. The corresponding concentration of microorganisms leaving in any given volume of liquid is taken from the normalized dose response curve. The computation table for the application of the SFM is given below. The data in columns (1) and (3) are from the computation table prepared in Step 2 above, except that the data in column (3) are divided by 100. The data in column (2) are from the normalized dose response curve obtained as part of the process analysis for the design of the chlorine contact basin.

Normalized time, θ (1)	Number of organisms remaining, $N(\theta)$ MPN/100 mL (2)	$E(\theta) \times \Delta\theta$ (3)	Number of organisms remaining in effluent, ΔN MPN/100 mL (4)

1.70	0.03	0.00032	—
1.80	0.01	0.00006	—
1.90	0.003	0.00001	—
2.00	0.001	0.00000	—
Total		1.00000	446.53

b. The number of organisms in the effluent leaving the chlorine contact basin is:

$$\text{Organisms in effluent } N = \sum[N(\theta) \times E(\theta)\Delta\theta] = 447 \text{ MPN/100 mL}$$

c. By comparison, if it was assumed that the basin had performed as an ideal plug-flow reactor, then the organism concentration in the effluent would have been estimated to be 100 MPN/100 mL.

Comment The SFM method of analysis used to determine the number of organisms in the effluent is useful for estimating the performance of reactors with varying amounts of dispersion such as chlorine contact basins.

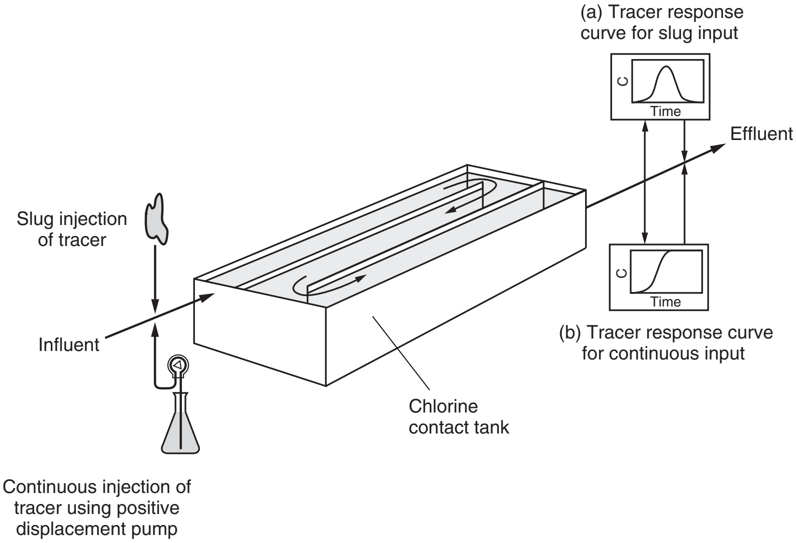
Assessing the Hydraulic Performance of Existing Chlorine Contact Basins

To be assured that a chlorine contact basin performs properly, most regulatory agencies request that tracer studies be conducted to determine the hydraulic characteristics of the chlorine contact basin. The types of tracers that have been used, the conduct of tracer tests, and analysis of tracer data are reviewed briefly below.

Compounds Used as Tracers. Tracers of various types are used commonly to assess the hydraulic performance of reactors used for wastewater disinfection. Dyes and chemicals that have been used successfully in tracer studies include congo red, fluorescein, fluosilicic acid (H_2SiF_6), hexafluoride gas (SF_6), lithium chloride (LiCl), Pontacyl Brilliant Pink B, potassium, potassium permanganate, rhodamine WT, sodium floride (NaF), and sodium chloride (NaCl). Pontacyl Brilliant Pink B (the acid form of rhodamine WT) is especially useful in the conduct of dispersion studies because it is not readily adsorbed onto surfaces. Because fluorescein, rhodamine WT, and Pontacyl Brilliant Pink B can be detected at very low concentrations using a flourometer, they are the dye tracers used most commonly in the evaluation of the performance of wastewater treatment facilities.

Figure 12–25

Schematic of setup for the conduct of a tracer study of a plug-flow chlorine contact basin using either a slug of tracer added to flow or a continuous input of tracer. The tracer response curve is measured continuously.



Conduct of Tracer Tests. In tracer studies, a tracer (i.e., a dye, most commonly) is introduced into the influent end of the reactor or basin to be studied (see Fig. 12–25). The time of its arrival at the effluent end is determined by collecting a series of grab samples for a given period of time or by measuring the arrival of a tracer using instrumental methods (see Fig. 12–25). The method used to introduce the tracer controls the type of response observed at the downstream end. Two types of tracer input methods are used, the choice depending on the reactor influent and effluent configurations. The first method involves the injection of a quantity of tracer (sometimes referred to a pulse or slug of tracer) over a short period of time. Initial mixing is usually accomplished with a static mixer or an auxiliary mixer. With the slug injection method it is important to keep the initial mixing time short relative to the detention time of the reactor being measured. The measured output is as described on Fig. 12–25(a). In the second method, a continuous step input of tracer is introduced until the effluent concentration matches the influent concentration. The measured response is as shown on Fig. 12–25(b). It should also be noted that another response curve can be measured after the dye injection has ceased and the dye in the reactor is flushed out.

Analysis of Tracer Test Response Curves. Tracer response curves, measured using a slug or continuous injection of a tracer, are known as C (concentration versus time) and F (fraction of tracer remaining in the reactor versus time) curves, respectively. The fraction remaining is based on the volume of water displaced from the reactor by the step input of tracer. The generalized results of three different dye tracer tests are shown on Fig. 12–26. As shown on Fig. 12–26, each of the three basins is subject to differing amounts of short circuiting. Length-to-width ratios (L/W) of at least 20 to 1 (preferably 40 to 1) and the use of baffles and guide vanes helps to minimize short circuiting. In some small plants, chlorine contact basins have been constructed of large diameter sewer pipe. The beneficial effect of using submerged baffles to improve the hydraulic efficiency of serpentine chlorine contact basins is illustrated on Fig. 12–23.

Tracer curves, such as shown on Figs. 12–25 and 12–26, are used to assess the hydraulic efficiency of chlorine contact basins. Parameters used to assess the hydraulic efficiency of chlorine contact basins are summarized in Table 12–19 and are illustrated on Fig. 12–27. As discussed previously, the mean, modal, and t_{10} times have been used to define the

Figure 12–26

Typical chlorine contact basin tracer response curves for three different basins with the same hydraulic detention time. The degree of short circuiting is illustrated clearly by the shape of the tracer curve.

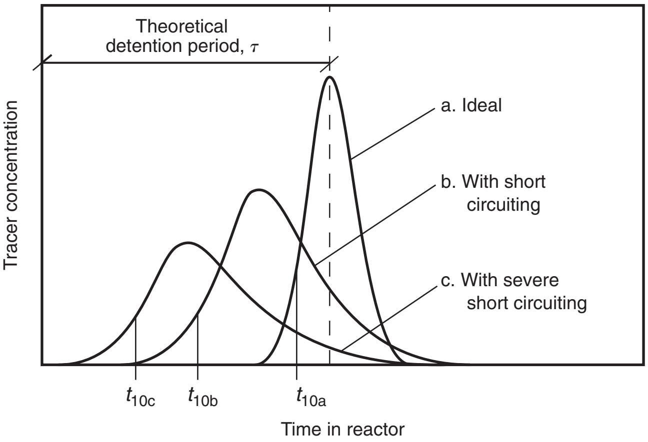


Table 12–19

Various terms used to describe the hydraulic performance of chlorine contact basins[a]

Term	Definition
τ	Theoretical hydraulic residence time (*V*, volume/*Q*, flowrate).
t_i	Time at which tracer first appears.
t_p	Time at which the peak concentration of the tracer is observed (mode).
t_g	Mean time to reach centroid of the residence time distribution (RTD) curve (see Appendix H).
t_{10}, t_{50}, t_{90}	Time at which 10, 50, and 90 percent of the tracer has passed through the reactor.
t_{90}/t_{10}	Morrill Dispersion Index, MDI (Morrill, 1932).
1/MDI	Volumetric efficiency as defined by Morrill (1932).
t_i/τ	Index of short circuiting. In an ideal plug-flow reactor, the ratio is 1, and approaches 0 with increased mixing.
t_p/τ	Index of modal retention time. Ratio will approach 1 in a plug-flow reactor, and 0 in a complete-mix reactor. For values of the ratio greater than or less than 1 the flow distribution in the reactor is not uniform.
t_g/τ	Index of average retention time. A value of 1 would indicate that full use is being made of the volume. A value of the ratio greater than or less than 1 indicates the flow distribution is not uniform.
t_{50}/τ	Index of mean retention time. The ratio t_{50}/τ is a measure of the skew of the RTD curve. A value of t_{50}/τ of less than 1 corresponds to an RTD curve that is skewed to the left. Similarly, for values greater than 1.0 the RTD curve is skewed to the right.
$t/\tau = \theta$	Normalized time, used in the development of the normalized RTD curve.
$\tau_{\Delta c} \approx \dfrac{\sum t_i C_i \Delta t_i}{\sum C_i \Delta t_i}$	Expression used to determine the mean hydraulic residence time, τ, if the concentration versus time tracer response curve is defined by a series of discrete time step measurements, where t_i is time at *i*th measurement C_i is concentration at *i*th measurement, and Δt_i is time increment about C_i.
$\sigma^2_{\Delta c} \approx \dfrac{\sum t_i^2 C_i \Delta t_i}{\sum C_i \Delta t_i} - (\tau_{\Delta c})^2$	Expression used to determine variance for a concentration versus time tracer response curve, which is defined by a series of discrete time step measurements.

[a] Adapted from Morrill (1932), Fair and Geyer (1954), and U.S. EPA (1986).

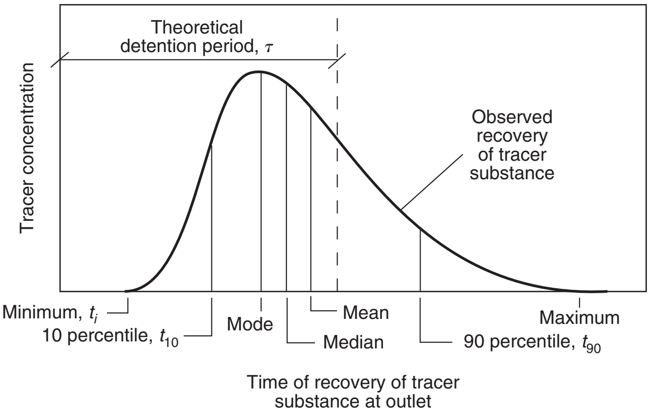

Figure 12–27

Definition sketch for the parameters used in the analysis of concentration versus time tracer response curves.

contact time in the CT relationship. The analysis of a tracer response curve is illustrated in Example 12–8. Additional details on the analysis of tracer response curves may be found in Appendix I and in Crittenden et al. (2012).

EXAMPLE 12–8 **Analysis of Tracer Data for an Existing Chlorine Contact Basin** The following tracer data have been gathered during a tracer test of a chlorine contact basin. During the tracer test, the total chlorine residual measured at the tank outlet was 4.0 mg/L. Using these data determine the mean hydraulic residence time (HRT), the variance, and the t_{10} time. Determine the CT values corresponding to the mean HRT and the t_{10} time. To further assess the performance of the chlorine contact basin, determine the Morrill Dispersion Index (MDI) and the corresponding volume efficiency (1/MDI) as defined in Table 12–19.

Time, min	Tracer concentration, μg	Time, min	Tracer concentration, μg
0.0	0.0000	144	9.333
16	0.000	152	16.167
40	0.000	160	20.778

136	3.722		

Solution

1. Determine the mean hydraulic residence time and variance for the tracer response data using equations given in Table 12–19.

a. Set up the required computation table. In setting up the computation table given below, the Δt value was omitted as it appears in both the numerator and in the denominator of the equations used to compute the residence time and the corresponding variance.

Time, t, min	Conc., C, μg	$t \times C$	$t^2 \times C$	Cumulative conc., μg	Cumulative percentage

136	3.722	506.219	68,845.81	6.78	6.63
144	9.333	1343.995	193,535.31	16.11	15.75
152	16.167	2457.384	373,522.37	32.28	31.58
160	20.778	3324.480	531,916.80	53.06	51.91
168	19.944	3350.592	562,899.46	73.00	71.41
176	14.111	2483.536	437,102.34	87.11	85.22
184	8.056	1482.230	272,730.39	95.17	93.10
192	4.333	831.994	159,742.77	99.50	97.34
200	1.556	311.120	62,224.00	101.06	98.87
208	0.889	184.891	38,457.37	101.94	99.73
216	0.278	60.005	12,961.04	102.22	100.00
224	0.000	0.000			
Total	102.222	16,702.229	2,757,959.48		

[a] 0.056 + 0.333 = 0.39.

[b] (0.39/102.222) × 100 = 0.38.

b. Determine the mean hydraulic residence time.

$$\tau_{\Delta c} = \frac{\sum t_i C_i \Delta t_i}{\sum C_i \Delta t_i} = \frac{16{,}702.23}{102.22} = 163.4 \text{ min} = 2.7 \text{ h}$$

c. Determine the variance.

$$\sigma^2_{\Delta c} = \frac{\sum t_i^2 C_i \Delta t_i}{\sum C_i \Delta t_i} - (\tau_{\Delta c})^2 = \frac{2{,}757{,}959.48}{102.22} - (163.4)^2 = 280.5 \text{ min}^2$$

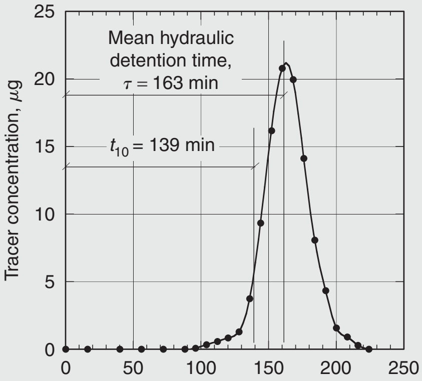
$$\sigma_{\Delta c} = 16.7 \text{ min}$$

d. Determine the t_{10} time using the cumulative percentage values. Because of the short time interval, a linear interpolation method can be used.

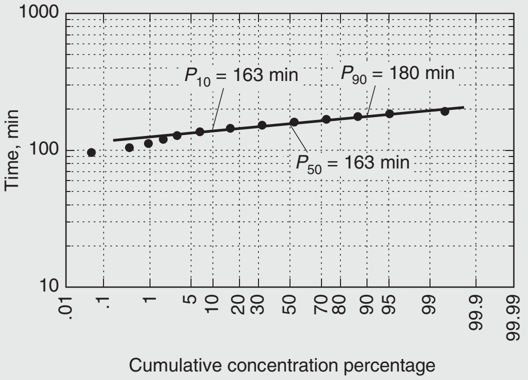
$$(15.75\% - 6.63\%)/(144 \text{ min} - 136 \text{ min}) = 1.14\%/\text{min}$$

$$t_{10} = 136 + (10\% - 6.63\%)/\,(1.14\%/\text{min}) = 139.0 \text{ min}$$

e. Identify the mean hydraulic residence and t_{10} times on the tracer curve.



2. Another technique that can be used to obtain the above times is to plot the cumulative concentration data on log-probability paper. Such a plot is also useful for determining the MDI. The required plot is given below.



The mean hydraulic retention and t_{10} times are read directly from the above plot.

t_{50} = 163 min

t_{10} = 139 min

3. Determine the corresponding CT values for the mean HRT and the t_{10} time determined above in Step 1.

CT (modal) = (4.0 mg/L)(163.4 min) = 654 mg·min/L

CT (t_{10}) = (4.0 mg/L)(139 min) = 556 mg·min/L

4. Determine the MDI and the corresponding volume efficiency using the expressions given in Table 12–19 and the values from the plot given in Step 2 above.

a. The Morrill Dispersion Index is

$$\text{Morrill Dispersion Index, MDI} = \frac{P_{90}}{P_{10}} = \frac{180}{139} = 1.30$$

c. The corresponding volumetric efficiency for the chlorine contact basin is

$$\text{Volumetric efficiency, \%} = \frac{1}{\text{MDI}} = \frac{1}{1.3} \times 100 = 77\%$$

Comment The variance computed in Step 1 is useful in assessing the dispersion in the chlorine contact basin (see Example I–1 in Appendix I; Crittenden et al., 2012). The CT values, based on the modal and t_{10} times, exceed the CT value of 450 mg·min/L required in California. It is important to note that if the tracer curve is very skewed, it may not be possible to achieve effective disinfection, especially if the t_{10} value is used. Thus, the design of a chlorine contact basin to achieve near plug flow is of critical importance. The MDI value (1.30) is characteristic of a chlorine contact basin with low dispersion. A MDI value below 2.0 has been established by the U.S. EPA as an effective design (U.S. EPA, 1986). Similarly, the volumetric efficiency is high, signifying near-ideal plug flow with a small amount of axial dispersion.

Outlet Control and Chlorine Residual Measurement

The flow at the end of the contact basin may be metered by means of a V-notch or rectangular weir or a Parshall flume. Control devices for chlorination in direct proportion to the flowrate may be operated from these meters or from the main plant flowmeter. Final determination of the success of a chlorine contact basin must be based on samples taken and analyzed to correlate chlorine residual and the MPN of coliform or other indicator organisms. When the chlorine residual is used for chlorinator control, chlorine residual sample pumps should be located at the front end of the first pass of the contact basin after rapid mixing to allow time for the initial demand to be met. Chlorine residual measurements should also be taken at the contact basin outlet to ensure compliance with the regulatory agency requirements. In the event that no chlorine contact basin is provided and the effluent pipeline is used for contact, the sample can be obtained at the point of chlorination, held for the theoretical detention time, and the residual determined. The sample is then dechlorinated and subsequently analyzed for bacteria using standard laboratory procedures.

Chlorine Storage Facilities

Storage and handling facilities for chlorine can be designed with the aid of information developed by The Chlorine Institute. Although all the safety devices and precautions that must be designed into the chlorine handling facilities are too numerous to mention, the following are fundamental:

1. Chlorine gas is toxic and very corrosive. Adequate exhaust ventilation with intakes at floor level should be provided because chlorine gas is heavier than air. The ventilation system should be capable of at least 60 air changes per hour with the exhaust directed vertically upwards.
2. Chlorine storage and chlorinator equipment rooms should be walled off from the rest of the plant and should be accessible only from the outdoors. A fixed glass viewing window should be included in an inside wall to check for leaks before entering the equipment rooms. Fan controls should be located at the room entrance. Air purifying respirators or self-contained breathing apparatus (SCBA) should also be located nearby in protected but readily accessible locations.
3. Temperatures in the scale and chlorinator areas should be controlled to avoid freezing.
4. Dry chlorine liquid and gas can be handled in black steel piping, but chlorine solution is highly corrosive and should be handled in Schedule 80 polyvinylchloride (PVC) piping.
5. Adequate storage of standby cylinders should be provided. The amount of storage should be based on the availability and dependability of the supply and the quantities used. Cylinders in use are set on scales and the loss of weight is used as a positive record of chlorine dosage.

6. Chlorine cylinders should be protected from direct sunlight in warm climates to prevent overheating of the full cylinders.
7. In larger systems, chlorine residual analyzers should be provided for monitoring and control purposes to prevent the under- or over-dosing of chlorine.
8. The chlorine storage and feed facilities should be protected from fire hazards. In addition, chlorine leak detection equipment should be provided and connected to an alarm system.

Chemical Containment Facilities

In 1991, the International Conference of Building Officials revised Article 80: Hazardous Materials of the Uniform Fire Code (UFC). The revisions were extensive and covered a variety of issues. The provisions of the new code apply to new facilities and to old facilities as well, if it is determined that they constitute a distinct hazard to life or property. The new code provisions are contained in the following divisions apply to the chemicals used for disinfection: I General Provisions, II Classification by Hazard, III Storage Requirements, and IV Dispensing, Use, and Handling. The classification of hazardous materials used for wastewater disinfection are summarized in Table 12–20. Storage requirements include provisions for spill control and containment, ventilation, treatment, and storage. Emergency scrubbing systems, usually using a caustic solution, are also required to neutralize leaking chlorine and sulfur dioxide gas. Many of the same topics contained in the storage requirements section also apply to the dispensing, use, and handling. Hazardous material management, provision for standby power, security, and alarms are among the additional topics covered. It is extremely important to review current UFC regulations in the design of new facilities and in the refurbishing of existing facilities. Furthermore, the U.S. EPA and many states, as well as OSHA, have implemented chemical safety regulations requiring formal hazard reviews, air dispersion modeling of release scenarios, and emergency response preparedness.

Dechlorination Facilities

Dechlorination of chlorinated effluents is accomplished most commonly using sulfur dioxide. Where granular activated carbon is used for the removal of residual organic material, the carbon can also be used for the dechlorination of chlorinated effluents.

Sulfur Dioxide. The principal elements of a sulfur dioxide dechlorination system include the sulfur dioxide containers, scales, sulfur dioxide feeders (sulfonators), solution

Table 12–20

Classification of hazardous materials used in wastewater disinfection

Category	Typical chemicals
Physical Hazards	
Compressed gases	Oxygen, ozone, chlorine, ammonia, sulfur dioxide
Oxidizers	Oxygen, ozone, chlorine, hydrogen peroxide, acids, chlorine
Health Hazards	
Highly toxic material	Chlorine, chlorine dioxide, ozone, acids, bases
Corrosives	Acids, bases, chlorine, sulfur dioxide, ammonia, hypochlorite, sodium bisulfite
Other health hazards—irritants, suffocating, etc.	Chlorine, sulfur dioxide, ammonia

injectors, diffuser, mixing chamber, and interconnecting piping. For facilities requiring large withdrawal rates of SO_2, evaporators are used because of the low vaporization pressure of 240 kN/m^2 at 21°C (35 lb$_f$/in.^{2} at 70°F). Common sulfonator sizes are 216, 864, and 3409 kg/d (475, 1900, and 7500 lb/d). The key control parameters of this process are (1) proper dosage based on precise (amperometric) monitoring of the combined chlorine residual and (2) adequate mixing at the point of application of sulfur dioxide.

Sodium Bisulfite. Sodium bisulfite is available as white powder, a granular material, or as a liquid. The liquid form is used most commonly for dechlorination at wastewater treatment facilities. Although available in solution strengths up to 44 percent, a 25 percent solution is most typical to minimize viscosity increases during cold weather. In most applications, a diaphragm type pump is used to meter the sodium bisulfite. The reaction between sodium bisulfite and chlorine residual was presented previously [see Eqs. (12–42 and 12–43)]. Based on Eq. (12–42), each mg/L of chlorine residual requires about 1.46 mg/L of sodium bisulfite and 1.38 mg/L of alkalinity as $CaCO_3$ will be consumed.

Granular Activated Carbon. The common method of activated carbon treatment used for dechlorination is downflow through either an open or enclosed vessel. The activated carbon system, while significantly more costly than other dechlorination approaches, may be appropriate when activated carbon is being used as an advanced wastewater treatment process. Typical hydraulic loading rates and contact times for activated carbon columns used for dechlorination are 3000 to 4000 L/m^2·d and 15 to 25 min, respectively.

12–7 DISINFECTION WITH OZONE

Although historically used primarily for the disinfection of water, recent advances in ozone generation and solution technology have made the use of ozone economically more competitive for the disinfection of treated wastewater. Further, interest in the use of ozone for disinfection has also been renewed because of its ability to reduce or eliminate trace constituents. Ozone can also be used in water reuse applications for the removal of soluble refractory organics, in lieu of the carbon adsorption process. The characteristics of ozone, the chemistry of ozone, the generation of ozone, an analysis of the performance of ozone as a disinfectant, and the application of the ozonation process are considered in the following discussion.

Ozone Properties

Ozone is an unstable gas produced when oxygen molecules dissociate into atomic oxygen. Ozone can be produced by electrolysis, photochemical reaction, and radiochemical reaction by electrical discharge. Ozone is often produced by ultraviolet light and lightning during a thunderstorm. The electrical discharge method is used for the generation of ozone in water and wastewater disinfection applications. Ozone is a blue gas at normal room temperatures, and has a distinct odor. Ozone can be detected at concentrations of 2×10^{-5} to 1×10^{-4} g/m^3 (0.01 to 0.05 ppm$_v$, by volume). Because ozone has an odor, it can usually be detected by the human olfactory system before health concerns develop. The stability of ozone in air is greater than it is in water, but in both cases is on the order of minutes. Gaseous ozone is explosive when the concentration reaches about 240 g/m^3 (20 percent weight in air). The properties of ozone are summarized in Table 12–21. The solubility of ozone in water is governed by Henry's law. Typical values of Henry's constant for ozone are presented in Table 12–22.

Table 12–21

Properties of ozone[a]

Property	Unit	Value
Molecular weight	g	48.0
Boiling point	°C	−111.9 ± 0.3
Freezing point	°C	−192.5 ± 0.4
Latent heat of vaporization at 111.9°C	kJ/kg	14.90
Liquid density at −183°C	kg/m^3	1574
Gaseous density at 0°C and 1 atm	g/mL	2.154
Solubility in water at 20.0°C	mg/L	12.07
Vapor pressure at −183°C	kPa	11
Vapor density compared to dry air at 0°C and 1 atm	unitless	1.666
Specific volume of vapor at 0°C and 1 atm	m^3/kg	0.464
Critical temperature	°C	−12.1
Critical pressure	kPa	5532.3

[a] Adapted in part from Rice (1996), U.S. EPA (1986), White (1999).

Ozone Chemistry

Some of the chemical properties displayed by ozone may be described by its decomposition reactions which are thought to proceed as follows:

$$O_3 + H_2O \rightarrow HO_3^+ + OH^- \qquad (12\text{–}58)$$

$$HO_3^+ + OH^- \rightarrow 2HO_2 \qquad (12\text{–}59)$$

$$O_3 + HO_2 \rightarrow HO\cdot + 2O_2 \qquad (12\text{–}60)$$

$$HO\cdot + HO_2 \rightarrow H_2O + O_2 \qquad (12\text{–}61)$$

The dot (·) that appears next to the hydroxyl and other radicals is used to denote the fact that these species have an unpaired electron. The free radicals formed, HO_2 and HO·, have great oxidizing powers and are active in the disinfection process. These free radicals also possess the oxidizing power to react with other impurities in aqueous solutions.

Table 12–22

Values of Henry's constant for ozone[a]

Temperature, °C	Henry's constant, atm/mole fraction
0	1940
5	2180
10	2480
15	2880
20	3760
25	4570
30	5980

[a] U.S. EPA (1986).

Table 12–23

Impact of wastewater constituents on the use of ozone for wastewater disinfection

Constituent	Effect
BOD, COD, TOC, etc.	Organic compounds that comprise the BOD and COD can exert an ozone demand. The degree of interference depends on their functional groups and their chemical structure
NOM (natural organic matter)	Affects the rate of ozone decomposition and the ozone demand
Oil and grease	Can exert an ozone demand
TSS	Increases ozone demand and shielding of embedded bacteria
Alkaliniy	No or minor effect
Hardness	No or minor effect
Ammonia	No or minor effect, can react at high pH
Nitrite	Oxidized by ozone
Nitrate	Can reduce effectiveness of ozone
Iron	Oxidized by ozone
Manganese	Oxidized by ozone
pH	Effects the rate of ozone decomposition
Industrial discharges	Depending on the constituents, may lead to a diurnal and seasonal variations in the ozone demand
Temperature	Affects the rate of ozone decomposition

Effectiveness of Ozone as a Disinfectant

Ozone is an extremely reactive oxidant and it is generally believed that bacterial kill through ozonation occurs directly because of cell wall disintegration (cell lysis). The impact of the wastewater characteristics on ozone disinfection is reported in Table 12–23. The presence of oxidizable compounds will cause the ozone inactivation curve to have a shoulder affect as discussed previously for chlorine (see Fig. 12–6). Tailing will also occur in the presence of residual floc particles.

Ozone is also a very effective viricide and is generally believed to be more effective than chlorine. The relative germicidal effectiveness of ozone for the disinfection of different microorganisms was presented previously in Table 12–5. Ozonation does not increase dissolved solids and disinfection effectiveness is not affected by ammonium ion. Although ozone is not necessarily impacted by water pH, ozone residual is more stable in acidic environments and less stable in waters with caustic pH. Therefore, it is typically easier to achieve disinfection when pH is reduced than when pH is greater than neutral. For these reasons, ozonation is considered as an alternative to either chlorination or hypochlorination, especially where dechlorination may be required and high purity oxygen facilities are available at the treatment plant.

Modeling the Ozone Disinfection Process

In practice, an ozone contactor will be comprised of three or more compartments or chambers (see Fig. 12–31 in discussion of ozone reactor characteristics). Water depth is typically 4.6 to 6 m (15 to 20 ft). Ozone is typically added to first or the first and second of the compartments and the remaining compartments serve as contact compartments. The detention time in the first compartment, used to meet the immediate ozone demand (i.e., peroxidation), is short, typically 2 to 4 min. Contact time in the subsequent compartments will vary from 3 to 10 min depending on the rate of ozone utilization.

Over the years a number of different mathematical relationships have been developed to model the disinfection process with ozone. The most common of these is Eq. (12–6) repeated here for convenience.

$$\log \frac{N_t}{N_o} = -\Lambda_{\text{base }10}(\text{CT}) \tag{12–6}$$

Values for the coefficient of specific lethality, Λ, are given in Table 12–11. Of the values given in Table 12–11, those for viruses, *Cryptosporidium,* and *Giardia* cysts are the most reliable as they can be derived from the published U.S. EPA CT tables (U.S. EPA, 2003a).

Because ozone is sparingly soluble, bench and/or pilot-scale studies (see Fig 12–28), using the same retention time as the full-scale reactor, are conducted to assess (1) the immediate ozone demand, (2) the amount of ozone that can be transferred to the liquid, and (3) the ozone decay profile along the reactor. The information gathered is used to determine the CT value and the level of inactivation that can be expected in the full-scale reactor. The amount of ozone that is utilized or transferred to the liquid is computed using the following expression:

$$\text{Ozone dose mg/L} = \frac{Q_g}{Q_l}(C_{g,\text{in}} - C_{g,\text{out}}) \tag{12–62}$$

where Q_g = gas flowrate, L/min
Q_l = liquid flowrate, L/min
$C_{g,\text{in}}$ = concentration of ozone in feed gas, mg/L
$C_{g,\text{out}}$ = concentration of ozone in off-gas, mg/L

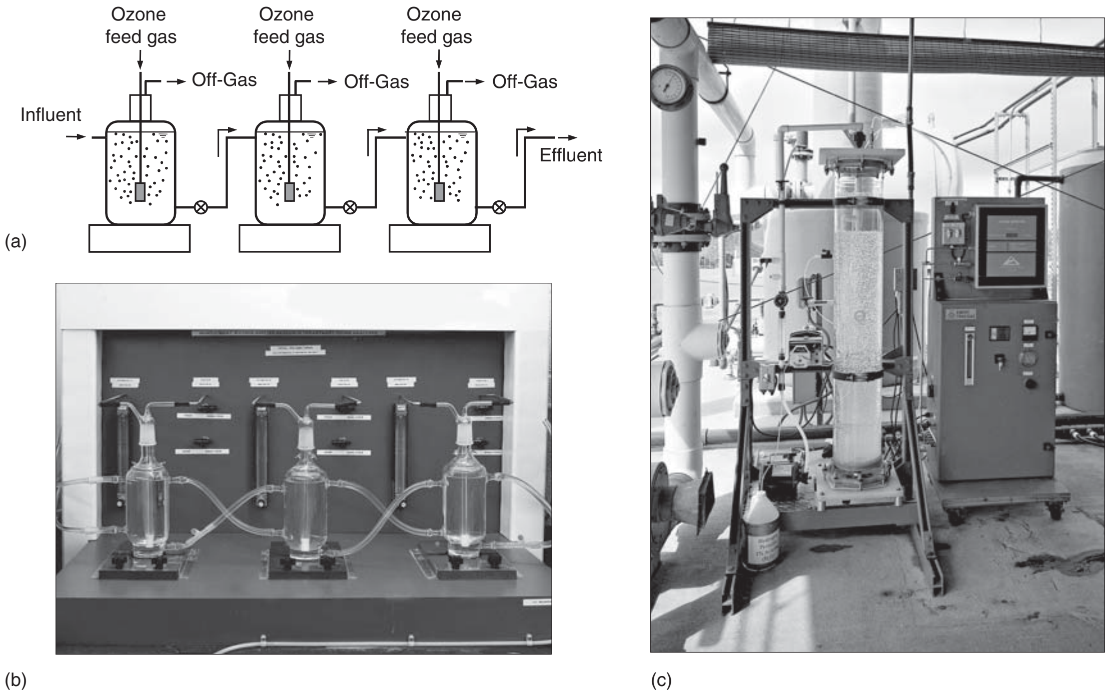


Figure 12–28

Typical ozone test reactors: (a) schematic of setup for bench-scale ozone testing, (b) view of bench-scale ozone test reactors, and (c) pilot-scale ozone test reactor.

The bench and/or pilot-scale reactors are operated in a continuous mode at various ozone concentrations. Once steady-state has been reached, both the water and ozone dosing are stopped, and the ozone decay is observed with time. The continuous operation simulates the compartments where ozone is being added and accounts for the immediate demand of the wastewater. The decay curve is used to estimate the residual ozone concentrations in the downstream compartments. Analysis of bench-scale ozone test data is illustrated in Example 12–9. Computation of the CT for an ozone contactor is illustrated in Example 12–10.

EXAMPLE 12–9 **Estimate the Immediate Ozone Requirement for a Typical Secondary Effluent** Estimate the immediate ozone demand from the following bench scale steady-state ozone test data collected at 20°C. Determine the first-order equation for the corresponding decay data.

The steady-state test results are

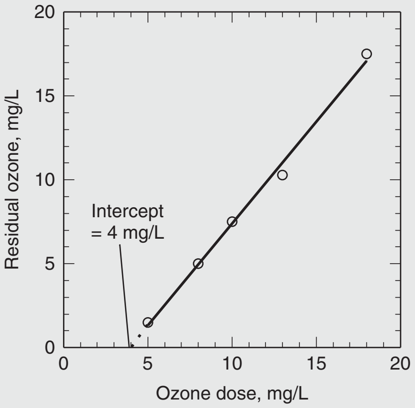
Test	Ozone dose, mg/L	Ozone residual, mg/L
1	5	1.5
2	8	5.0
3	10	7.5
4	13	10.3
5	18	17.5

The corresponding decay data are

Time	Ozone residual, mg/L
0	4.02
4	2.58
7	1.72
10	1.28

Solution

1. Plot the bench scale steady-state data and determine the immediate ozone demand.
   a. The required plot is given below.



b. Determine the immediate ozone demand.
The immediate ozone demand corresponds to the intercept on the *x*-axis. From the above plot the value is equal to 4 mg/L.

2. Plot the bench scale steady-state decay data and determine an appropriate first-order equation.
   a. The required plot is given below.

   b. The corresponding first-order equation is

$$C_{\text{residual ozone}} = (4.0\text{ mg/L})e^{-0.116t}$$

where t = contact time, min

Comment The existence of an immediate ozone demand is the reason why the first compartment where ozone is added is generally not considered in establishing the CT value for an ozone contactor. The CT value can be determined from the decay curve by considering the reactor as a whole or by considering each compartment individually.

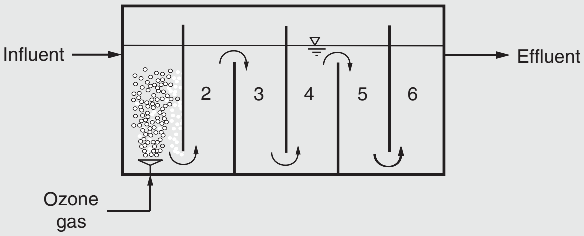
Required Ozone Dosages for Disinfection

The required ozone dosage for disinfection can be estimated by considering (1) the initial ozone demand, based on the results of a bench scale test as illustrated above, and (2) the corresponding decay curve. Computation of the CT value for an existing ozone reactor is illustrated in Example 12–10. The ozone dosage required to meet the initial demand depends on the constituents in the wastewater and is site specific and, in most cases, will be significantly greater than the dose required for disinfection of the coliform group of microorganisms. Based on the coefficient of lethality, Λ, values given in Table 12–11, it is clear that the ozone dosages required to meet total coliform standards are a fraction of those required for the inactivation of *Cryptosporidium* and *Giardia lamblia*. In most cases, bench and/or pilot-scale studies (see Fig. 12–28) will need to be conducted to establish the required dosage ranges.

Estimation of the CT Value

In water treatment, the CT value can be computed in four different ways as defined in the *LT2ESWTR Toolbox Guidance Manual* (U.S. EPA, 2010). The t_{10} approach is as follows. The CT value for an ozone contactor can be estimated as the summation of the average ozone concentration in each compartment, with the exception of the first compartment, times the detention time in each compartment. The time in each compartment is based on the t_{10} time (see Table 12–19) measured across all of the compartments divided by the proportional volume of each compartment. The first compartment is omitted, as noted above, as it is used to meet the immediate ozone demand and does not contribute to disinfection. Additional details may be found in the *LT2ESWTR Toolbox Guidance Manual* (U.S. EPA, 2010).

EXAMPLE 12–10 **Estimate the CT Value for an Ozone Contactor and Corresponding Log Reduction in Cryptosporidium** Estimate the CT value for the ozone contactor shown below and the log-reduction of *Cryptosporidium* that can be achieved. If the log reduction is greater than 2, estimate the number of reaction compartments that would be needed to achieve a 2-log reduction. The detention time of each compartment of the ozone contactor is 3 min. Assume the decay curve developed in Example 12–9 is applicable and that the t_{10}/t ratio is 0.6. The observed ozone concentration at the end of the first compartment is 4 mg/L.



Solution

1. Using the decay curve from Example 12–9, determine the residual ozone concentration at the end of each compartment starting with compartment 2.

Compartment no.	Ozone residual, mg/L
2	2.82[a]
3	1.99
4	1.41
5	0.99
6	0.88

[a] $C = (4\ \text{mg/L})e^{-0.116 \times t}$

$= (4\ \text{mg/L})e^{-0.116 \times 3} = 2.82\ \text{mg/L}$

2. Using the data from Step 1, determine the CT value for the ozone contactor, noting that the theoretical detention time in each reactor is 3 min and the t_{10}/t ratio is 0.6.

$$\text{CT} = \sum_{i=2}^{b} C_i T_i = [(2.82 + 1.99 + 1.41 + 0.99 + 0.88)\ \text{mg/L}](3\ \text{min} \times 0.6)$$

$$= 14.6\ \text{mg}\cdot\text{min/L}$$

3. Estimate the log reduction that can be achieved for *Cryptosporidium* using the information given in Table 12–5.
From Table 12–5, the estimated log reduction that can be achieved is 3 plus logs.

4. Check the log reduction that can be achieved using Eq. 12–6.
   a. The coefficient of specific lethality for cryptosporidium from Table 12–11 is 0.256 L/mg•min (base 10).
   b. The log reduction using Eq. (12–6) is

$$\log \frac{N_t}{N_o} = -\Lambda_{\text{base }10}\text{CT} = (0.256\ \text{L/mg}\cdot\text{min})(13.7\ \text{mg}\cdot\text{min/L}) = 3.74$$

5. Estimate the number of compartments that would be needed to achieve a 2-log reduction in *Cryptosporidium*.
   a. Assuming only one reaction compartment is needed, determine the CT value.
   CT = (2.82 mg/L)(3 min × 0.6) = 5.1 < 8.25 (from Table 12–5), hence an additional compartment is needed.
   b. Assuming two reaction compartments are needed, determine the CT value.
   CT = [(2.82 + 1.99) mg/L](3 min × 0.6) = 8.6 > 8.25, hence two compartments should be used.

Byproduct Formation and Control

As with chlorine, the formation of unwanted DBPs is one of the problems associated with the use of ozone as a disinfectant. The formation and control of DBPs when using ozone are considered in the following discussion.

Formation of DBPs Using Ozone for Disinfection. One advantage of ozone is that it does not form chlorinated DBPs such as THMs and HAAs (see Table 12–14). Ozone does, however, form other DBPs (see Table 12–24) including aldehydes, various acids, and aldo- and keto-acids when significant amounts of bromide are not present. In the presence of bromide, the following DBPs may also be produced: bromoform, brominated acetic acid, bromopicrin, brominated acetonitriles, cyanogen bromide, and bromate (see Table 12–24). On occasion, hydrogen peroxide can also be generated. The specific amounts and the relative distribution of compounds depend on the nature of the precursor compounds that are present. Because the chemical characteristics of wastewater vary from location to location, pilot testing will be required to assess the effectiveness of ozone as a disinfectant.

Control of DBP Formation Using Ozone for Disinfection. Because the nonbrominated compounds appear to be readily biodegradable, they can be removed by passage through a biologically active filter, by soil application, or by other biologically active processes. The removal of inorganic, brominated DBPs is more complex. Bench and pilot-scale testing is recommended to determine if brominated DBPs will be problematic. If it is expected that brominated DBPs will remain problematic, it may be appropriate to investigate an alternative means of disinfection such as by UV irradiation.

Environmental Impacts of Using Ozone

It has been reported that ozone residuals can be acutely toxic to aquatic life (Ward and DeGraeve, 1976). Several investigators have reported that ozonation can produce some toxic mutagenic and/or carcinogenic compounds. These compounds are usually unstable, however, and are present only for a matter of minutes in the ozonated water. White (1999) has reported that ozone destroys certain harmful refractory organic substances, such as humic

Table 12–24

Representative disinfection byproducts resulting from the ozonation of wastewater containing organic and selected inorganic constituents[a]

Class	Representative compounds
Acids	Acetic acids Formic acid Oxalic acid Succinic acid
Aldehydes	Acetaldehyde Formaldehyde Glyoxal Methyl glyoxal
Aldo-and ketoacids	Pyruvic acid
Brominated byproducts[b]	Bromate ion Bromoform Brominated acetic acids Bromopicrin Brominated acetonitriles Cyanogen bromide
Other	Hydrogen peroxide

[a] Adapted, in part, from U.S. EPA (1999a, 2002).

[b] The bromide ion must be present to form brominated byproducts.

acid (precursor of trihalomethane formation) and malathion. Whether toxic intermediates are formed during ozonation depends on the ozone dose, the contact time, and the nature of the precursor compounds. White (1999) has also reported that ozone treatment ahead of chlorination for disinfection purposes reduces the likelihood for the formation of THMs.

Ozone residual quenching is still required to meet OSHA indoor and outdoor ambient air quality standards. Ozone quenching of the off-gas is also required prevention or limit the corrosion of downstream piping and equipment. Where required, hydrogen peroxide, sodium bisulfite, and calcium thiosulfate have been used to quench residual ozone.

Other Benefits of Using Ozone

An additional benefit associated with the use of ozone for disinfection is that the dissolved oxygen concentration of the effluent will be elevated to near saturation levels as ozone rapidly decomposes to oxygen after application. The increase in oxygen concentration may eliminate the need for reaeration of the effluent to meet required dissolved oxygen water quality standards.

Ozone Disinfection Systems Components

A complete ozone disinfection system, as illustrated on Fig. 12–29, is comprised of the following components: (1) facilities for the preparation of the feed gas, (2) power supply, (3) the ozone generation facilities, (4) two alternative types of facilities for contacting the ozone with the liquid to be disinfected (inline or sidestream), and (5) facilities for the destruction of ozone in the off-gas (Rice, 1996; Rakness, 2005). Additional details on the design of ozone systems and related components may be found in a recently published book by Rakness (2005).

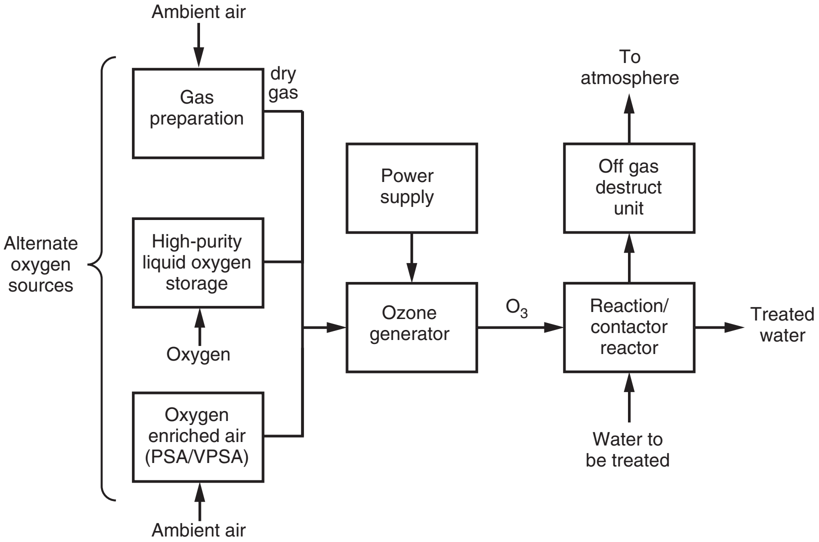


Figure 12–29

Schematic flow diagram for complete ozone disinfection system with alternative air sources. (Adapted from U.S. EPA, 1986.)

Preparation of Feed Gas. Ozone can be generated using air, high purity oxygen, or oxygen enriched air. If air is used for ozone generation, it must conditioned by removing the moisture and particulate matter before being introduced into the ozone generator. The following steps are involved in conditioning the air: (1) gas compression, (2) air cooling and drying, and (3) air filtration. If high purity oxygen is used, the conditioning steps are not required. The liquid oxygen (LOX) supply is stored onsite and is either generated onsite or trucked in as needed. In the oxygen enriched air system, high purity oxygen is generated onsite with a vacuum pressure swing adsorption (AVPAS) system or pressure swing adsorption (PSA) system for smaller treatment plants. Both oxygen generation systems have facilities for adsorbing moisture, which can damage the ozone generator dielectrics, and for the removal of hydrocarbons and nitrogen to enhance the purity of the oxygen. The choice of feed gas is influenced by the local cost of high purity oxygen.

Power Supply. The major requirement for power is for the production of ozone from oxygen. Additional power is required for preparation of the feed gas, contacting the ozone, destroying the residual ozone, and for the controls, instrumentation, and monitoring facilities. The energy requirements for the major components are reported in Table 12–25.

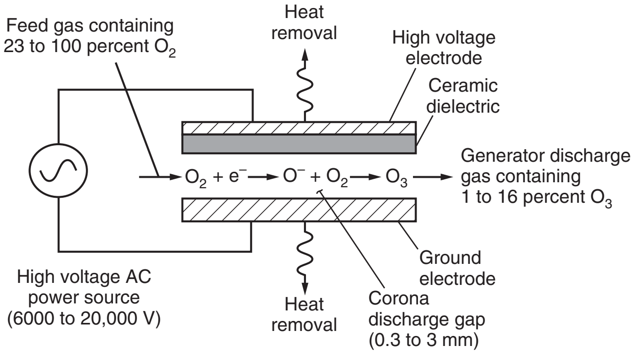
Table 12–25

Typical energy requirements for the application of ozone

Component	kWh/lb ozone	kWh/kg ozone
Air preparation (compressor and dryers)	2–3	4.4–6.6
Ozone generation		
Air feed	6–9	13.2–19.8
Pure oxygen	3–6	6.6–13.2
Ozone contacting	1–3	2.2–6.6
All other uses	0.5–1	1.2–2.2

Figure 12–30

Schematic detail of the generation of ozone. (Adapted from U.S. EPA, 1986.)



Ozone Generation. Because ozone is chemically unstable, it decomposes to oxygen very rapidly after generation, and thus must be generated onsite. The most efficient method of producing ozone today is by electrical discharge. Ozone is generated either from air or high purity oxygen when a high voltage is applied across the gap of narrowly spaced electrodes (see Fig. 12–30). The high energy corona created by this arrangement dissociates one oxygen molecule, which reforms with two other oxygen molecules to create two ozone molecules. The gas stream generated by this process from air will contain about 1 to 3 percent ozone by weight, and from pure oxygen about 8 to 12 percent ozone. Ozone concentrations up to 12 percent can now be generated with the latest medium frequency ozone generators.

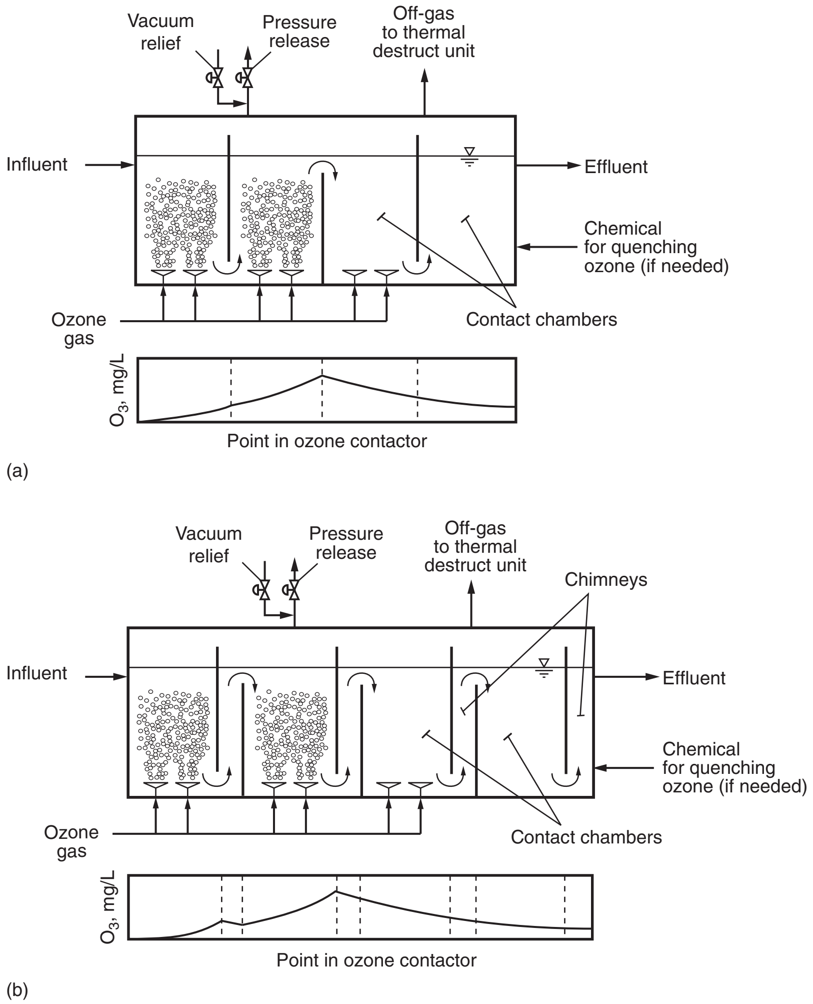
Inline Ozone Contact/Reaction Reactors. The concentration of ozone generated from either air or pure oxygen is so low that the transfer efficiency to the liquid phase is an extremely important economic consideration. To optimize ozone dissolution, deep and covered contact chambers are normally used. Two four-compartment ozone contact reactors are shown schematically on Fig. 12–31 without and with chimneys. The chimneys shown on Fig. 12–31(b) are used to enhance the countercurrent flow within the reactor. The chimneys also provide locations for ozone residual sampling.

Ozone is introduced by means of porous diffusers or injectors into the bottom of the first and second, and in some cases, the third chamber. Fast ozone reactions occur in the first chamber. The combined water-ozone mixture then enters the second chamber where slower reactions occur. Disinfection generally occurs in the second chamber. The third and fourth chambers are used to complete the slow reactions and to allow the ozone to decompose. The first and second chambers are identified as the *reaction* chambers. The third and fourth chambers, without ozone addition, are known as the *contact* chambers. The number of chambers used will depend on the treatment objectives.

Sidestream Ozone Contact/Reaction System. With the ability to generate higher concentrations of ozone (e.g., 10 to 12 percent), sidestream injection of ozone (see Fig. 12–32) is now a viable alternative to the use of porous diffusers in deep tanks as described above. As shown on Fig. 12–32, the ozone injection system is independent of the ozone contactor. The ozone is injected under pressure through a Venturi injector. Two sidestream configurations are used: (1) one with the inclusion of a degas vessel and (2) one without. The purpose of the degas vessel is to minimize the DO level in the water which has been ozonated and (2) to minimize the number of gas bubbles in the downstream pipe which serves as a reactor. The pipeline into which the ozonated water is injected also serves as a reactor prior to the discharge into the contactor (Rakness, 2005).

Figure 12–31

Schematic of typical four compartment ozone contactors: (a) without chimneys and (b) with chimneys. The chimneys in (b) are used to enhance the counter current flow through the reactor.



Destruction of Off-Gases. The off-gases from the contact chamber and the degas vessel must be treated to destroy any remaining ozone as it is an extremely irritating and toxic gas. Off-gas is destroyed to a concentration of <0.1 ppm$_v$. The product formed by destruction of the remaining ozone is pure oxygen which can be recycled if pure oxygen is being used to generate the ozone.

12–8 OTHER CHEMICAL DISINFECTION METHODS

Because of the concerns over the effectiveness of disinfection processes and concern over the formation of DBPs, ongoing research is continuing into the evaluation of alternative disinfection methods. The use of peracetic acid, peroxone, sequential chlorination, and combined disinfection processes are introduced and considered briefly in this section. Pasteurization, a physical method, is considered in Sec. 12–10. Because research on these and other disinfection methods is ongoing, current conference proceedings and literature must be consulted for the latest findings.

Peracetic Acid

In the late 1980s, the use of peracetic acid (PAA) was proposed as a wastewater disinfectant. Peracetic acid, made up of acetic acid and hydrogen peroxide, has been used for many years as a disinfectant and sterilizing agent in hospitals. Peracetic acid is also used as a bactericide and fungicide, especially in food processing. Interest in the use of PAA as a wastewater disinfectant arises from considerations of safety and the possibility that its use will not result in the formation of DBPs. The use of PAA is considered briefly in this section as an example of the continuing search for alternative disinfectants to replace chlorine.

Peracetic Acid Chemistry and Properties. Commercially available PAA, also known as ethaneperoxide acid, peroxyacetic acid, or acetyl hydroxide, is only available as a

Table 12–26

Properties of various peracetic acid (PAA) formulations[a]

Property	Unit	PAA, % 1.0	PAA, % 5	PAA, % 15
Weight PAA	%	0.8–1.5	4.5–5.4	14–17
Weight hydrogen peroxide	%	min 6	19–22	13.5–16
Weight acetic acid	%	9	10	28
Weight available oxygen	Wt, %	3–3.1	9.9–11.5	9.3–11.1

Specific gravity		1.10	1.10	1.12

[a] Adapted from Solvay Chemicals, Inc. (2013).

quaternary equilibrium solution containing acetic acid, hydrogen peroxide, peracetic acid, and water. The pertinent reaction is as follows.

$$\underset{\text{Acetic acid}}{CH_3CO_2H} + \underset{\text{Hydrogen peroxide}}{H_2O_2} \rightleftarrows \underset{\text{Peracetic acid}}{CH_3CO_3H} + H_2O \tag{12–63}$$

The undissociated PAA (CH_3CO_3H) is considered to be the biocidal form in the equilibrium mixture, however, the hydrogen peroxide may also contribute to the disinfection process. Hydrogen peroxide is also more stable than PAA. The properties of PAA are summarized in Table 12–26.

Effectiveness of Peracetic Acid as a Disinfectant. The effectiveness of PAA has been studied by Lefevre et al. (1992); Lazarova et al. (1998); Liberti et al. (1999); Gehr (2000, 2006); Koivunen (2005b); and Gehr et al. (2003), among others. A recent review was published by Kitis (2004). The findings to date are mixed concerning the bactericidal effectiveness of PAA, as well as the impact of wastewater characteristics on the effectiveness of PAA, especially when used alone. When combined with UV the effectiveness of PAA appears to be enhanced significantly (see discussion of combined disinfectants presented below). It has been hypothesized that the principal means by which disinfection is accomplished by PAA may be by the release of hydroxyl radicals ($HO^\bullet$) and the active oxygen resulting from secondary reactions (Caretti and Lubello, 2003). The current literature must be consulted for more information on the application of PAA.

In a report by the U.S. EPA (1999b), PAA was included among a total of 5 possible disinfectants for use on combined sewer overflows (CSOs). Based on data for disinfection of secondary treatment plant effluents, it was suggested that PAA be strongly considered for CSO disinfection. Among the desirable attributes listed are absence of persistent residuals and byproducts, not affected by pH, short contact time, and high effectiveness as a bactericide and viricide.

Formation of Disinfection Byproducts. Based on the limited data available, the principal end products identified were CH_3COOH (acetic acid or vinegar), O_2, CH_4, CO_2, and H_2O, none of which are considered toxic in the concentrations typically encountered.

Use of Peroxone as a Disinfectant

Peroxone is the combination of ozone (or ultraviolet light) with hydrogen peroxide. When hydrogen peroxide is added with ozone, it will quench ozone residual. In reacting with dissolved ozone (or reacting with photons of light from a UV process) it becomes an advanced oxidation process (AOP), which is characterized by the prolific generation of hydroxyl radicals (OH•). These OH• are stronger and less selective than ozone or other oxidants in regard to destroying target synthetic or naturally occurring micropollutants and microorganisms. The use of peroxone as an advanced oxidation process is discussed in Chap. 6.

Sequential Chlorination

Developed by the Sanitation Districts of Los Angeles County, *sequential chlorination* is a two-step disinfection process. In the first step, chlorine is added to nitrified filtered effluent to produce a free chlorine residual (FCR). As noted previously, free chorine, because of its high germicidal effectiveness, rapidly inactivates both bacteria and viruses. It also reacts with NDMA precursors to make them less available for subsequent NDMA formation. In the second step, ammonia and additional chlorine, if needed, are added to form chloramines, which provide additional bacterial and viral disinfection and minimize the formation of THMs. At the lowest free chlorine CT values tested (2 to 4 mg•min/L), it was possible to achieve an average of more than 6-log MS2 bacteriophage inactivation. With respect to DBP formation, the levels of THMs increased while the corresponding levels of NDMA decreased as compared to conventional chloramination. The sequential chlorination process has been developed to provide an alternative to the prescriptive CT value of 450 mg•min/L at a minimum modal contact time of 90 min required in the CDPH reclamation criteria [CCR, Section 60301.230(a)] (Maguin et al., 2009; Friess et al., 2013).

Combined Chemical Disinfection Processes

Interest in the sequential or simultaneous use of two or more disinfectants has increased within the last few years, especially in the water supply field. Reasons for the increased interest in the use of multiple disinfectants include (U.S. EPA, 1999a):

- The use of less reactive disinfectants, such as chloramines, has proven to be quite effective in reducing the formation of DBPs, and more effective for controlling biofilms in the distribution system.
- Regulatory and consumer pressure to produce water that has been disinfected to achieve high levels of inactivation for various pathogens has forced both the water and wastewater industry to search for more effective disinfectants. To meet more stringent disinfection standards, higher disinfectant doses have been used which, unfortunately, have resulted in the production of increased levels of DBPs.
- Based on the results of recent research it has been shown that the application of sequential disinfectants is more effective than the additive effect of the individual disinfectants. When two (or more) disinfectants are used to produce a synergistic effect by either simultaneous or sequential application to achieve more effective pathogen inactivation, the process is referred to as interactive disinfection (U.S. EPA, 1999a).

Currently, extensive research is being conducted on these processes. Some examples for the use of combined and/or sequential application of disinfectants are presented in Table 12–27. Because the application of multiple disinfectants is, at present, site specific, depending on the microorganism, the disinfection technologies employed, and other non-disinfection process objectives, the current literature must be reviewed to assess the suitability and effectiveness of combined disinfection technologies. For example, in Australia, combined use of chlorination and UV is becoming the norm in water-reuse applications.

Table 12–27

Effectiveness of combined disinfectants and processes for water and wastewater treatment[a,b]

Combined disinfectants	Response	Reference
In water treatment		
Ozone (O_3), UV, and chloramines replaced chlorination	Increase in CT credits by as much as 3 to 5 logs	Malley (2005)
Sequential sonification and chlorine	Increase in effectiveness over use of sonification or chlorine alone	Plummer and Long (2005)
Ozone and free chlorine, ozone and monochloramine, chlorine dioxide and free chlorine, chlorine dioxide, chlorine, and monochloramine	Synergistic response observed in the inactivation of *C. parvum* oocysts	Li et al. (2001)
Sequential UV and chlorine for inactivation of adenoviruses	Increase in effectiveness over use of UV or chlorine alone	Sirikanchana et al. (2005)
In wastewater treatment		
Free chlorine and combined chlorine	Reduced CT times for the inactivation of virus	Maguin et al. (2009), Friess et al. (2013)
Peracetic acid (PAA) and UV	Increase in effectiveness over use of UV or PAA alone	Chen et al. (2005), Lubello et al. (2002)
PAA and UV and PAA and ozone	Increase in effectiveness over use of PAA and UV alone	Caretti and Lubello (2005)
PAA and hydrogen peroxide (H_2O_2), H_2O_2 and UV, and H_2O_2 and O_3	No improved effectiveness	Caretti and Lubello (2005), Lubello et al. (2002)
Ozone, PAA, H_2O_2 and copper (Cu)	PAA and H_2O_2 alone had no effect, addition of 1 mg/L Cu had a dramatic effect	Orta de Velasque et al. (2005)
PAA/UV and H_2O_2/UV	PAA/UV had synergistic effects, whereas H_2O_2/UV did not	Koivunen (2005a)
Ultrasound and UV	Increase in effectiveness over use of UV alone	Blume et al. (2002) see also Blume and Neis (2004)

[b] Additional combinations are reviewed in U.S. EPA (1999a).

12–9 ULTRAVIOLET (UV) RADIATION DISINFECTION

The germicidal properties of ultraviolet (UV) light sources have been used in a wide variety of applications since the use of UV was pioneered in the early 1900s, having been discovered first in the 1880s. First used on high quality water supplies, the use of UV light as a wastewater disinfectant evolved during the 1990s with the development of new lamps, ballasts, and ancillary equipment. With the proper combination of UV dose and water quality, UV irradiation has proven to be an effective disinfectant for bacteria, protozoa, and viruses in both unfiltered and filtered secondary effluent, while not contributing to the formation of toxic byproducts. In several cases, UV has even been proven to be effective at disinfecting primary effluents. To develop an understanding of the application of UV for the disinfection of wastewater the following topics are considered in this section: (1) source of UV radiation, (2) UV system configurations, (3) the germicidal effectiveness of UV irradiation, (4) modeling the UV disinfection process, (5) estimating the UV dose,

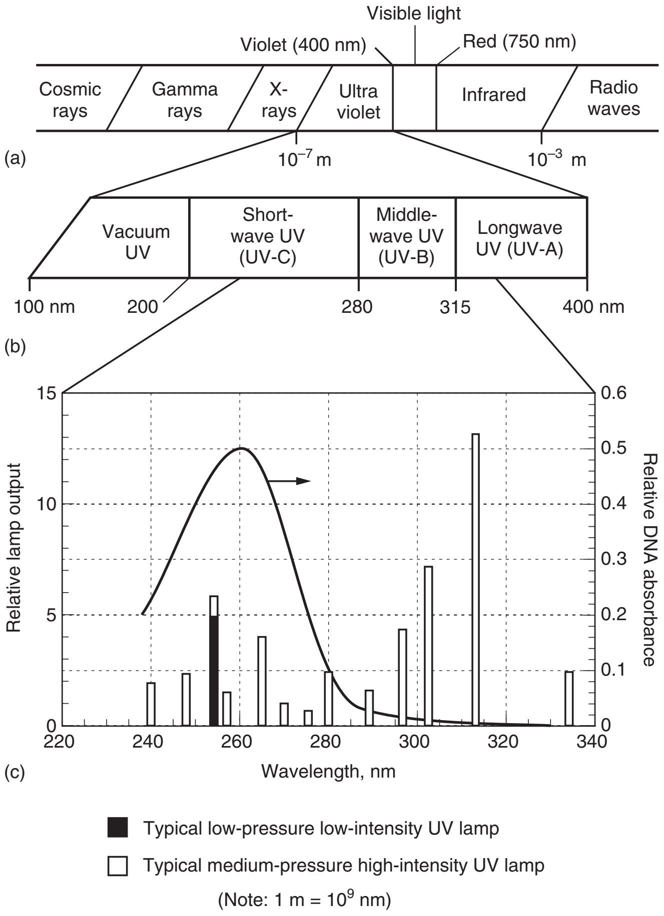

Figure 12–33

Definition sketch for ultraviolet (UV) radiation disinfection: (a) identification of the ultraviolet radiation portion of the electromagnetic spectrum, (b) identification of the germicidal portion of the UV radiation spectrum, and (c) UV radiation spectra for both low-pressure low-intensity and medium-pressure high-intensity UV lamps and the relative UV absorption for DNA superimposed over spectra of the UV lamps.

(6) UV disinfection guidelines, (7) analysis of a UV disinfection system, (8) operational issues with UV systems, and (9) the environmental impacts of disinfection with UV radiation.

Source of UV Radiation

The portion of the electromagnetic spectrum in which UV radiation occurs, is between 100 and 400 nm [see Fig. 12–33(a)]. The UV radiation range is characterized further according to wavelength as longwave (UV-A), also known as near-ultraviolet irradiation, middlewave (UV-B), and shortwave (UV-C), also known as far UV. The germicidal portion of the UV radiation band is between about 220 and 320 nm, principally in the UV-C range. The UV wavelengths between 255 to 265 nm are considered to be most effective for microbial inactivation [see Fig. 12–33(c)]. Most commonly, UV radiation is produced by striking an electric arc between two electrodes in specially designed lamps containing liquid mercury, as well as other gas mixtures. The energy generated by the excitation of the liquid mercury causes it to vaporize. Mercury in its gaseous form excites electrons in the lamps thus producing photons of UV light.

When used for water and wastewater disinfection, quartz sleeves are most often used to isolate the UV lamps from direct water contact and to control the lamp wall temperature by buffering the effluent temperature extremes to which the UV lamps are exposed, thereby maintaining a fairly uniform UV lamp output. In another less common configuration, the

Table 12–28

Typical operational characteristics for UV lamps

Item	Unit	Type of lamp Low-pressure low-intensity	 Low-pressure high-intensity	 Medium-pressure high-intensity
Power consumption	W	40–100	200–500[a]	1000–13,000
Lamp current	mA	350–550	Variable	Variable
Lamp voltage	V	220	Variable	Variable
Germicidal output/input	%	30–50	35–50	15–20[b]
Lamp output at 254 nm	W	25–27	60–400	100–2000
Lamp operating temperature	°C	35–50	100–150	600–800
Pressure	mm Hg	0.007	0.01–0.8	10^2–10^4
Lamp length	m	0.75–1.5	1.8–2.5	0.3–1.2
Lamp diameter	mm	15–20	Variable	Variable
Sleeve life	y	4–6	4–6	1–3
Ballast life	y	10–15	10–15	3–5
Estimated lamp life	h	8000–12,000	9000–15,000	3000–8000

[a] Up to 1200 W in very high output lamp.

[b] Output in the most effective germicidal range (~255 – 265 μm, see Fig. 12–33).

water to be disinfected is passed through proprietary plastic tubes that are themselves surrounded by UV lamps. The output of UV disinfection systems also decreases with time due to a reduction in the electron pool within the UV lamp, deterioration of the electrodes, and the aging of the quartz sleeve. Lamps with other gas mixtures and without electrodes, as described below, are also used to generate UV light.

Types of UV Lamps

The principal electrode-type lamps used to produce UV light fall into three categories based on the lamp's internal operating parameters: *low-pressure low-intensity, low-pressure high-intensity,* and *medium-pressure high-intensity* systems. Comparative information on the operational characteristics of these three types of UV lamps is presented in Table 12–28. In the brief discussion of these types of UV lamps presented below, it is important to note that UV lamp technology is changing rapidly. It is, therefore, imperative that current manufacturers' literature be consulted when designing a UV disinfection facility. The ballasts used in conjunction with UV lamps are also discussed briefly.

Low-Pressure Low-Intensity UV Lamps. Low-pressure low-intensity mercury-argon electrode type UV lamps [see Fig. 12–34(a)] are used to generate a broad spectrum of essentially monochromatic radiation in the UV-C region with an intense peak at a wavelength of 253.7 nm (essentially 254 nm) and a lesser peak at about 184.9 nm. The peak at 254 nm is close to the 260 nm wavelength considered to be most effective for microbial

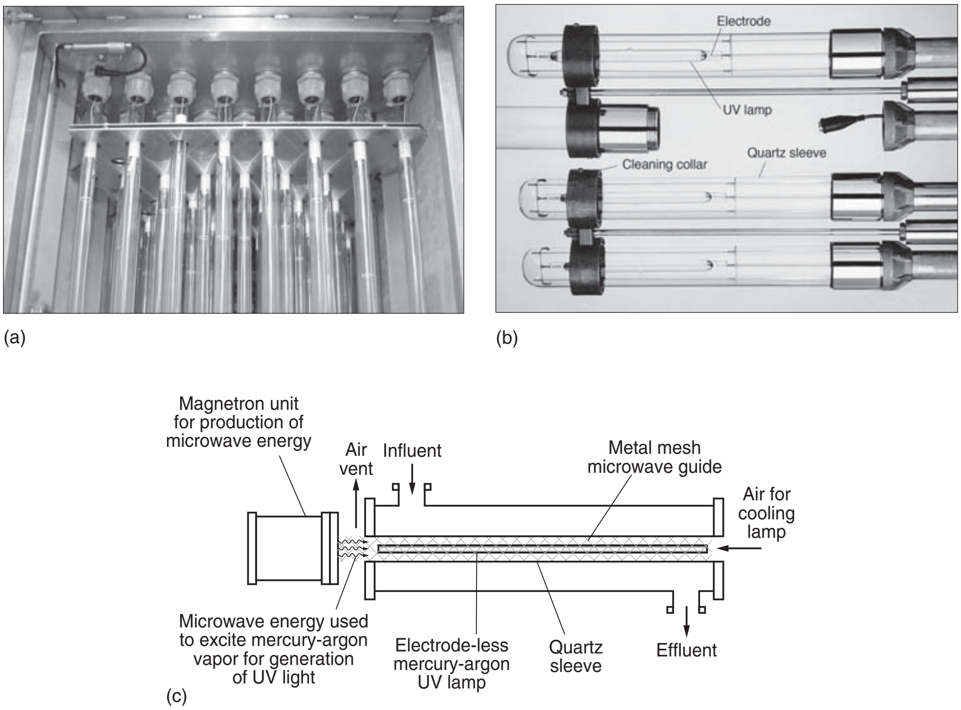

Figure 12–34

Typical examples of UV lamps: (a) low-pressure low-intensity, (b) medium-pressure high-intensity lamps with cleaning device, and (c) schematic illustration of the electrode-less microwave driven UV lamp [see Fig. 12–36(d)].

inactivation. Compared to power input, approximately 30 to 50 percent of the lamp's UV energy output is monochromatic at 254 nm, making it an efficient choice for disinfection processes. Also, approximately 85 to 88 percent of the lamp's output is monochromatic at 254 nm, making it an efficient choice for disinfection processes. Because there is an excess of liquid mercury in the low-pressure low-intensity UV lamp, the mercury vapor pressure is controlled by the coolest part of the lamp wall. If the lamp wall does not remain relatively near the optimum temperature of 40°C, some of the mercury will condense back to its liquid state thereby decreasing the number of mercury atoms available to release photons of UV; hence UV output declines.

Low-Pressure High-Intensity UV Lamps. Low-pressure high-intensity UV lamps are similar to the low-pressure low-intensity lamps [see Fig.12–34(a)] with the exception that a mercury-indium amalgam is used in place of liquid mercury. Use of the mercury amalgam allows greater UV-C output, typically from 2 to 10 times the output of conventional low-intensity lamps. Similar to low-pressure low-intensity lamps, low-pressure high-intensity lamps are very efficient at converting lamp input power into UV light. Compared to power input, approximately 35 to 50 percent of the lamp's UV energy output is monochromatic at 254 nm. Low-pressure high-intensity UV lamps operate at temperatures of 100 – 150°C. The amalgam in the low-pressure high-intensity UV lamps is used to maintain a constant level of mercury atoms, and, thus, provides greater stability over a broad temperature range. The UV output of low-pressure high-intensity lamps can be modulated between 30 and 100 percent. The range of modulation varies between different lamps. Current manufacturer's literature should be reviewed for lamp specifications as new low-pressure high-intensity lamps are being developed continuously.

Medium-Pressure High-Intensity UV Lamps. A number of medium-pressure high-intensity UV lamps have been developed over the last decade. Medium-pressure high-intensity UV lamps, which operate at temperatures of 600 to 800°C and vapor pressures of 10^2 to 10^4 mm Hg, generate polychromatic irradiation [see Fig. 12–33(c)]. Medium-pressure high-intensity UV lamps [see Fig. 12–34(b)] generate approximately 20 to 50 times the total UV-C output of low-pressure high-intensity UV lamps. Although the UV output of medium-pressure high-intensity lamps is significantly higher compared to low-pressure low-and high-intensity lamps, their efficiency is much lower. Compared to power input, only 15 to 20 percent of the lamp UV energy output is within the germicidal UV range. The use of medium-pressure high-intensity lamps is limited primarily to potable water supplies, large wastewater facilities, stormwater overflows, or on space-limited sites because fewer lamps are required and the footprint of the disinfection system is greatly reduced. The UV output of medium-pressure high-intensity lamps can be modulated across a range of power settings (typically 30 to 100 percent) without significantly changing the spectral distribution of the lamp. The particular UV lamp selected by UV system manufacturers is chosen on the basis of an integrated design approach in which the UV lamp, ballast, and reactor design are interdependent.

Alternative UV Lamp Technologies. A number of alternative technologies have been developed. Typically, they have not been used at the municipal scale, but this may change in the future. Some examples of the types of lamps that are being developed and applied include (1) the pulsed energy broad-band xenon lamp (pulsed UV), (2) the narrow band excimer UV lamp, (3) the mercury-argon electrode-less microwave powered high-intensity UV lamp, and (4) UV light emitting diodes (LED) lamp.

The pulsed UV lamp produces polychromatic light at high levels of radiation. It is estimated that the radiation produced by the pulsed UV lamp is 20,000 times as intense as sunlight at sea level. The disinfection effectiveness provided by pulsed UV lamps has been researched in some detail (O'Brien et al., 1996; EPRI, 1996; Mofidi et al., 2001). Narrow band excimer lamps produce essentially monochromatic light in three wavelengths: 172, 222, and 308 nm depending on the gas used in the lamp. Gases that have been used for the purpose include xenon (Xe), xenon chloride (XeCl), krypton (Kr), and krypton chloride (KrCl). In the microwave powered UV lamp, UV light is generated by striking a mercury-argon filled electrode-less UV lamp with microwave energy generated with a magnetron [see Fig. 12–34(c)]. Because the lamp does not contain electrodes, longer lamp life (3 to 5 y) is claimed, though no third-party certification has been completed. Based on preliminary results, it appears that the UV LED lamps currently under development will compete directly with conventional UV technologies. At present, there is no LED lamp technology that can compete with high output UV lamps.

As noted above, because developments in UV technology are occurring at such a rapid pace, it is essential that the current literature be consulted when designing UV disinfection systems. Note that in most cases, emerging technologies do not have a proven track record of cost-effective, reliable performance.

Ballasts for UV Lamps. A ballast is a type of transformer that is used to limit the current to a lamp. Because UV lamps are arc discharge devices similar to fluorescent lamps, the more current in the arc, the lower the resistance becomes. Without a ballast to limit current, the lamp would destroy itself. Thus, matching the lamp and ballast is of critical importance in the design of UV disinfection systems. Three types of ballasts are used: (1) standard (core coil), (2) energy efficient (core coil), and standard electronic (solid-state). In general, electronic ballasts are about 10 percent more energy efficient than magnetic ballasts. Electronic ballasts are now used most commonly for controlling the UV lamps used for disinfection.

UV Disinfection System Configurations

In addition to the type of lamp used, UV systems for the disinfection of wastewater can also be classified according to whether the flow occurs in open or closed channels. Each of these system configurations is described below.

Open Channel Disinfection Systems. The principal components of low-pressure low-and high-intensity open channel UV systems used for the disinfection of wastewater are illustrated on Fig. 12–35. As shown, lamp placement can be horizontal and parallel to the flow [see Fig. 12–35(a)], vertical and perpendicular to the flow [see Fig. 12–35(c)], or inclined (e.g. diagonal) to the flow [see Fig. 12–35(e)]. Each module contains a specified number of UV lamps encased in quartz sleeves. The total number of lamps is specific to each application, but the number of lamps in each module depends on the channel and overall system configuration and lamp manufacturer. The lamp spacing is manufacturer and lamp type specific and can range from 75 mm (3 in.) to 150 mm (6 in.). The inclined lamp UV systems are a relatively recent development. Stated advantages include the use of longer lamps with higher output, which reduces the total required number of lamps; improved system hydraulics and performance; and ease of installation, maintenance, and operation.

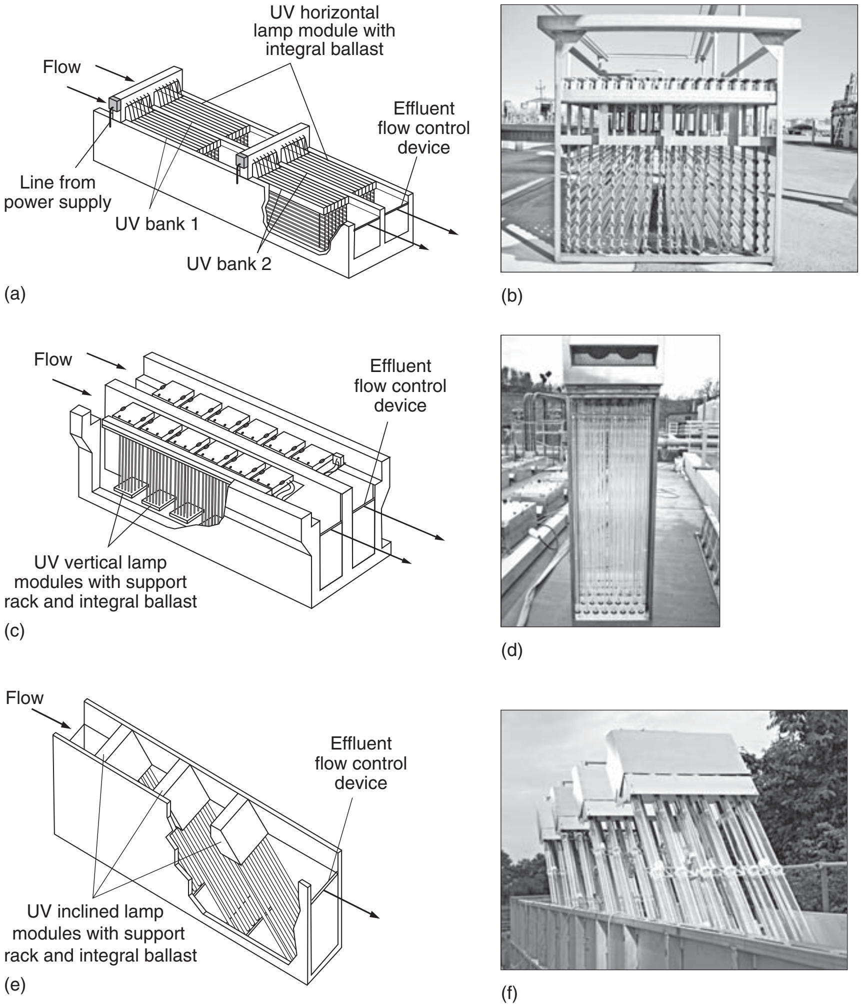

Figure 12–35

Isometric cut-away and photographic views of typical open channel UV disinfection systems: (a) horizontal lamp system parallel to flow (adapted from Trojan Technologies, Inc.), (b) view of one UV bank of a horizontal lamp system removed for cleaning, (c) vertical lamp system perpendicular to flow (adapted from Infilco Degremont, Inc.), (d) vertical lamp module removed from channel for cleaning, (e) inclined (45°) lamp system (adapted from Xylem, Inc.), and (f) view of inclined lamp UV system with lamps elevated out of the channel (courtesy of Xylem, Inc.).

An extended serpentine fixed sharp-crested weir, automatic level controlled adjustable weir, or a weighted flap gate (not recommended) is used to control the depth of flow through each disinfection channel. Proper level control is essential to (1) maintain submergence of the lamps at all times, (2) prevent short circuiting by ensuring that the water level above the top lamp is not too high, and (3) adequately seal the channel to prevent undisinfected water from bleeding through to the effluent channel when a bank of lamps is out of service. An inadequate level control device can often be the cause of poor UV disinfection performance.

Each channel typically contains two or more banks of UV lamps in series, and each bank is comprised of a number of modules (or racks of UV lamps). It is important to note that a standby bank or channel is normally provided for system reliability. The design flowrate is usually divided equally among a number of open channels. Typical examples of horizontal and vertical low-pressure low-high-intensity UV disinfection systems are shown on Fig. 12–35(c) through 12–35(f), respectively. A typical medium-pressure UV disinfection system is shown on Figs. 12–36(a) and 12–36(b). The lamps are arranged in

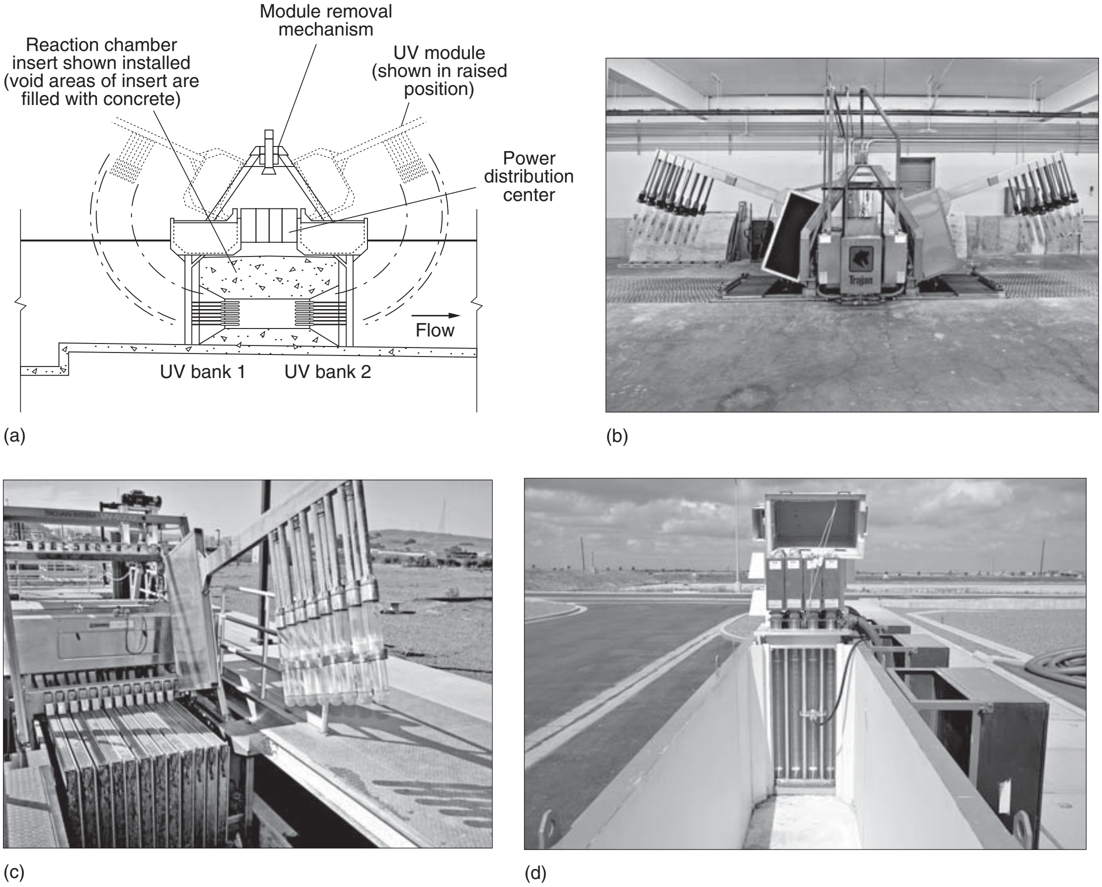

Figure 12–36

Typical examples of medium-pressure and microwave open channel UV disinfection systems: (a) schematic view through UV reactor (adapted from Trojan Technologies), (b) typical medium pressure UV system installed in open channel, (c) medium pressure UV system with one lamp module out of the reactor, and (d) microwave UV lamps with magnetron located above lamps [see Fig. 12–34(c)] in vertical orientation in open channel (adapted from Quay Technologies, Ltd).

modules and are positioned in a reactor with a fixed geometry [see Fig. 12–36(c)]. The lamp cleaning sleeves can be seen on Fig. 12–36(c). Vertical mercury-argon electrode-less microwave powered high-intensity UV lamps are shown on Fig. 12–36(d).

Closed Channel Disinfection Systems. A number of low- and medium-pressure high-intensity UV disinfection systems are designed to operate in closed channels or pipes. Two UV system configurations are used. In the first configuration, the direction of flow is perpendicular to the placement of the lamps, as shown on Fig. 12–37(a). In the second configuration, the direction of flow is parallel to the UV lamps [see Fig. 12–37(b)]. Because high-intensity UV lamps operate at a lamp wall temperature of between 600 to 800°C, the UV output of these lamps is unaffected by the effluent temperature. A typical medium-pressure UV disinfection reactor is shown on Figs. 12–37(c) and 12–37(d). A closed system pulsed UV reactor is shown on Fig. 12–37(f).

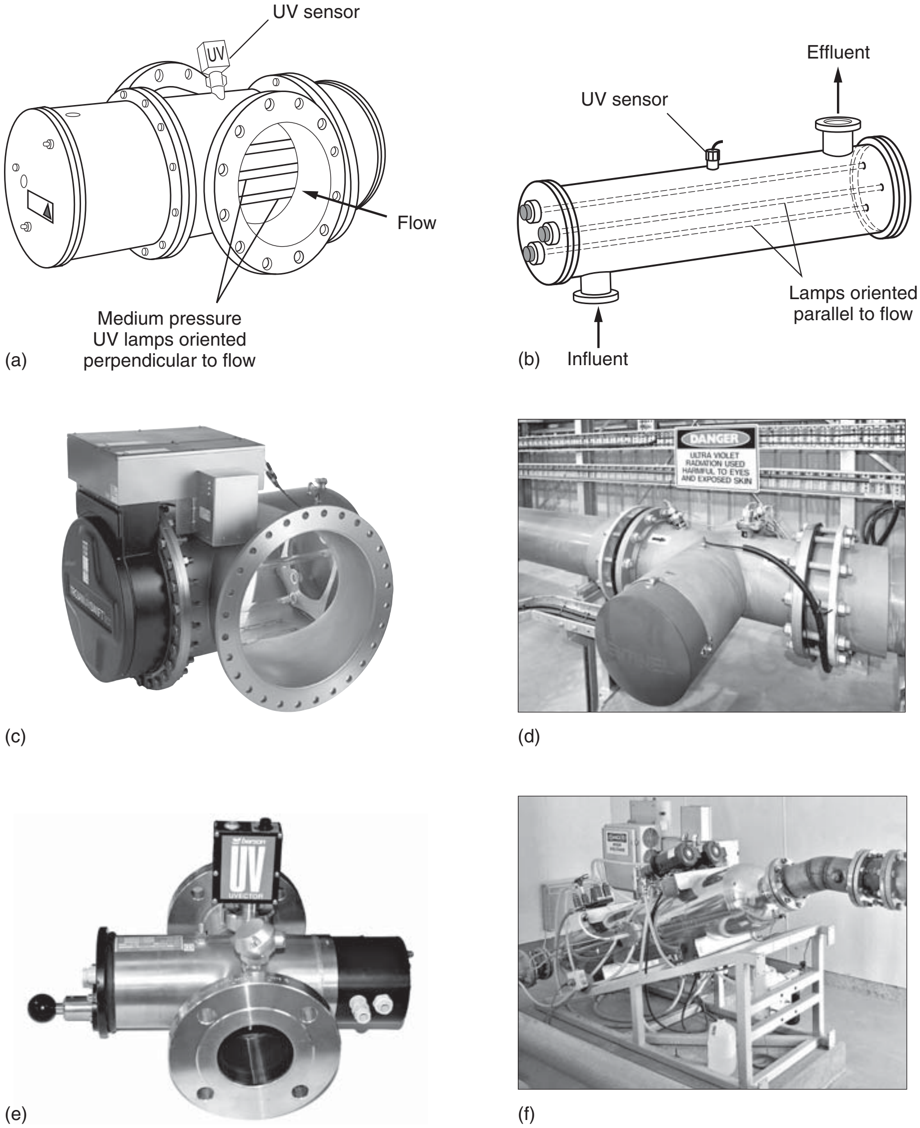

Figure 12–37

Quartz Sleeve Cleaning Systems

In UV disinfection systems, various physical and chemical characteristics of the water result in fouling of the quartz sleeves that encase each UV lamp. During operation of a UV lamp in wastewater, factors such as interfacial temperature, reactor hydraulics, and the quartz microstructure and topography allow attachment of inorganic debris and organic films or greases onto the protective quartz sleeve surrounding the lamp. These deposits absorb UV light and decrease the intensity of UV light penetration into the wastewater. The decrease in UV intensity leads to a decrease in UV dose resulting in reduction in disinfection performance. Fouling has been found to be complex and is difficult to predict. It also tends to be site-specific, owing mainly to the chemical and biological nature of the liquid matrix being treated by the UV system. To overcome quartz sleeve fouling, the majority of UV systems on the market have in-situ sleeve cleaning systems. These cleaning systems, as discussed below, can be divided into 2 categories: (1) mechanical, and (2) chemical-mechanical.

Mechanical Cleaning Systems. The first cleaning system category—mechanical cleaning—involves the use of a wiper that runs along the length of the quartz sleeve and removes large debris and scrapes off a degree of built up scaling. These types of systems are relatively effective in high quality effluents, but their performance can be compromised in high sleeve fouling effluents. Two items should be considered when designing a UV system with a mechanical wiper. The first is to apply an appropriate quartz sleeve fouling factor when sizing UV disinfection systems. Appropriate quartz sleeve fouling factors are considered subsequently. The second item that must be considered during design of the UV system is to include provisions for periodic (period of time is site specific) out-of-channel cleaning of the UV system. The external cleaning can be done manually with a manufacturer specified acid-based cleaning product for smaller UV systems or in an external acid bath (see Fig. 12–38) built for UV modules and with a crane for module channel removal and insertion into the bath.

Chemical-Mechanical Cleaning Systems. The second cleaning system category—chemical-mechanical—has been proven to be very effective at removing all

Figure 12–38

(a) (b)

scaling from quartz sleeves and maintaining a near 100 percent UV light output through the life of the system. Chemical-mechanical cleaning systems typically utilize two wipers that contain a small volume of an acidic gel (either phosphoric or citric acid based). This chemical gel remains in a canister surrounding each quartz sleeve and is replaced annually. Although a chemical-mechanical cleaning system has been shown to be more effective than mechanical cleaning alone, a quartz sleeve fouling factor should be applied to UV system sizing in any case.

Mechanism of Inactivation by UV Irradiation

Ultraviolet light is a physical rather than a chemical disinfecting agent. The mechanism of inactivation and photoreactivation are important concepts to understand as they are some of the fundamental principles of UV disinfection.

Inactivation Mechanisms. UV radiation penetrates the cell wall of the microorganism and is absorbed by the nucleic acids (DNA and RNA), which guide the development of all living organisms. Damage to the nucleic acid interferes with normal cell processes such as cell synthesis and cell division. Deoxyribonucleic acid (DNA) controls the structure, while ribonucleic acid (RNA) controls the metabolic processes. Typically, DNA is a double-stranded helical structure with four nucleotides: adenine, guanine, thymine, and cytosine, while RNA is a single-stranded structure with the nucleotides adenine, guanine, uracil, and cytosine.

Exposure to UV radiation damages DNA by manipulating adjacent thymine molecules as illustrated on Fig. 12–39. The process of forming double bonds is known as dimerization. Cytosine-cytosine and cytosine-thymine dimers can also be formed. Thus, organisms rich in thymine such as protozoans *C. parvum* and *G. lamblia* tend to be more sensitive to UV radiation (see Table 12–5) (Mofidi et al., 2001; Mofidi et al., 2002). Uracil and cytosine are the corresponding molecules in RNA. Viruses contain either DNA or RNA, which is either single or double stranded. Adenovirus contains double-stranded DNA, which is considered as a possible explanation for its high sensitivity to UV light (Sommer et al., 2001). Exposure to UV radiation can also cause more severe damage, such as breaking chains, cross-linking DNA with itself, and cross-linking DNA with other proteins. (Crittenden et al., 2005). In general, UV irradiation must form a significant number of bonds or other damage to the cell to be effective, which is the case with the doses delivered in properly sized UV disinfection systems.

Figure 12–39

Formation of double bonds in microorganisms exposed to ultraviolet radiation.

Replication stops at dimer

Microbial Growth Phase and Resistance to UV Irradiation. In addition to the mechanisms discussed above, it has been found that the growth phases of organisms can inherently provide protection against disinfectants. As noted in Chap. 7 there are four readily identifiable stages that cells undergo: lag growth phase, exponential growth phase, stationary growth phase, and death phase. The effect that different phases of growth cycle may have on UV susceptibility of *E. coli* has been evaluated by Modifi et al. (2002). It appears that when cell DNA is not actively dividing, bacteria may be more resistant to UV disinfection. Thus, if naturally occurring bacteria are not stressed by environmental factors, they may exhibit a similar spectrum of resistance to UV disinfection. Based on these findings, knowledge of the cell growth stage is of importance in establishing bacterial dose-response relationships.

Microbial Repair Following UV Irradiation. Because some organisms are able to maintain some metabolic activities after being exposed to UV radiation, they may be able to repair the damage caused by the exposure. Many organisms in nature have evolved mechanisms for reversing UV damage. Two different types of mechanisms are involved: (1) photoreactivation and (2) dark repair.

Photoreactivation. Photoreactivation involves specific enzymes that can repair sections of damaged DNA after being energized by exposure to light. The mechanism of photoreactivation, first discovered in 1949 for *Streptomyces griseus* by Kelner (1949) and for bacteriophage by Dulbecco (1949), was demonstrated to be enzyme-catalyzed (Rupert, 1960). The enzyme responsible for DNA repair is named *photolyase*. Photoreactivation can be described as the two-step enzymatic reaction between photolyase and its substrate, pyrimidine dimers (Friedberg et al., 1995). The first step is for photolyase to recognize any dimers (see Fig. 12–39) and specifically bind them to form an enzyme-substrate complex. The first step is light-independent and, therefore, can occur even under dark conditions. The enzyme-dimer complex is stable and goes through the second repair step in which the dimers are broken utilizing the energy of light at wavelengths between 310 and 490 nm. The second step is dependent only on light input.

For example, the *E. coli* photolyase has a round shape with a hole inside, which recognizes and structurally binds to the pyrimidine dimers sticking out from the genome DNA. Once the pyrimidine dimers are repaired (i.e., broken) and the structure is changed, the bind is loosened and the enzyme leaves the dimer (Friedberg et al., 1995). In the case of pathogenic parasites, the effects of photoreactivation are unclear. Based on infectivity studies, it was reported that the oocysts of *Cryptosporidium parvum* did not undergo photoreactivation (Rochelle et al., 2004). In another study, it has been reported that repair of the pyrimidine dimers did occur in oocysts of *Cryptosporidium parvum* (Oguma et al., 2001). What appears to be happening is that the repair of DNA following UV irradiation may not be sufficient for the organism to regain its infectivity. Although the necessary enzymes needed for repair are missing in viral DNA, the enzymes of the host cell can be used to accomplish the repair.

It should also be noted that the ability for an organism to repair itself appears to depend on a number of factors including UV dose (the effect is diminished at higher UV doses), UV wavelength, UV light intensity, and exposure time to photoreactivating light (Martin and Gehr, 2005). *Escherichia coli* exposed to monochromatic low-pressure UV light were able to repair themselves, whereas *Escherichia coli* exposed to polychromatic medium-pressure UV light were unable to repair themselves (Zimmer and Slawson, 2002; Oguma et al., 2002). However, *Legionella pneumophila* exhibited very high photoreactivation ability after exposure to either low-pressure or medium-pressure UV light (Oguma et al., 2004). From a review of some recent published findings, it appears that if effluent that has undergone UV disinfection is subsequently kept in the dark for approximately 3 hours, the regrowth potential is reduced significantly (Martin and Gehr, 2005). Clearly, more research needs to be done to understand what is causing the effect observed with medium-pressure UV light.

Dark Repair. In the early 1960s it was found that UV-induced DNA damage could be repaired without light (Hanawalt et al., 1979). Dark repair appears to be accomplished by two mechanisms: (1) excision repair and (2) recombination repair. In excision repair, enzymes remove the damaged section of DNA, and in recombination repair, the damaged DNA is regenerated using a complementary strand of DNA. Although the necessary enzymes needed for repair are missing in viral DNA, the enzymes of the host cell can be used to accomplish the repair. Contrary to photoreactivation, with high specificity to pyrimidine dimers, dark repair can act on various kinds of damage in the genome. Dark repair is a rather slow process compared to photoreactivation.

Germicidal Effectiveness of UV Irradiation

The overall effectiveness of the UV disinfection process depends on a number of factors including (1) the chemical characteristics of the wastewater to be irradiated, (2) the presence of particles, (3) the characteristics of the microorganisms, and (4) the physical characteristics of the UV disinfection system. Before considering these subjects, it is appropriate to consider the definition of UV dose to provide a frame of reference for the discussion of the factors affecting UV disinfection. The material presented below will also be useful in assessing the modeling of the UV process that is considered subsequently.

Definition of UV Dose. The effectiveness of UV disinfection is based on the UV dose to which the microorganisms are exposed. The UV dose, D, as defined previously, is given by Eq. (12–8), which is repeated here for convenience.

$$D = I_{\text{avg}} \times t \tag{12–8}$$

where D = UV dose, mJ/cm^2 (note mJ/cm^2 = mW·s/cm^2)
I_{avg} = average UV intensity, mW/cm^2
t = exposure time, s

Note that the UV dose term is analogous to the dose term used for chemical disinfectants (i.e., CT). As given by Eq. (12–8), the UV dose can be varied by changing either the intensity or exposure time. Additional details on the measurement of UV dose may be found in Linden and Mofidi (2003) and Jin et al. (2006).

Effect of Chemical Constituents in Wastewater. The constituents in wastewater can have a significant impact on the average UV intensity. The impact is measured in term of absorbance and transmittance. The reduction in UV intensity with distance is defined by Beers-Lambert Law, repeated here for convenience from Chap. 2.

$$\log\left(\frac{I}{I_o}\right) = -\varepsilon(\lambda)Cx = k(\lambda)x = [A(\lambda)/x]x \tag{2–19}$$

where I = light intensity at distance x from the light source, mW/cm^2
I_o = light intensity at light source, mW/cm^2

$\varepsilon(\lambda)$ = molar absorptivity (also known as the extinction coefficient) of the light-absorbing solute at wavelength λ, L/mole·cm
C = concentration of light-absorbing solute, mole/L
x = light path-length, cm
$k(\lambda)$ = the absorptivity, cm^{-1}
$A(\lambda)$ = absorbance, dimensionless

Although the absorbance, $A(\lambda)$, is dimensionless, it is often reported in units of cm^{-1}, which corresponds to absorptivity $k(\lambda)$. If the length of the light path is 1 cm, absorptivity is equal to the absorbance. In UV practice, it is more common to use transmittance, which is defined as

$$\text{Transmittance, } T, \% = \left(\frac{I}{I_o}\right) \times 100 \qquad (2\text{–}21)$$

Typical absorbance and transmittance values for wastewater after several different treatment processes are presented in Table 12–29.

Dissolved constituents impact UV disinfection either directly via absorbance (increasing absorbance serves to attenuate UV light to a larger degree) or via fouling of UV lamp sleeves such that a reduced intensity is applied to the bulk liquid medium. The effects of constituents found in effluent from different wastewater treatment processes are reported in Table 12–30. One of the most perplexing problems encountered in the application of UV disinfection for wastewater disinfection is the variation typically observed in the absorbance (or transmittance) at treatment plants. Often, the variations in transmittance are caused by industrial discharges, which can lead to diurnal as well as seasonal variations. Common industrial impacts are related to the discharge of inorganic and organic dyes, wastes containing metals, and complex organic compounds.

Of the inorganic compounds that affect transmittance, iron is considered to be the most important with respect to UV light absorbance because dissolved iron can absorb UV light directly. Organic compounds containing double bonds and aromatic functional groups can also absorb UV light. Absorbance values for a variety of compounds found in wastewater are given in Table 12–31. From a review of the information presented in Table 12–31, it is clear that the presence of iron in wastewater can have a significant impact on the use of UV. If iron salts are used within the treatment process, the economic benefits of changing to another chemical (e.g., alum) should be evaluated to determine whether the cost savings of having a smaller UV system are greater than the capital and operating costs of switching to the new chemical. It is also important to note that stormwater inflows can cause wide variations, especially when humic materials from terrestrial sources are present. In general, the solution to the problem of varying transmittance levels may require monitoring of industrial

Table 12–29

Absorbance and transmittance values for various wastewaters at a wavelength of 254 nm

Type of wastewater	Absorbance, a.u./cm	Transmittance[a],%
Primary	0.70 to 0.30	20 to 50
Secondary	0.35 to 0.15	45 to 70
Nitrified secondary	0.25 to 0.10	56 to 79
Filtered secondary	0.25 to 0.10	56 to 79
Microfiltration	0.10 to 0.04	79 to 91
Reverse osmosis	0.05 to 0.01	89 to 98

[a] $T, \% = 10^{-A(\lambda)} \times 100$.

Table 12–30

Impact of wastewater constituents on the use of UV radiation for wastewater disinfection

Constituent	Effect
BOD, COD, TOC, etc.	No or minor effect, unless humic materials comprise a large portion of the BOD
NOM (natural organic matter)	Strong absorbers of UV radiation
Oil and grease	Can accumulate on quartz sleeves of UV lamps, can absorb UV radiation
TSS	Absorption of UV radiation, can shield embedded bacteria
Alkalinity	Can impact scaling potential. Also affects solubility of metals that may absorb UV light
Hardness	Calcium, magnesium and other salts can form mineral deposits on quartz tubes, especially at elevated temperatures
Ammonia	No or minor effect
Nitrite	No or minor effect
Nitrate	No or minor effect
Iron	Strong absorber of UV radiation, can precipitate on quartz tubes, can become embedded in suspended solids and shield bacteria by absorption
Manganese	Strong absorber of UV radiation
pH	Can affect solubility of metals and carbonates
TDS	Can impact scaling potential and the formation of mineral deposits
Industrial discharges	Depending on the constituents (e.g., dyes), may lead to a diurnal and seasonal variations in the transmittance
Stormwater inflow	Depending on the constituents, may lead to short term as well as seasonal variations in the transmittance

Table 12–31

UV Absorbance of water and common chemicals found in wastewater

Compound	Form or designation	Molar absorption coefficient, L/mole·cm	Threshold concentration, mg/L
Ferric iron	Fe[III]	3069	0.057
Ferrous iron	Fe[II]	466	9.6
Hypochlorite ion	OCl^-	29.5	8.4
N-nitrosodimethylamine	NDMA	1974	
Nitrate	NO^{3-}	3.4	
Natural organic matter	NOM	80 to 350	
Ozone	O_3	3250	0.071
Zinc	Zn^{2+}	1.7	187
Water	H_2O	6.1×10^{-6}	

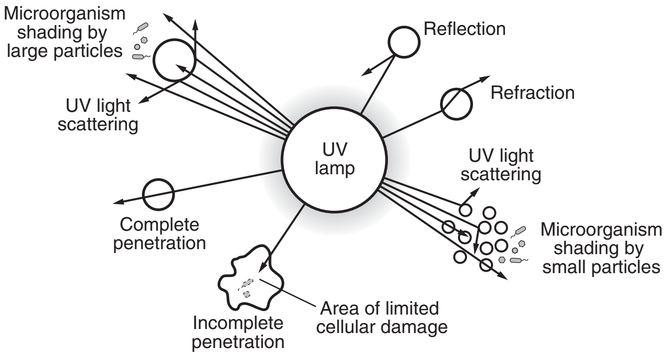

Figure 12–40

Particle interactions that effect the effectiveness of UV disinfection including microorganism shading; light scattering, reflection, and refraction; and incomplete penetration.

discharges, the implementation of source control programs, and correcting sources of infiltration. In some cases, biological treatment will mitigate the influent variations. In some extreme situations, the conclusion may be that UV disinfection is not practical.

Where the implementation of UV disinfection is being assessed, it is useful to install online transmittance monitoring equipment to document the variations that occur in the transmittance with time. Alternatively, a bench-top photometer may be used to sample UV transmittance manually. Sampling with a photometer will provide "snapshots" of UV transmittance as opposed to constant measurements from an online monitor. If enough "snapshots" are taken, fairly accurate UV transmittance trending data can be determined, which may be equal in accuracy to the online monitoring data.

Effect of Particles. The presence of particles in the wastewater to be irradiated can also impact the effectiveness of UV disinfection (Qualls et al., 1983; Parker and Darby, 1995; Emerick et al., 1999). The manner in which particles can affect UV performance is illustrated on Fig. 12–40. Many organisms of interest in wastewater (e.g., coliform bacteria) occur both in a dispersed state (i.e., not bound to other objects) and a particle-associated state (i.e., bound to other objects such as other bacteria or cellular debris). Coliform bacteria are of particular importance because of the central role they play in discharge permits [i.e., coliform bacteria are used as indicators for the presence of other pathogenic organisms (see Chap. 2) and their inactivation is assumed to correlate with the inactivation of other pathogenic organisms]. Dispersed coliform bacteria are inactivated readily because they are exposed fully to the average UV light intensity as compared to particle-embedded microorganisms (see Fig. 12–40). Treatment process related disinfection problems, when disinfecting unfiltered effluent, usually result from the influence of particle associated organisms (see also Fig. 12–5). In fact, coliform bacteria can associate with particles to such a degree that they are completely shielded from UV light resulting in a residual coliform bacteria concentration post UV irradiation.

It has been observed in activated sludge effluents that a minimum particle size (on the order of 10 μm) governs the ability to shield coliform bacteria from UV light (Emerick et al., 2000). Due to the inherent porous nature of activated sludge particles, particles smaller than that critical size are unable to reduce the applied intensity and thus embedded organisms are inactivated in a manner similar to dispersed organisms. Particles greater than the critical size can either reduce the applied UV intensity, leading to a reduced inactivation rate for organisms associated with the particle, or shield coliform bacteria. Particle size does not appear to be a governing factor once the critical size is exceeded because coliform bacteria are located randomly within particles, are not typically located in the most shielded regions within particles, and common enumeration techniques typically exclude the larger sized particles.

Table 12–32

Typical UV dosages required to achieve different effluent total coliform disinfection standards for various wastewaters

Type of wastewater	Initial coliform count, MPN/100 mL	UV dose, mJ/cm², Effluent standard, MPN/100 mL: 1000	200	23	≤2.2
Raw wastewater	10^7–10^9	20–50			
Primary effluent	10^7–10^9	20–50			
Trickling filter effluent	10^5–10^6	20–35	25–40	40–60	90–110
Activated sludge effluent	10^5–10^6	20–30	25–40	40–60	90–110
Filtered activated sludge effluent	10^4–10^6	20–30	25–40	40–60	80–100
Nitrified effluent	10^4–10^6	20–30	25–40	40–60	80–100
Filtered nitified effluent	10^4–10^6	20–30	25–40	40–60	80–100
Microfiltration effluent	10^1–10^3	5–10	10–15	15–30	40–50
Reverse osmosis	~0	—	—	—	5–10
Septic tank effluent	10^7–10^9	20–40	25–50		
Intermittent sand filter effluent	10^2–10^4	10–20	15–25	25–35	50–60

Characteristics of the Microorganisms. The effectiveness of the UV disinfection process depends on the characteristics of the microorganisms as well as the microorganism group. Typical values for the disinfection of coliform organisms with UV light for various wastewaters are reported in Table 12–32. It should be noted that the dosage values given in Table 12–32 are only meant to serve as a guide for the initial estimation of the required UV dose. The range of the reported values reflects the variable nature of wastewater. The relative effectiveness of UV irradiation for disinfection of representative microorganisms of concern is in wastewater is reported in Table 12–33. As with the values given in Table 12–5, the values given in Table 12–33 are only meant to serve as a guide in assessing the relative UV dose required for different microorganisms. Knowledge concerning the required UV dose for specific pathogen inactivation is changing continuously as improved methods of analysis are applied. For example, before infectivity studies were conducted, it was thought that UV irradiation at reasonable dosage values (i.e., less than 200 mJ/cm^2) was not effective for the inactivation of *Cryptosporidium parvum* and *Giardia lamblia*. However, based on infectivity studies, it has been found that both of these protozoans are inactivated with extremely low UV dosage values (typically in the range of 5 to 15 mJ/cm^2) (Linden et al., 2001; Mofidi et al., 2001; Mofidi et al., 2002). The current literature should be consulted to obtain the most contemporary information regarding required UV dosages for the inactivation of specific microorganisms.

Impact of System Characteristics. Problems with the application of Eq. (12–8) for use in the design of UV disinfection reactors are associated with (1) inaccurate knowledge of the average UV intensity and (2) the exposure time associated with all of the pathogens passing through a UV disinfection system. In practice, field-scale UV disinfection

Table 12–33

Estimated relative effectiveness of UV radiation for the disinfection of representative microorganisms of concern in wastewater

Organism	Dosage relative to total coliform dosage
Bacteria	
Escherichia coli (E.coli)	0.6–0.8
Fecal coliform	0.9–1.0
Pseudomonas aeruginosa	1.5–2.0
Salmonella typhosa	0.8–1.0
Streptococcus fecalis	1.3–1.4
Total coliform	1.0
Vibrio cholerae	0.8–0.9
Viruses	
Adenovirus	6–8
Coxsackie A2	1.2–1.2
MS-2 bacteriophage	2.2–2.4
Polio type 1	1.0–1.1
Rotavirus SA 11	1.4–1.6
Protozoa	
Acanthamoeba castellanii	6–8
Cryptosporidium parvum	0.4–0.5
Cryptosporidium parvum oocysts	1.3–1.5
Giardia lamblia	0.3–0.4
Giardia lamblia cysts	0.3–0.4

[a] Relative doses based on discrete non clumped single organisms in suspension. If the organisms are clumped or particle associated, the relative dosages have no meaning.

reactors have dose distributions resulting from both the internal intensity profiles and exposure time distribution. The internal intensity profiles are a reflection of the nonhomogeneous placement of lamps within the system, lack of ideal radial mixing within the system, the scattering/absorbing effects of particulate material, and the absorbance of the liquid medium. The distribution associated with exposure time is a reflection of non-ideal hydraulics leading to longitudinal mixing.

One of the most serious problems encountered with UV disinfection systems in both open and closed channel systems is achieving a uniform velocity field in the approach and exit to and from the UV banks. Achieving a uniform velocity field can be especially difficult when UV systems are retrofitted into existing open channels, such as converted chlorine contact basins. A second equally serious problem with UV system hydraulics is even flow distribution between channels whether the channels are new or are a retrofit of existing structures. An uneven flow split can lead to overdosing in one channel and most importantly, underdosing in the other(s) therefore compromising disinfection performance. Ensuring ideal flow distribution to multiple channels and uniform velocities within those channels is critical. To optimize the hydraulic performance of UV disinfection systems, computational fluid dynamics (CFD) modeling should be considered.

Estimating UV Dose

The first step in assessing the performance of a UV disinfection system is to determine the UV dose needed to inactivate the challenge microorganism to a level prescribed by the treatment plant discharge permit and/or is protective of public health in water reuse applications. Three methods have been used to estimate the UV dose. In the first method, an average UV dose is determined by assuming an average system UV intensity and exposure time. The average UV intensity is estimated using a computational procedure known as the point source summation (PSS) method (U.S. EPA, 1992). Over the past decade, the PSS method has been used less frequently by designers due to its failure to account for system-specific hydraulics (i.e., ideal hydraulic behavior is assumed in the PSS that never occurs in field-scale disinfection systems). At present, this method should not be used to determine UV dose.

The second method involves the use of CFD to integrate both the distribution of UV intensities and velocity profiles within the reactor to obtain a distribution of UV doses within a system (Batchley et al., 1995). Although the CFD method is promising, its use is limited at the present time (2013) because (1) the methodology is not standardized, (2) the methodology has been unable to predict disinfection performance adequately, and (3) the reporting of a distribution of UV doses, even if accurate, is problematic for UV disinfection system specification. In the third, and most widely used method, the UV dose is determined using a collimated beam bioassay. Use of the bioassay approach in designing UV disinfection systems is discussed below.

Determination of UV Dose by Collimated Beam Bioassay. The most common and industry accepted procedure for determining the required UV dose for the inactivation of challenge microorganisms involves the use of a collimated beam and a small reactor (i.e., a Petri dish) to which a known UV dose is applied. Typical collimated beam devices are shown on Fig. 12–41. Use of a monochromatic low-pressure low-intensity

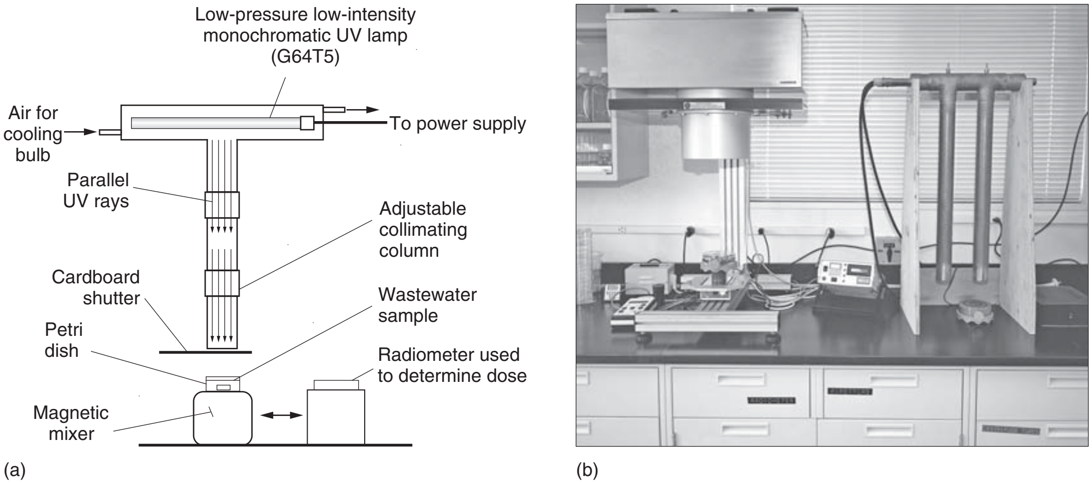

Figure 12–41

Collimated beam device used to develop dose-response curves for UV disinfection: (a) schematic and (b) view of two different types of collimated beam devices. The collimated beam on the left is of European design; the collimated beam on the right is of the type shown schematically in (a).

lamp in the collimated beam apparatus allows for accurate characterization of the applied UV intensity. Use of a batch reactor allows for accurate determination of exposure time. The applied UV dose, as defined by Eq. (12–8), can be controlled by simply varying the exposure time and maintaining a constant, known UV intensity. Because the geometry is fixed, the depth-averaged UV intensity within the Petri dish sample (i.e., the batch reactor) can be computed using the following relationship.

$$D = I_o t(1 - R)P_f\left[\frac{(1 - 10^{-k_{254}d})}{2.303(k_{254}d)}\right]\left(\frac{L}{L + d}\right) \tag{12–64}$$

$$D = I_o t(1 - R)P_f\left[\frac{(1 - e^{-2.303k_{254}d})}{2.303(k_{254}d)}\right]\left(\frac{L}{L + d}\right) \tag{12–65}$$

where D = average collimated beam UV dose ($I_o \times t$), mJ/cm^2
I_o = incident UV intensity averaged over the surface of the sample before and after irradiating sample, mW/cm^2
t = exposure time, s
R = reflectance at the air water interface at 254 nm
P_f = Petri dish factor
k_{254} = absorbance of sample, absorptivity, a.u./cm (base 10)
d = depth of sample, cm
L = distance from lamp centerline to liquid surface, cm

The term $(1 - R)$ on the right side of Eq. (12–64) accounts for the reflectance at the air water interface. The value of R is typically about 2.5 percent. The term P_f accounts for the fact that the UV intensity may not be uniform over the entire area of the Petri dish. The value of P_f is typically greater than 0.9. The term within the brackets is the depth averaged UV intensity within the Petri dish and is based on the Beers-Lambert Law (see Example 2–5, Chap. 2). The final term is a correction factor for the height of the UV light source above the sample. The application of Eq. (12–64) is illustrated in Example 12–11.

The uncertainty of the computed UV dose can be estimated using the sum of the variances as given by either of the following expressions:

Maximum Uncertainty

$$U_D = \pm \sum_{n=1}^{N}\left|U_{V_n}\frac{\partial D}{\partial V_n}\right| \tag{12–66}$$

Best Estimate of Uncertainty

$$U_D = \pm\left[\sum_{n=1}^{N}\left(U_{V_n}\frac{\partial D}{\partial V_n}\right)^2\right]^{1/2} \tag{12–67}$$

where U_D = uncertainty of UV dose value, mJ/cm^2
U_{V_n} = uncertainty or error in variable n
V_n = variable n
$\partial D/\partial V_n$ = partial derivative of the expression with respect to the variable V_n
N = number of variables

The maximum estimate of uncertainty as given by Eq. (12–66) represents the condition where every error will be a maximum value. The best estimate of uncertainty, as given by Eq. (12–67), is used most commonly because it is unlikely that every error will be a maximum at the same time and the fact that some errors may cancel each other. The application of Eq. (12–67) is illustrated in Example 12–11. Knowledge of the average UV intensity and exposure time allows calculation of the average applied UV dose using Eq. (12–8). The UV dose is then correlated to the microorganism inactivation results as discussed below.

EXAMPLE 12–11 **Determination of UV Dose Delivered in Collimated Beam Test** The following measurements were made to establish the UV dose using a collimated beam. Using these data determine the average UV dose delivered to the sample and best estimate of the uncertainty associated with the measurement.

$I_o = 5 \pm 0.35$ mW/cm^2 (accuracy of meter ±7%)

$t = 60 \pm 1$ s

$R = 0.025$ (assumed to be the correct value)

$P_f = 0.94 \pm 0.02$

$k_{254} = 0.065 \pm 0.005$ cm^{-1}

$d = 1 \pm 0.05$ cm

$L = 40 \pm 0.5$ cm

Solution

1. Using Eq. (12–64) estimate the UV dose delivered by the collimated beam.

$$D = I_o t(1 - R)P_f\left[\frac{(1 - 10^{-k_{254}d})}{2.303(k_{254}d)}\right]\left(\frac{L}{L + d}\right)$$

$$= (5 \times 60)(1 - 0.025)(0.94)P_f\left[\frac{(1 - 10^{-0.065 \times 1})}{2.303(0.065 \times 1)}\right]\left(\frac{40}{40 + 1}\right)$$

$$= (300)\,(0.975)\,(0.94)\,(0.928)\,(0.976) = 249 \text{ mJ/cm}^2$$

2. Determine the best estimate of uncertainty for the computed UV dose. The uncertainty of the computed dose can be estimated using Eq. (12–67). The procedure is illustrated for one of the variables and summarized for the remaining variables.

   a. Find the variability in the measured UV dose due to the variability of the measured time t. The partial derivative of the expression used in step one with respect to t is

$$U_t\frac{\partial D}{\partial t} = U_t\left\{I_o(1 - R)P_f\left[\frac{(1 - 10^{-k_{254}d})}{2.303(k_{254}d)}\right]\left(\frac{L}{L + d}\right)\right\}$$

$$U_t\frac{\partial D}{\partial t} = (1)\left\{5(1 - 0.025)(0.94)\left[\frac{(1 - 10^{-0.065 \times 1})}{2.303(0.065 \times 1)}\right]\left(\frac{40}{40 + 1}\right)\right\}$$

$$= 4.15 \text{ mJ/cm}^2$$

$$U_{D,t} = \pm\left[\left(U_t\frac{\partial D}{\partial t}\right)^2\right]^{1/2} = \pm[(4.15 \text{ mJ/cm}^2)^2]^{1/2} = \pm 4.15 \text{ mJ/cm}^2$$

   Percent = $100\, U_{D,t}/D = 100(4.15/249) = 1.67\%$

   b. Similarly, for the remaining variables, the corresponding values of the partial derivatives are as given below:

   $U_{D,I_o} = 17.44$ mJ/cm^2 and 7.0%

   $U_{D,P_f} = 5.30$ mJ/cm^2 and 2.13%

   $U_{D,k_{254}} = 1.40$ mJ/cm^2 and 0.56%

   $D_{D,d} = 1.21$ mJ/cm^2 and 0.49%

   $U_{D,L} = 0.076$ mJ/cm^2 and 0.03%

c. The best estimate of uncertainty using Eq. (12–67) is

$$U_D = \pm\,[(4.15)^2 + (17.44)^2 + (5.30)^2 + (1.40)^2 + (1.21)^2 + (0.076)^2]^{1/2}$$

$$= \pm 18.8 \text{ mJ/cm}^2$$

$$\text{Percent} = (100 \times 18.8)/249.0 = 7.55 \text{ percent}$$

3. Based on the above uncertainty computation the most likely UV dose is

$$D = 249 \pm 19 \text{ mJ/cm}^2$$

Comment Based on the best estimate of uncertainty, the most conservative estimate of the UV dose that can be delivered consistently, based on the collimated beam test, is 230 mJ/cm^2 (249 − 19). The maximum uncertainty would correspond to the summation of the individual errors and would be ± 30 mJ/cm^2.

Bioassay Testing. To assess the degree of microbial inactivation that can be achieved at a given UV dose, the concentration of microorganism is determined before and after exposure in a collimate beam (see Fig. 12–41). Microorganisms inactivation is measured using the most probable number (MPN) procedure or the membrane filtration test for bacteria, a plaque count procedure for viruses, or an animal infectivity procedure for protozoa. To verify the accuracy of the laboratory collimated beam dose-response test data, the collimated beam test must be repeated to obtain statistical significance. To be assured that stock solution of the challenge microorganisms is mono-dispersed, the laboratory inactivation test data must fall within an accepted set of quality control limits. Quality control limits proposed by the National Water Research Institute (NWRI, 2003) and the U.S. EPA (2003b) for Bacteriophage MS2 are as follows.

NWRI

$$\text{Upper bound: } -\log_{10}(N/N_o) = 0.040 \times D + 0.64 \tag{12–68a}$$

$$\text{Lower bound: } -\log_{10}(N/N_o) = 0.033 \times D + 0.20 \tag{12–68b}$$

U.S. EPA

$$\text{Upper bound: } -\log_{10}(N/N_o) = -9.6 \times 10^{-5} \times D^2 + 4.5 \times 10^{-2} \times D \tag{12–69a}$$

$$\text{Lower bound: } -\log_{10}(N/N_o) = -1.4 \times 10^{-4} \times D^2 + 7.6 \times 10^{-2} \times D \tag{12–69b}$$

where D = UV dose, mJ/cm^2

As will be illustrated in Example 12–12, the bounds proposed by the U.S. EPA are more lenient as compared to those used by NWRI. Similar bounding curves have been proposed for *B. subtilus* (U.S. EPA, 2003b). The NWRI guidelines are used for water reuse applications.

EXAMPLE 12–12 Verification of Laboratory Procedures for Bacteriophage MS2 Response The following collimated beam test results were obtained for a stock solution of bacteriophage MS2 which is to be used to test a UV reactor. These results are used to verify that the laboratory test results are acceptable and define the dose response equation.

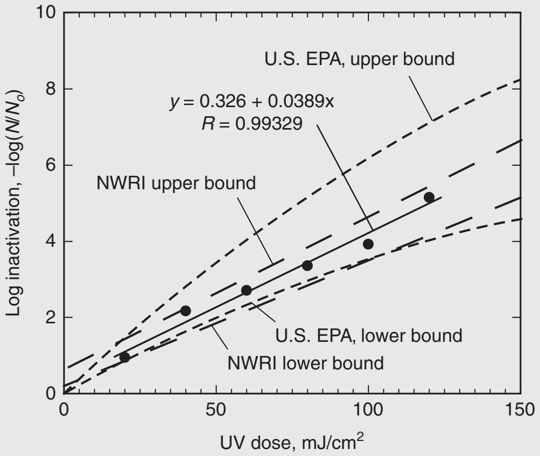
Dose, mJ/cm^2	Surviving concentration, phage/mL	Log survival,[a] log (phage/mL)	Log inactivation
0	1.00E + 07	7.000	0.000
20	1.12E + 06	6.049	0.951[b]
40	7.41 + 04	4.870	2.130
60	1.95E + 04	4.290	2.710
80	4.37E + 03	3.640	3.360
100	1.02E + 03	3.009	3.991
120	7.08E + 01	1.850	5.150

[a] The rule followed in the log transformation of a number is to retain in the mantissa the same number of significant figures as in the number that is being transformed.

[b] Sample calculation: Log inactivation = 7.000 − 6.049 = 0.951.

Solution

1. Plot the collimated beam test results and compare to the quality control range expressions provided in the NWRI [Eqs. 12–68(a) and 12–68(b)] and U.S. EPA [Eqs. 12–69(a) and 12–69(b]) UV Guidelines. The results are plotted on the figure given below.



2. As shown in the above plot all of data points fall within the acceptable range as defined by both NWRI and U.S. EPA.
3. Define the dose response relationship. Based on a linear regression analysis, the UV dose response relationship is

$$\text{UV dose} = \frac{\text{log inactivation} - 0.326}{0.0389}$$

Comment In general, when conducting bioassay testing, the initial concentration of MS2 should be 2-log higher than the number of logs of inactivation to be achieved. Irradiated samples should be diluted so that number of plaque forming units per plate is between 20 and 200 (NWRI, 2012).

Reporting and Using Bioassay Collimated Beam Test Results. The results of collimated beam bioassays are reported in the form of a dose response curve as developed in Example 12–12 and shown on Fig. 12–42. The inactivation curve shown on Fig. 12–42(a)

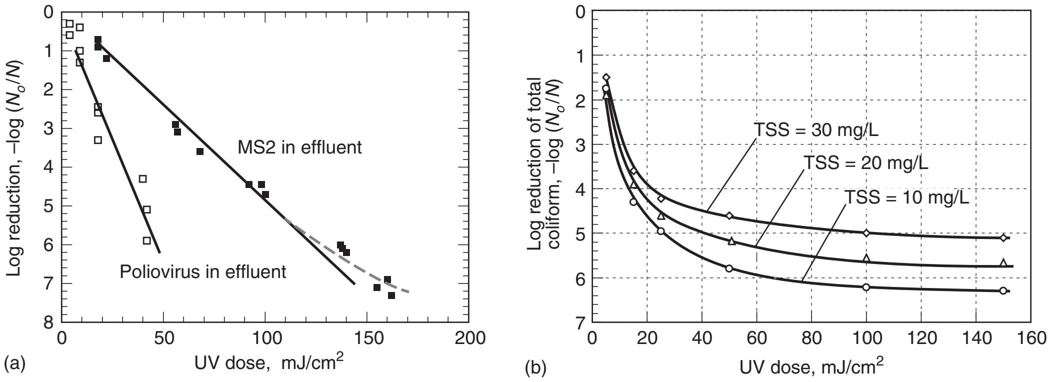


Figure 12–42

Typical dose response curves for UV disinfection developed from data obtained using a collimated beam device: (a) for dispersed microorganisms (Cooper et al., 2000) and (b) wastewater containing varying concentrations of TSS.

is for discrete organisms (MS2 and poliovirus) exposed to UV light, whereas the curve shown on Fig. 12–42(b) is for total coliform treated wastewater containing particulate material. In practice, the linear portion of the dose response curve for MS2 coliphage typically is between 20 and 120 mJ/cm^2. Below about 20 mJ/cm^2 there is uncertainty in the measurements and in the nature of the operative disinfection mechanism. Beyond about 120 mJ/cm^2 the presence of particles and/or particle clumping in wastewater samples causes a shoulder effect similar to the tailing effect observed with chlorine disinfection (see Fig. 12–6). In the literature, a polynomial curve passing through the origin is often used to fit all of the dose response data including the shoulder effect. The problem with a polynomial curve fit is that there is no theoretical basis for its use and the operative disinfection mechanisms are not the same at low and high UV doses. However, in the region where most UV reactors are tested, there is little difference between the linear and polynomial dose response curves. Additional details on the collimated beam protocol using MS2 coliphage can be found in the NWRI Guidelines (2012).

Ultraviolet Disinfection Guidelines

The National Water Research Institute and the American Water Works Association Research Foundation published "Ultraviolet Disinfection Guidelines for Drinking Water and Wastewater Reclamation" (NWRI, 1993; NWRI and AWWARF, 2000; NWRI, 2003; NWRI, 2012). The following elements are considered in the UV guidelines: (1) reactor design, (2) reliability design, (3) monitoring and alarm design, (4) the field commissioning test, (5) performance monitoring, and (6) an engineering report for unrestricted effluent reuse applications. Some of the items may not be applicable when utilizing UV disinfection for less demanding applications.

The guidelines that cover reclaimed water are similar to those that cover drinking water systems. The primary difference is that recommended (or mandatory) doses are provided for reclaimed water systems, whereas there is no mention of recommended doses for non-reclaimed wastewater applications. For reclaimed water systems, the recommended design UV doses for various effluents are 100 mJ/cm^2 for media filtration or equivalent effluent, 80 mJ/cm^2 for membrane filtration effluent, and 50 mJ/cm^2 for reverse osmosis effluent. The different dose requirements reflect the different virus density concentrations expected within each type of treatment process effluent. For example, the dosage of 100 mJ/cm^2 for media filtration effluent is intended to provide 5 logs of poliovirus inactivation with a factor of safety of about 2.

In addition to differing dose recommendations as a function of effluent quality, there are differing design transmittance recommendations. For granular medium and other types of filtration, microfiltration, and reverse osmosis effluents, the design transmittance's are 55, 65, and 90 percent, respectively. The differing transmittance values are based on field observations made to date, though site-specific variation does occur and should be accounted for. All UV disinfection systems installed for either drinking water or unrestricted reuse applications must undergo validation testing prior to their installation. Although the guidelines do not apply to the disinfection of non reclaimed wastewater, the general design issues addressed are applicable. The IUVA Manufacturer's Council has published a "low dose" bioassay approach (IUVA, 2011).

Relationship of UV Guidelines to UV System Design

The design of a UV disinfection system involves a number of issues including (1) determination of the UV dose required, based on bioassay testing, for adequate inactivation of the challenge (target) microorganism(s), (2) selection of manufacturer-specific validated UV disinfection reactors or systems, (3) determination of process operational parameters and UV system configuration (e.g., the number of lamps per module, modules per bank, banks per channel, and the overall number of channels) and, in some circumstances, (4) conduct of a spot-check bioassay test on the full-scale system to check compliance with the required UV design performance. For reclaimed wastewater applications, the first issue is addressed directly in the UV guidelines as discussed above. For the majority of applications which are not disinfecting for reclaiming water, an appropriate dose must be selected. Guidance on dose selection is provided in Table 12–33. Beyond this guidance, collimated beam tests should be performed on the actual wastewater to determine an appropriate dose to use for UV system design. A final resource for dose selection is information from UV equipment manufacturers, who maintain an extensive databases detailing dose requirements for varying disinfection limits, varying solids contents, and varying plant processes.

The general procedure for validating a UV reactor and some important guidance on design aspects are also included in the guidelines. Because of their fundamental importance in understanding the application of UV disinfection systems, these issues are discussed in the text and illustrated in the examples that follow.

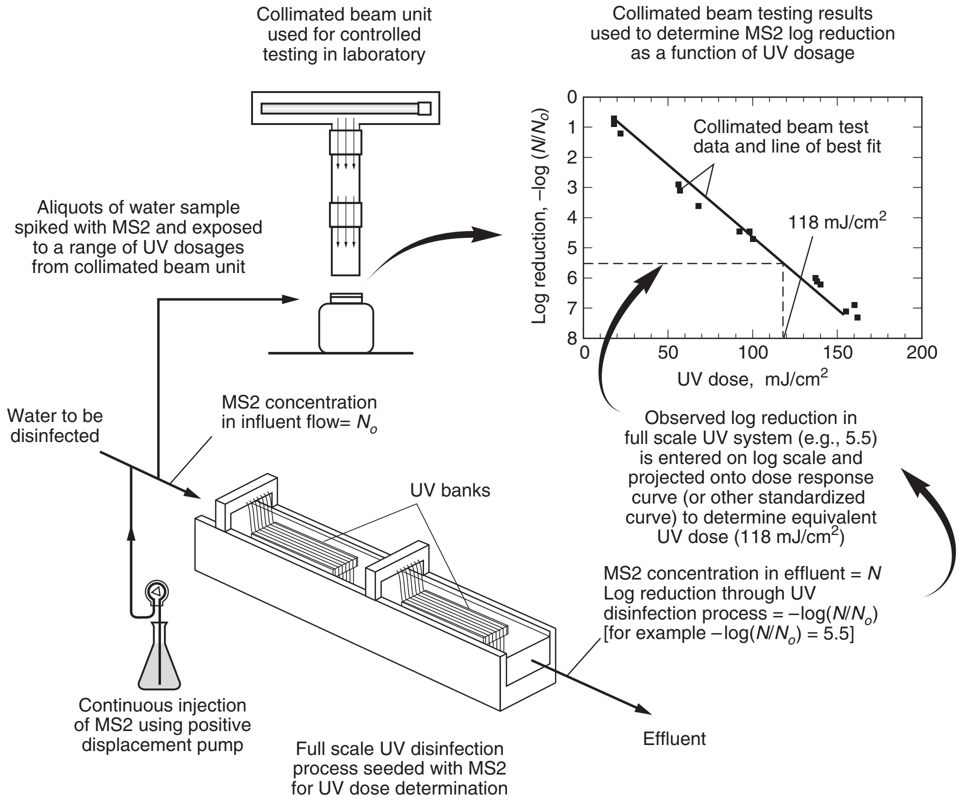
Validation of UV Reactor or System Performance

Validation testing consists of quantifying the level of inactivation of a virus surrogate (e.g., Bacteriophage MS2) by the UV disinfection reactor or system as a function of a number of process variables such as flowrate, transmittance, sensor settings, water level (where appropriate), and power settings. To quantify the inactivation achieved through the UV disinfection system, the UV dose response of the challenge microorganism to be used is determined using a collimated beam illustrated on Fig. 12–43. The inactivation observed through the UV disinfection reactor or system is compared to the UV dose response to establish a term called *reduction equivalent dose* (RED) or *delivered dose*, which corresponds to the UV dose delivered by the UV disinfection system. It should be noted that the RED is specific to the challenge organism and the test conditions.

In the past, validation testing was done once a UV system was installed and operational. To avoid unnecessary testing and the risk that an installed system does not perform adequately, validation testing is now typically completed by UV equipment manufacturers at test centers in the United States or at selected treatment facilities around the world. The manufacturers then provide design engineers with design information on which to base the

Figure 12–43

Schematic illustration of the application of biodosimetry as used to determine the performance of a test or full scale VU reactor.



design of a full-scale installation. The process flow diagram used for testing both open and closed UV reactors is illustrated on Fig. 12–44. In general, validation testing of UV disinfection equipment, using the setup shown on Fig. 12–44(a), consists of the following steps:

1. Selection of representative test water for use in the validation testing of the disinfection system.
2. Selection of the configuration of the UV disinfection system to be tested (i.e., 1, 2, 3, etc. UV banks in series). If the power to the UV lamps cannot be turned down to simulate the end of life lamp performance for a portion of the testing, then aged UV lamps must be used in the test.
3. Hydraulic performance testing of the UV disinfection system is done to verify the uniformity of the approach and exit velocities.
4. Quantification of the inactivation of the test organism (e.g., MS2) through the UV test reactor [see Fig. 12–44(b)] as a function of hydraulic loading rate and other variables.
5. Simultaneous with the field testing, a collimated beam test is conducted on the test water to determine the inactivation response of the viral test organism as a function of applied UV dose. The laboratory test data must fall within the area bounded by Eqs. (12–68a) and (12–68b) or Eqs. (12–69a) and (12–69b) given previously.
6. Assign UV doses to the pilot reactor or system based on the standardized dose response relationship (see NWRI, 2012). In the past, the dose response relationship developed from the collimated beam test was used.
7. Based on the assigned UV dose and the operative control parameters, manufacturers will develop design equations for the test reactor or system.

The steps required in conducting a validation test are illustrated in Example 12–13.

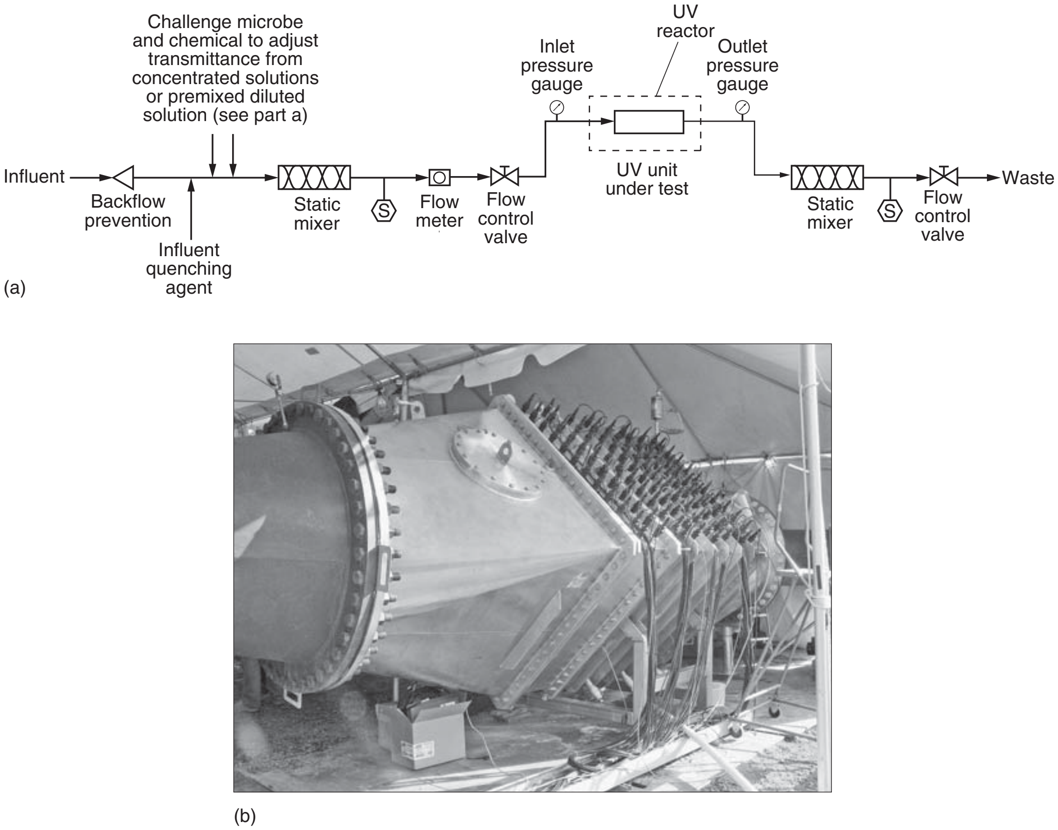


Figure 12–44

Validation testing of UV reactors: (a) schematic of the experimental test setup and (b) view of large closed UV reactor undergoing validation testing.

EXAMPLE 12–13 **Analysis of Pilot Test Results Used to Validate Performance of UV Reactor or Disinfection System** A manufacturer has supplied a pilot scale UV disinfection system whose performance is to be validated as a function of lamp hydraulic loading rate and water quality only. Other important variables such as power variation and water level variation are not included in this example. Operational curves are to be based on flowrate alone and flowrate and transmittance. For this test, the manufacturer chose to make use of a four-lamp per bank pilot facility with three banks in series to achieve the total applied dose. Each bank of lamps is hydraulically independent of subsequent banks. The engineer and owner are interested in knowing the range of flowrates and water quality over which the UV system can deliver a UV dose of 80 mJ/cm^2, before any design correction factors are applied. Assume the MS2 UV dose response curve given in Example 12–12 will be used for the analysis of the test results. The test program and the results of the field tests are as follows.

Solution

1. Develop test program.

   The testing was conducted on tertiary effluent from a local water reclamation facility. New lamps were placed in the pilot facility, as it would take more than a year to age the lamps. Normal transmittance of the tertiary effluent used is 75 percent. The first series of tests was conducted at a transmittance of 75 percent. In the second series of tests a transmittance reducing agent (e.g., SuperHume® or coffee) was injected into the effluent stream to lower the transmittance to 55 percent. The manufacturer has specified that the UV disinfection system should be tested for hydraulic loading rates ranging from 20 to 80 L/min·lamp, calculated as the flow in L/min·bank divided by the number of lamps in one bank. It should be noted that in a three-bank system, often each bank is tested separately to determine whether there are any inlet or outlet hydraulic conditions that would impact performance.

Because the titer of the virus indicator (i.e., MS2 bacteriophage) to be used for performance testing was approximately 1 × 10^{11} phage/mL, it was decided to test the system under the conditions outlined in the following table.

Hydraulic loading rate, L/min·lamp (1)	Flowrate, L/min·bank (2)	Virus titer Concentration, phage/mL (3)	Virus titer injection flowrate, L/min (4)	Approximate resulting virus concentration in process flow, phage/mL (5)
20	80	1E+11	0.008	1E+7
40	160	1E+11	0.016	1E+7
60	240	1E+11	0.024	1E+7
80	320	1E+11	0.032	1E+7

Notes on column entries:

(1) Desired range to be tested as specified by the manufacturer.

(2) The pilot system contained three banks with 12 lamps total; however, the hydraulic loading rate is only based upon the flowrate through one bank, which makes the calculation more similar to a velocity determination. Thus, at a hydraulic loading rate of 20 L/min·lamp, the process flowrate is equal to 80 L/min·bank [(20 L/min·lamp)(4 lamps/bank)].

(3) Provided by the laboratory.

(4) It was desired to obtain a virus titer in the process flow of about 1 × 10^7 phage/mL. Therefore, at 80 L/min, the solution containing the virus had to be injected at a rate of 0.008 L/min to obtain the desired initial titer.

2. Test results at 75 percent transmittance.

In conducting the test, each flowrate was tested randomly with respect to order. Three distinct replicate samples were collected per flowrate. An inlet and outlet sample (i.e., that contained the concentration of phage prior to any inactivation) was collected with each process replicate.

a. The inlet test results at 75 percent transmittance are as follows:

Flowrate, L/min·lamp	Replicate	Inlet concentration, phage/mL	Log-transformed inlet conc., log(phage/mL)[a]	Average log-transformed inlet conc., log(phage/mL)
20	1	5.25E+06	6.720	
20	2	1.00E+07	7.000	6.927
20	3	1.15E+07	7.061	
40	1	1.00E+07	7.000	
40	2	1.23E+07	7.090	7.067
40	3	1.29E+07	7.111	

(*continued*)

(*Continued*)

Flowrate, L/min·lamp	Replicate	Inlet concentration, phage/mL	Log-transformed inlet conc., log(phage/mL)[a]	Average log-transformed inlet conc., log(phage/mL)
60	1	1.23E+07	7.090	
60	2	1.05E+07	7.021	7.030
60	3	9.55E+06	6.980	
80	1	1.23E+07	7.090	
80	2	1.20E+07	7.079	7.023
80	3	7.94E+06	6.900	

[a] The rule followed in the log transformation of a number is to retain in the mantissa the same number of significant figures as in the number that is being transformed.

b. The outlet test results at 75 percent transmittance, based on triplicate samples, are as follows. Only the average log-transformed outlet concentration values from the 75 percent transmittance test are given. The procedure followed in obtaining these values was the same as illustrated above for the inlet test results.

Flowrate, L/min·lamp	Number of banks	Average log-transformed outlet conc., log(phage/mL)
20	2[a]	2.233
40	3	1.832
60	3	3.232
80	3	3.591

[a] Notice that at the low flowrate investigated (20 L/min·lamp), only two operational banks were investigated rather than 3. Only two banks were tested because three operational banks resulted in no detectable viruses in the effluent. Because the banks were hydraulically independent, it is allowed under the UV Guidelines to investigate the inactivation for only two banks and extrapolate to performance expected for additional banks of lamps.

3. Test results at 55 percent transmittance.
For the purposes of this example, assume the average log-transformed inlet concentration values from the 75 percent transmittance test apply to the 55 percent transmittance test. Only the average of the triplicate log-transformed outlet concentration values from the 55 percent transmittance test are given. The procedure followed in obtaining these values was the same as illustrated above for the 75 percent test.

Flowrate, L/min·lamp	Number of banks	Average log-transformed outlet conc., log(phage/mL)
20	3	1.703
40	3	3.987
60	3	4.662
80	3	4.997

4. Using the test data and the given information develop the necessary UV regression equation for 75 percent transmittance based on **flowrate** only.
   a. Set up computation table to determine the UV dose based on the test results. Using the measured phage data determine the corresponding UV dose based on the log-linear regression expression developed in Example 12–12.

Flowrate, L/min·lamp	Average phage concentration, log(phage/mL)			Assigned UV dose, mJ/cm²	Log transformed values	
	Inlet	Outlet	Diff.		Flowrate	UV dose
20	6.927	2.233	7.041[a]	172.6[b]	1.301	2.237
40	7.067	1.832	5.235	126.2	1.602	2.101
60	7.03	3.232	3.798	89.3	1.778	1.951
80	7.023	3.591	3.432	79.8	1.903	1.902

[a] The inactivation for this flowrate was extrapolated from the two-bank results. Because the system is a three-bank system, the inactivation for three banks is 150 percent greater than the inactivation observed with two operational banks [7.041 = (6.927 − 2.233) × 1.5].

[b] Sample calculation. Using the linear regression expression derived from the collimated beam test in Example 12–12, the equivalent UV dose at a flowrate of 20 L/min·lamp is:

$$\text{UV dose} = \frac{\text{log inactivation} - 0.326}{0.0389}$$

$$\text{UV dose, mJ/cm}^2 = \frac{7.041 - 0.326}{0.0389} = 172.6$$

   b. Develop the UV operational design equation.
      i. Use a linear regression analysis to develop a regression equation based on water flowrate. Other equations are possible, depending on the control strategy (e.g., flowrate and transmittance, flowrate, transmittance, and power setting).
      ii. To complete a regression analysis, the flowrate and UV dose data must first be log transformed. The data are log transformed to develop a linear relationship that can be used with the linear dose response curve developed using the collimated beam (see Example 12–12). The log transformed data are presented in columns 6 and 7 in the table developed in Step 4.
      iii. Using the UV dose (column 7) as the dependent variable and the flowrate (column 6) as the independent variable, the following results are obtained using the linear regression analysis program in Excel or other statistical analysis program.

Model Parameters

Source	Value
Intercept	2.997
X1	−0.577

      iv. The equation for UV dose as a function of flowrate, based on the regression analysis, is

$$\log(\text{UV dose}) = 2.997 - 0.577\,(\log \text{flowrate}) \text{ or}$$

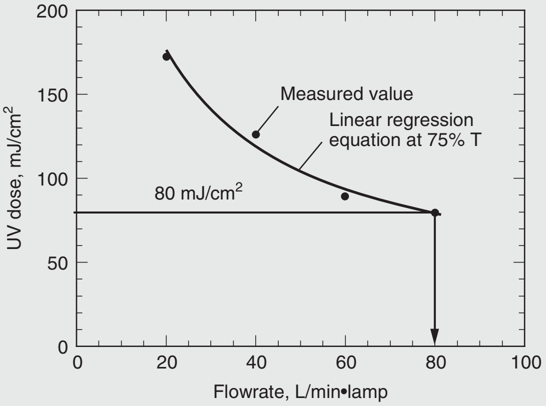
$$\text{UV dose, mJ/cm}^2 = (10^{2.997})[(\text{flowrate})^{-0.577}]$$

where the unit for flowrate is L/min·lamp

Note: The above dose equation is the delivered dose based upon three UV banks operating in series and with a UV transmittance (UVT) of 75 percent.

If the test had been conducted with one UV bank, the UV dose for two or three banks would be obtained by multiplying the regression equation for one UV bank by 2 or 3, respectively.

c. Plot the regression equation for UV dose versus the UV lamp hydraulic loading rate based on the results of the single variable (i.e., flowrate) linear regression analysis.



d. Determine the range of flowrates over which the UV disinfection system will deliver a UV dose of 80 mJ/cm^2. From the plot given above, the range of flows is up to 80 L/min·lamp.

5. Using the test data and the given information develop the necessary UV design curve based on **flowrate and transmittance**.

a. Set up computation table to determine the UV dose based on the test results. Using the measured phage data determine the corresponding UV dose based on the linear regression expression developed in Example 12–12.

Flowrate, L/min·lamp	T, %	Average phage concentration, log(phage/mL) Inlet	Outlet	Diff.	Assigned UV dose, mJ/cm^2	Log transformed values Flowrate	Transmittance	UV dose
20	75	6.927	2.233	7.041	172.6	1.301	1.875	2.237
40	75	7.067	1.832	5.235	126.2	1.602	1.875	2.101
60	75	7.03	3.232	3.798	89.3	1.778	1.875	1.951
80	75	7.023	3.591	3.432	79.8	1.903	1.875	1.902
20	55	6.927	1.703	5.224	125.9	1.301	1.740	2.100
40	55	7.067	3.987	3.08	70.8	1.602	1.740	1.850
60	55	7.03	4.662	2.368	52.5	1.778	1.740	1.720
80	55	7.023	4.997	2.026	43.7	1.903	1.740	1.640

b. Develop the operational design equation.

i. Use a linear regression analysis to develop an operational equation based on water flowrate and transmittance.

ii. To complete a regression analysis, the flowrate and UV dose data must first be log transformed. The log transformed data are presented in columns 7, 8, and 9 in the above table.

iii. Using the UV dose (column 9) as the dependent variable and the flowrate (column 7) and transmittance (column 8) as the independent variables, the following results are obtained using the linear regression analysis program in Excel or other statistical analysis program.

Model Parameters

Source	Value
Intercept	0.097
X1	−0.673
X2	1.631

iv. The equation for UV dose as a function of flowrate and transmittance, based on the linear regression analysis, is

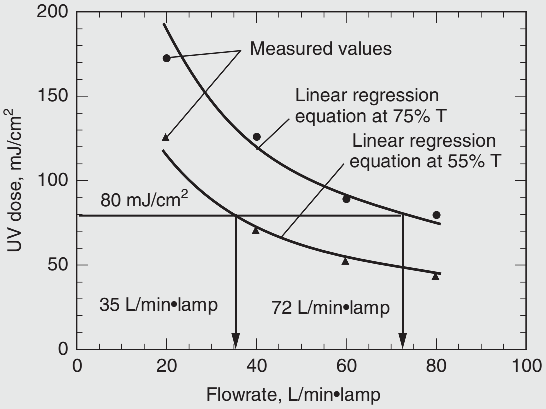
$$\log(\text{UV dose}) = 0.097 - 0.673\,(\log \text{flowrate}) + 1.631\,(\log \text{transmittance}) \text{ or}$$

$$\text{UV dose, mJ/cm}^2 = (10^{0.097})[(\text{flowrate})^{-0.673}][(\text{transmittance})^{1.631}]$$

where the units for flowrate and transmittance are L/min•lamp and percent, respectively.

Note: The above dose equation is the delivered UV dose based upon three banks operating in series and with UVT varying from 55 to 75 percent. If the UV validation test had been conducted with one bank, the UV dose for two or three banks would be obtained by multiplying the regression equation for one bank by 2 or 3, respectively.

c. Based on the results of the multiple variable (e.g., flowrate and transmittance) linear regression analysis, plot the curves of UV dose versus the UV lamp hydraulic loading rate for 75 and 55 transmittance, The required curves are shown on the following plot. It should be noted that the curve resulting from the multiple linear regression analysis for 75 percent transmittance is not exactly the same as that derived from the single variable (i.e., flowrate) linear regression analysis developed in Step 5. The reason for the difference is that the regression analysis with two variables must cover a significantly broader range of values as compared to a single variable regression analysis.



d. Determine the range of flowrates over which the UV disinfection system will deliver a UV dose of 80 mJ/cm². From the plot given above, the range of flowrates is up to 72 L/min·lamp at 75 percent transmittance and up to 35 L/min·lamp at 55 percent transmittance.

Comment When the lamps are new and the protective quartz sleeves are clean, it may not be necessary to operate all three banks, depending on the actual UV dose requirements of the full scale disinfection system.

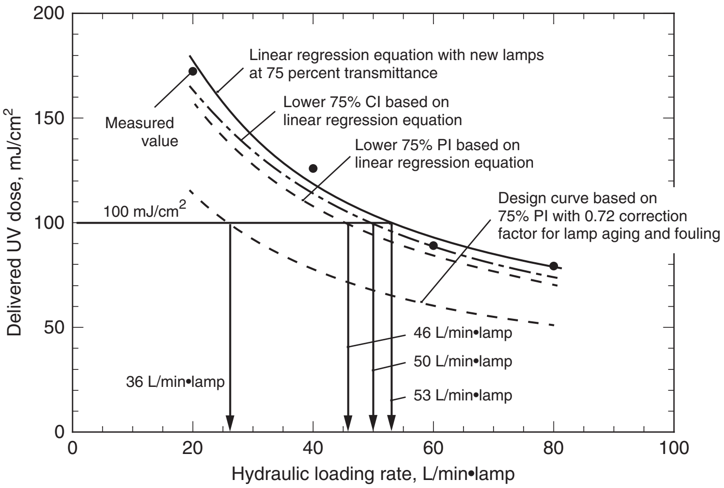
Factors Affecting UV System Design

Factors that affect the minimum number of UV lamps necessary for disinfection are (1) the UV lamp hydraulic loading rate based on the equipment validation test, (2) the level of confidence desired in meeting the permit requirements, and (3) the aging and fouling characteristics of the UV lamp/quartz sleeve assembly (discussed below). The validation of UV equipment has been considered in Example 12–13.

Confidence Level in Meeting Permit Limits. With respect to the level of confidence desired in the system performance it should be noted that the linear regression equations developed in Example 12–13 correspond to the line of best fit with half of the data points lying above and half lying below the predicted curve. Because some of the actual data points lie below the regression equation, a factor of safety must be used to account for the observed variability. One approach is to determine the confidence interval (CI) of the regression equation. Another is to develop a prediction interval (PI) based on the regression equation. The difference between the CI and the PI is as follows. The upper and lower CI for the regression analysis represents the interval in which the true average measurement is likely to lie if the procedure were repeated many times. Stated differently, a 75 percent confidence interval will contain the true mean value (not estimated value from data measurements) 75 percent of the time the interval is calculated. The upper and lower PI represents the interval in which a given percentage of new observations, independent of those used to develop the regression equation, will lie. Because there is more uncertainty in future measurements, the interval between the upper and lower PI limits is greater than that for the confidence interval, which is based on repeating the procedure an infinite number of times. The development of the PI is illustrated in Example 12–14. The relationship between the CI and PI and the regression equation are illustrated on Fig. 12–45.

Figure 12–45

Definition sketch illustrating the relationship between (1) the values measured in the UV reactor validation test, (2) the linear regression equation based on the measured values, (3) the lower 75 percent confidence interval (CI) based on the linear regression, (4) the lower 75 percent prediction interval (PI) based on the linear regression, and (5) the design curve based on the lower 75 percent PI with a combined correction factor for lamp aging and fouling.



Lamp Aging. As UV lamps age, the UV output from the lamps decreases. Aging factors range from 0.5 (NWRI default value in the absence of validation data to support a higher factor) to 0.98. However, manufacturers may gain approval of a higher (less conservative) factor if sufficient data are available to support an increase. As discussed previously, UV reactor validation is conducted with new lamps. Thus, when sizing a UV system, the validated performance must be de-rated by the lamp aging factor. For example, if 100 lamps are required to deliver a certain dose at a specific UVT, the UV system would need to be sized with 200 lamps so that when the lamps have aged and are producing 50 percent UV output compared to when they were new, the dose critical for disinfection is still being delivered. Lamp aging factors vary widely from vendor to vendor and from lamp to lamp. Aging factors range from 0.5 to 0.98.

Quartz Sleeve Fouling Factor. The correction factor for quartz sleeve fouling will vary between 0.7 and 0.95 depending on the cleaning system that is employed. For applications with high UVT, low solids and little iron present in the effluent, it is generally appropriate to accept a UV system vendor's validation of a higher factor (as high as 0.95 for mechanical cleaning systems). For chemical-mechanical cleaning system the fouling factor can be as high as 0.95 and should be validated independently of the UV system manufacturer. For any combination of low UVT, high solids, and high iron concentration in the effluent, a 0.8 (or lower) factor should be applied when sizing a UV system regardless of whether a UV system manufacturer has validation of a higher factor.

Application of Design Factors in UV System Sizing. With the variation of lamp aging factors from 0.5 to 0.98 and quartz sleeve fouling factors from 0.7 to 0.95, the combined design or correction factor can range from 0.35 to 0.94. The correction factor is applied to the PI to obtain the final design curve for the disinfection system. The importance of these correction factors can be assessed from a review of the plot given on Fig. 12–45. The design curve given on Fig. 12–45 is based on the lower 75 percent PI with a combined correction factor of 0.72 for lamp aging and fouling (0.72 factor based on an lamp aging factor of 0.9 and a quartz sleeve fouling factor of 0.8). Clearly, if the UV system had been designed on the basis of the manufacturer's design curve, the system would be undersized with respect to lamp aging and fouling. Determination of confidence and prediction intervals and the development of design equations taking into account lamp aging and fouling are illustrated in Example 12–14.

EXAMPLE 12–14 **Development of Operational UV Design Curves Taking into Account Variability and Aging and Fouling** Using the information from Example 12–13, develop design equations based on the PI alone and the PI with a factor for lamp aging and fouling. Also, determine the range of hydraulic loading rates over which the system can deliver a UV dose of 80 mJ/cm^2, based on the lower 75 percent PI with new lamps.

Solution Part A—Design equation based on flowrate alone

1. Define the lower 75 percent CI and PI limits for the regression equation developed in Example 12–13 based on flowrate alone. The regression equation is

   $$\text{UV dose, mJ/cm}^2 = (10^{2.997})[(\text{flowrate})^{-0.577}]$$

   where the unit for flowrate is L/min·lamp

   Based on the statistical analysis presented in Example 12–13, the assigned UV dose based on the field measurements, the predicted UV dose, the lower 75% CI, and the 75% PI values log transformed are given in the following table:

	Log-transformed values			
Flowrate, L/min·lamp	Assigned UV dose, mJ/cm^2	Predicted UV dose, mJ/cm^2	Predicted, 75% CI UV dose, mJ/cm^2	Predicted, 75% PI UV dose, mJ/cm^2
20	2.237	2.247	2.209	2.191
40	2.101	2.073	2.052	2.027
60	1.951	1.972	1.948	1.924
80	1.902	1.900	1.869	1.848

Although the lower 75 percent CI and PI values are obtained with a standard statistical program as given above, the procedure for determining these values is illustrated below for a linear regression expression with one variable–in this case, flowrate per lamp.

a. The lower 75 percent CI and PI intervals for the predicted mean response can be obtained using the following expressions:

   i. Confidence interval

$$\text{UV dose}_{75\%} = y_p - t_{\alpha/2} S \sqrt{\frac{1}{n} + \frac{(x - \bar{x})^2}{SS_{xx}}}$$

   ii. Prediction interval

$$\text{UV dose}_{75\%} = y_p - t_{\alpha/2} S \sqrt{1 + \frac{1}{n} + \frac{(x - \bar{x})^2}{SS_{xx}}}$$

where y_p = the predicted UV dose computed using the regression equation given above, mJ/cm^2
$t_{\alpha/2}$ = 1.706 which corresponds to the value of the t-distribution based on a 75% prediction level with $n - 2$ degrees of freedom
S = sample variance

$$S = \sqrt{\frac{\Sigma(y - y_p)^2}{n - 2}}$$

y = assigned UV dose from field measurements, mJ/cm^2
y_p = predicted UV dose, mJ/cm^2
n = number of sample pairs
x = flowrate, L/min·lamp
$\bar{x}$ = average flowrate, L/min·lamp
SS_{xx} = the sample corrected sum of squares

$$SS_{xx} = \sum_{1}^{n} (x - \bar{x})^2$$

b. Compute the values needed to determine the confidence intervals. Set up two computation tables, one for the UV dose and another for flowrate.

x	y	y_p	$(y - y_p)$	$(y - y_p)^2$
1.301	2.237	2.247	−0.010	0.000100
1.602	2.101	2.073	0.028	0.000784
1.778	1.951	1.972	−0.021	0.000441
1.903	1.902	1.900	0.002	0.000004
				0.001329

x	$(x - \bar{x})^a$	$(x - \bar{x})^2$
1.301	−0.345	0.119025
1.602	−0.044	0.001936
1.778	0.132	0.017424
1.903	0.257	0.066049
6.584		0.204434

[a] $\bar{x} = 6.584/4 = 1.646$

i. Solve for the sample variance, S.

$$S = \sqrt{\frac{0.001329}{4 - 2}} = 0.025778$$

ii. Solve for sample corrected sum of squares, SS_{xx}.

$$SS_{xx} = \sum_{1}^{n} (x - \bar{x})^2 = 0.204434$$

iii. Solve for the lower 75 percent CI at a flowrate of 40 L/min•lamp.

$$\text{UV dose}_{75\%\,\text{CI}} = y_p - t_{\alpha/2} S \sqrt{\frac{1}{n} + \frac{(x - \bar{x})^2}{SS_{xx}}}$$

The value of y_p, computed using the regression equation given above, is equal to 2.073. Thus,

$$\text{UV dose}_{75\%\,\text{CI}} = 2.073 - (1.706)(0.024434)\sqrt{\frac{1}{4} + \frac{0.001936}{0.204434}}$$

$$\text{UV dose}_{75\%\,\text{CI}} = 2.073 - (1.706)(0.024434)(0.509382) = 2.052$$

iv. Solve for the lower 75 percent PI at a flowrate of 40 L/min•lamp.

$$\text{UV dose}_{75\%\,\text{PI}} = y_p - t_{\alpha/2} S \sqrt{1 + \frac{1}{n} + \frac{(x - \bar{x})^2}{SS_{xx}}}$$

The value of y_p, computed using the regression equation given above, is equal to 2.073. Thus,

$$\text{UV dose}_{75\%\,\text{CI}} = 2.073 - (1.706)(0.024434)\sqrt{1 + \frac{1}{4} + \frac{0.001936}{0.204434}}$$

$$\text{UV dose}_{75\%\,\text{PI}} = 2.073 - (1.706)(0.024443)(1.122248) = 2.026$$

The CI and PI values computed manually are essentially the same as the values obtained from the linear regression analysis program as given in Step 1. Values computed manually may not be exact due to rounding errors that are magnified when dealing with log-transformed values.

2. Correct the lower 75 percent PI values for lamp aging and fouling.

   a. An overall correction factor of 0.72 is assumed for account for lamp aging and fouling. The correction factor for lamp aging is 0.9, based on the manufacturers recommendation. The corresponding fouling factor is 0.8. Note: the design engineer must decide if additional factors of safety may be required, depending on local conditions.

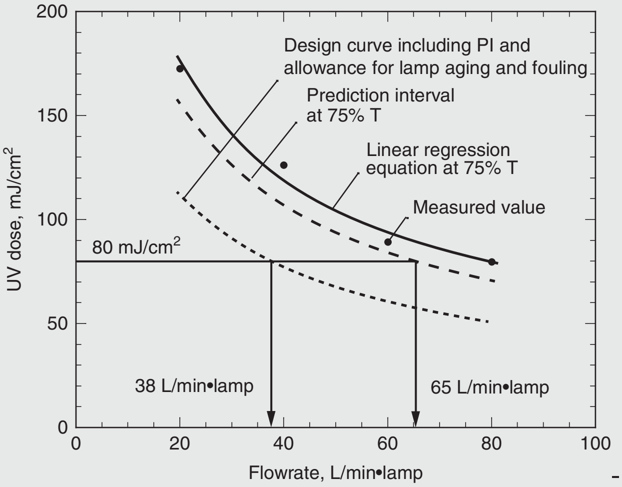
   The UV dose based on lamp aging and fouling is given in following table in which the log-transformed values have been transformed back to arithmetic form.

Flowrate, L/min·lamp	Assigned UV dose, mJ/cm^2	Predicted UV dose,[a] mJ/cm^2	Predicted UV dose at 75% PI, mJ/cm^2	Correction factor for lamp aging and fouling[b]	Design UVdose, mJ/cm^2
20	172.6	176.5	155.3	0.72	111.8
40	126.2	118.3	106.5	0.72	76.7
60	89.3	93.7	84.0	0.72	60.5
80	79.8	79.4	70.5	0.72	50.8

[a] From regression equation.

[b] Correction factor = Lamp aging factor (0.9) × fouling factor (0.8).

b. The measured values, the linear regression equation, the 75 percent PI curve, and the design curve based on the 75 percent PI and taking into account lamp aging and fouling are plotted on the following graph for 75 percent transmittance.



c. Determine the range of flowrates over which the UV disinfection system will deliver a UV dose of 80 mJ/cm^2, based on the lower 75 percent PI with new lamps. From the plot given above, the range of flowrates is up to 65 L/min·lamp at 75 percent transmittance.

3. Develop the design equations for the 75 percent PI curve, and the design curve based on the 75 percent PI and taking into account lamp aging and fouling for a transmittance value of 72 percent. The required equations can be be obtained by noting the ratio of the predicted PI UV dose to the predicted UV dose and the ratio of the design UV dose to the predicted UV dose as illustrated in the following table:

Predicted UV dose,[a] mJ/cm^2	Predicted UV dose at 75% PI, mJ/cm^2	Design UV dose,[b] mJ/cm^2	Ratio, PI/predicted UV dose	Ratio, Design/predicted UV dose
176.5	155.3	111.8	0.88	0.63
118.3	106.5	76.7	0.90	0.65
93.7	84.0	60.5	0.90	0.65
79.4	70.5	50.8	0.89	0.63

[a] From regression equation.

[b] Design equation based on PI with correction factor for lamp aging and fouling.

The ratios in the above table are not exact, because the prediction interval at the extremes of the range is greater than for the centermost values. Use of the ratio for the extremes of the range is conservative. Thus, the pertinent equations are

Design equation based on 75 percent PI

$$\text{UV dose, mJ/cm}^2 = (10^{2.997})[(\text{flowrate})^{-0.577}](0.88)$$

Design equation based on 75 percent PI and including lamp aging and fouling

$$\text{UV dose, mJ/cm}^2 = (10^{2.997})[(\text{flowrate})^{-0.577}](0.63)$$

where the unit for flowrate is L/min·lamp

Solution Part B—Design equation based on flowrate and transmittance

1. Define the lower 75 percent CI and PI limits for the regression equation developed in Example 12–13 based on flowrate and transmittance. The regression equation is

$$\text{UV dose, mJ/cm}^2 = (10^{0.097})[(\text{flowrate})^{-0.673}][(\text{transmittance})^{1.631}]$$

The computational procedure for the CI and PI values is similar to that illustrated above for a linear regression with one variable. In a multiple linear regression analysis, the computation of the CI and PI is more complicated because more three terms are involved. For this reason, the CI and PI values are usually determined using a standard statistical analysis program. The lower 75 percent CI and PI values for the regression equation are summarized in the following table for 75 and 55 percent transmittance.

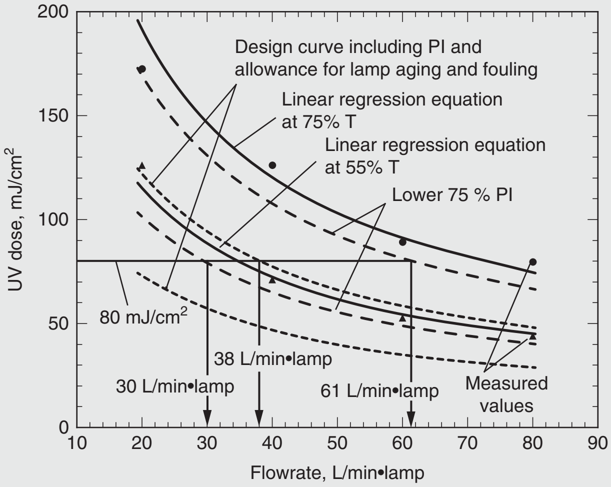
Log-transformed values				
Flowrate, L/min·lamp	Assigned UV dose, mJ/cm²	Predicted UV dose, mJ/cm²	Predicted, 75% CI UV dose, mJ/cm²	Predicted, 75% PI UV dose, mJ/cm²
75% transmittance				
1.30	2.237	2.280	2.248	2.227
1.60	2.101	2.077	2.056	2.029
1.78	1.951	1.959	1.936	1.910
1.90	1.902	1.875	1.847	1.824
55% transmittance				
1.30	2.100	2.060	2.028	2.006
1.60	1.850	1.857	1.835	1.809
1.78	1.720	1.739	1.715	1.690
1.90	1.640	1.654	1.627	1.604

2. Correct the lower 75 percent PI values for lamp aging and fouling.
   a. To account for lamp aging and fouling a correction factor of 0.72 will be applied. Note: the design engineer must decide if additional factors of safety may be required, depending on local conditions.

      The UV dose based on lamp aging and fouling is given in the following table in which the log-transformed values have been transformed back to arithmetic form.

Flowrate, L/min·lamp	Assigned UV dose, mJ/cm^2	Predicted UV dose, mJ/cm^2	Predicted UV dose at 75% PI, mJ/cm^2	Correction factor for lamp aging and fouling	Design UV dose, mJ/cm^2
75% transmittance					
20	172.6	190.5	168.5	0.72	121.4
40	126.2	119.5	107.0	0.72	77.0
60	89.3	91.0	81.3	0.72	58.5
80	79.8	74.9	66.6	0.72	48.0
55% transmittance					
20	125.9	114.7	101.5	0.72	73.1
40	70.8	72.0	64.4	0.72	46.4
60	52.5	54.8	49.0	0.72	35.3
80	43.7	45.1	40.1	0.72	28.9

b. The linear regression equation, the 75 percent PI curve, and the design curve taking into account lamp aging and fouling based on the lower 75 percent PI are plotted on the following graph for transmittance values of 75 and 55 percent.



c. Determine the range of flowrates over which the UV disinfection system will deliver a UV dose of 80 mJ/cm^2, based on the lower 75 percent PI with new lamps. From the plot given above the range of flowrates is up to 61 L/min·lamp at 75 percent transmittance and up to 30 L/min·lamp at 55 percent transmittance. The range of flowrates per lamp at 75 percent transmittance with aged and fouled lamps is up to 38 L/min·lamp.

3. Develop the design equations for the 75 percent PI curve, and the design curve based on the 75 percent PI and taking into account lamp aging and fouling for transmittance values varying from 55 to 75 percent. The required equations, developed as outlined above in Part 1, Step 4, are:

Design equation based on 75 percent PI.

$$\text{UV dose, mJ/cm}^2 = (10^{0.198})[(\text{flowrate})^{-0.674}][(\text{transmittance})^{1.5713}](0.88)$$

Design equation based on 75 percent PI and including lamp aging and fouling.

$$\text{UV dose, mJ/cm}^2 = (10^{0.198})[(\text{flowrate})^{-0.674}][(\text{transmittance})^{1.5713}](0.64)$$

where the units for flowrate and transmittance are L/min·lamp and percent, respectively.

Comment In both cases presented above and in previous sections discussing the impact of lamp aging and quartz sleeve fouling, the allowance made for these correction factors is significant as compared to the lower 75 percent PI. Thus, in evaluating UV disinfection systems, the selection of appropriate and validated lamp aging and fouling factors is of critical importance.

Selection and Sizing of a UV Disinfection System

Factors that affect the selection and sizing of a UV disinfection system include the selection and sizing of the UV disinfection reactor or system based on the UV design curve which takes into account the confidence and/or prediction interval associated with the hydraulic loading rate as determined in the equipment validation test and the lamp aging and fouling correction factors as illustrated in Example 12–13. The selection and sizing procedure for a UV disinfection system is illustrated in Example 12–15.

EXAMPLE 12–15 **Design of a UV Disinfection System for Secondary Effluent** Design a UV disinfection system for secondary effluent that will deliver a minimum design dose of 30 mJ/cm^2. Assume for the purpose of this example that the following data apply:

1. Wastewater characteristics
   a. Average design flowrate = 40,000 m^3/d = 27,778 L/min
   b. Maximum design flowrate = 100,000 m^3/d = 69,444 L/min (peak hour flow with recycle streams)
   c. Maximum total suspended solids = 20 mg/L
   d. Minimum transmittance = 65%
2. Fecal coliform discharge limit based on geometric mean
   200 FC/100 mL
3. System characteristics
   a. Horizontal lamp configuration
   b. From a validation study conducted on a single UV bank using the procedure described in Example 12–12, the following equation was developed based on the 75 percent PI with a lamp aging and fouling factor allowance of 72 percent.

   $$\text{UV dose, mJ/cm}^2 = (10^{-2.428})[(\text{flowrate})^{-0.650}][(\text{transmittance})^{3.126}](0.64)$$

   where the units for flowrate and transmittance are L/min·lamp and percent, respectively
   c. System headloss coefficient = 0.75 (manufacturer specific)
   d. Lamp/sleeve diameter = 23 mm
   e. Cross-sectional area of quartz sleeve = 4.15×10^{-4} m^2
   f. Lamp spacing = 75 mm (center to center)
   g. One standby UV bank will be required per channel

Solution

1. Determine the flowrate per lamp using the design equation based on the test conducted on a single UV bank. Based on the UV design equation for a dose of 30 mJ/cm^2, the corresponding flowrate per lamp is 258 L/min·lamp.

$$\text{Flowrate, L/min·lamp} = \left\{\frac{30}{(10^{-2.428})[(65)^{3.126}](0.64)}\right\}^{-(1/0.650)} = 258$$

2. Specify the flowrate range per UV channel assuming three channels will be in operation during peak flow conditions.
   i. Up to 24,000 L/min, use one channel
   ii. From 24,000 to 48,000 L/min, split the flow between two channels such that each channel receives up to 24,000 L/min.
   iii. From 48,000 to 72,000 L/min, split the flow between three channels such that each channel receives up to 24,000 L/min.
3. Determine the number of lamps required per bank.
   At 24,000 L/min, the total number of required lamps is:

$$\text{Lamps required, Lamps/bank} = \frac{(24{,}000\ \text{L/min·bank})}{(258\ \text{L/lamp·min})} = 93\ \text{lamps/bank}$$

4. Configure the UV disinfection system.
   Typically, 2, 4, 8, or 16 lamps per module are available. Using an 8 lamp module, 12 modules are required per bank for a total of 96 lamps per bank.

5. Determine the total number of lamps per channel including standby.

$$\begin{aligned}\text{Total number of lamps per channel} &= (2\ \text{banks/channel})(96\ \text{lamps/bank})\\ &= 192\ \text{lamps/channel}\end{aligned}$$

6. Determine total number of lamps.

$$\begin{aligned}\text{Total number of lamps per channel} &= (3\ \text{channel})(192\ \text{lamps/channel})\\ &= 586\ \text{lamps/channel}\end{aligned}$$

7. Check whether the headloss for the selected configuration is acceptable.
   a. Determine the channel cross-sectional area.

$$\begin{aligned}\text{Cross sectional area of channel} &= (12 \times 0.075\ \text{m})(8 \times 0.075\ \text{m})\\ &= 0.54\ \text{m}^2\end{aligned}$$

   b. Determine the net channel cross-sectional area by subtracting the cross sectional area of the quartz sleeves (4.15 × 10^{-4} m^2/lamp).

$$\begin{aligned}A_{\text{channel}} &= 0.54\ \text{m}^2 - [(12 \times 8)\ \text{lamps/bank}] \times (4.15 \times 10^{-4}\ \text{m}^2\text{/lamp})\\ &= 0.50\ \text{m}^2\end{aligned}$$

   c. Determine the maximum velocity in the channel.

$$v_{\text{channel}} = \frac{(24{,}000\ \text{L/min·channel})(0.001\ \text{m}^3\text{/L})(1\ \text{min/60s})}{0.5\ \text{m}^3} = 0.8\ \text{m/s}$$

   d. Determine the headloss per UV channel.

$$h_{\text{channel}} = 0.75\frac{v^2}{2g}$$

$$h_{\text{channel}} = \frac{(0.75)(0.80\text{ m/s})^2(1000\text{ mm/m})}{2(9.81\text{ m/s}^2)}(2\text{ banks}) = 49.0\text{ mm}$$

Note that 2 banks were used to determine system headloss. Use of two banks includes one redundant bank of lamps in each channel. The clear spacing between quartz sleeves is 52 mm (75 mm − 23 mm) and the headloss should not exceed this value.

8. Summarize the system configuration.
   System utilizes three channels, each channel containing two banks of lamps in series, one operational bank and one redundant bank. Each bank contains 12 modules, each of which contains 8 lamps.

Comment The majority of UV disinfection systems have the ability to turn banks of lamps on and off and vary power (and therefore UV output) to the banks that remain on. Turning UV lamps on and off is done automatically in response to varying flowrates and water quality (UVT). Varying the output of a UV system based on flow is accomplished by connecting a plant flowrate signal to the UV system's programmable logic controller (PLC). UVT can be manually entered based on readings taken from a bench-top photometer or based on continous readings from an online transmittance monitor.

Use of Spot-Check Bioassay to Validate UV System Performance

A spot-check-bioassay (SCB) test procedure has been developed to validate the performance of a newly installed and operational UV disinfection system. The test involves making a minimum of eight spot-check viral assays to demonstrate that the full-scale UV reactor performance complies with the design intent. Because new lamps are installed, the 75 percent PI is used as a reference. The CHPH has approved the use of the SCB test procedure to assess compliance of a full-scale disinfection reactor or system with the design intent. As implemented by CDPH, seven of the eight bioassay tests results must lie above the lower 75 percent PI predicted values. The rationale is that the percent ratio of seven out of eight is 87.5, which corresponds to the lower prediction interval. If more than one out of eight SCB test bioassays is below the PI curve, it is usually a clear indication that something may be wrong with the installation (e.g., poor inlet and outlet flow distribution, poor channel geometry, poor alignment, inappropriate weir placement, inappropriate flow control devices, inappropriate power settings, as well as other site conditions). If the installation site features can be corrected, they should be corrected, and the system should be retested. If the installation site features cannot be corrected, the UV system should be derated. The SCB test procedure along with the procedure for derating the UV system is illustrated in Example 12–16.

The SCB test procedure is similar to the procedure followed for UV reactor validation, as delineated in Example 12–14, Part A, with the exception that a wide range of operating conditions is evaluated. For example, consider a system comprised of two channels, each containing 4 banks of UV lamps. For such a system a typical test program might include four tests conducted under the following conditions:

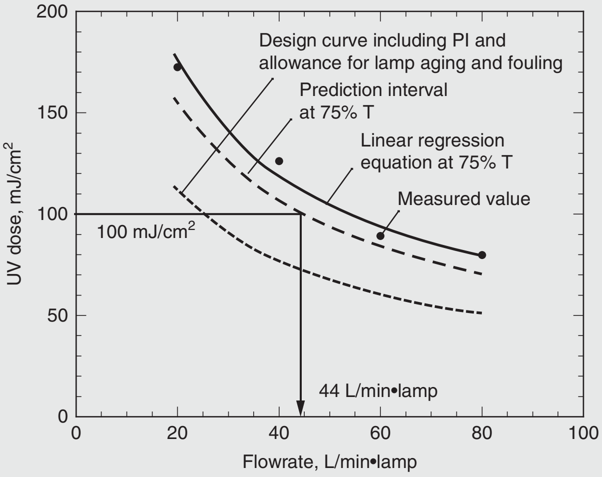
1. Maximum flowrate per lamp, minimum transmittance
2. Average flowrate per lamp, minimum transmittance
3. Maximum power setting, minimum transmittance
4. Minimum flowrate per lamp, minimum transmittance, first operational UV bank in sequence (i.e., 1, 2, 3, and 4)

Four additional tests could be conduced under the following conditions:

5. Ambient transmittance, maximum flowrate per lamp
6. Ambient transmittance, intermediate ballast output settings (60, 70, 80, or 90 percent)
7. Ambient transmittance, intermediate flowrates
8. Ambient transmittance, with the last operational UV bank in sequence (i.e., 1, 2, 3, and 4)

The goal of test 1 is to check performance under worst case conditions. The goal of test 2 is to check performance under typical flowrates and worst case water quality conditions. The goal of test 3 is to check performance under worst case water quality conditions at maximum power. The goal of tests 4 and 8 is to determine whether bank placement has an impact on operational performance. The goal of test 5 is to check performance under maximum flowrate per lamp and typical water quality conditions. The goal of test 6 is to check performance under different power settings. The goal of test 7 is to evaluate the performance of the UV system at various intermediate operating conditions. It should be noted that any number of test sequences can be used, as long as a wide range of operating conditions is evaluated.

EXAMPLE 12–16 **Conduct of Spot-check Bioassay to Validate Performance of Full-scale UV Disinfection System** A spot-check bioassay is to be conducted to validate the performance of a newly installed and operational UV disinfection system at a wastewater treatment plant. The UV system, validated in Example 12–14, is comprised of two channels, each containing four banks of lamps. Each bank contains 4 UV lamps oriented parallel to flow. The UV system was validated over a range of flowrates from 20 to 80 L/min·lamp at a transmittance of 75 percent. Based on the 75 percent PI, the UV system with new lamps will deliver a UV dose of 100 mJ/cm^2 up to a flowrate of 44 L/min·lamp, as shown in the following plot:



The regression equation is

$$\text{UV dose, mJ/cm}^2 = (10^{2.997})[(\text{flowrate})^{-0.577}]$$

The corresponding equation for the 75 percent PI is

$$\text{UV dose, mJ/cm}^2 = (10^{2.997})[(\text{flowrate})^{-0.577}](0.88)$$

Solution

1. Determine the maximum required flowrate for one channel.

   Max. flowrate = (4 lamp/bank)(44 L/min·lamp·bank) = 176 L/min

2. Determine the minimum required flowrate for one channel.

   Min. flowrate = (4 lamp/bank)(20 L/min·lamp·bank) = 80 L/min

3. Develop the test conditions.
   A minimum of eight spot-check viral assays must be conducted to demonstrate that full-scale UV reactor performance complies with the design intent.
   a. Bioassay test conditions.

Test No.	UVT, %	Operational banks	Flowrate, L/min	Hydraulic loading rate, L/min-lamp	Power setting, %
1	75	1, 2, 3	176	44	100
2	75	2, 3, 4	176	44	100
3	75	1, 3, 4	176	44	100
4	75	1, 2, 4	176	44	100
5	75	1, 2, 3	140	35	100
6	75	2, 3, 4	120	30	100
7	75	1, 3, 4	100	25	100
8	75	1, 2, 4	80	20	100

   b. Conduct spot-check bioassays.
      i. The first step is to conduct a quality assurance test to demonstrate that the laboratory procedures for the analysis of MS2 are valid (see Example 12–8).
      ii. The second step is to conduct the field spot-check bioassay tests. The log inactivation achieved from the field test and the assigned UV dose are as follows:

Test[a]	Log_{10} inactivation	UV Dose[b], mJ/cm^2
1	5.002	120.2
2	4.803	115.1
3	4.617	110.3
4	4.438	105.7
5	4.605	110.0
6	5.609	135.8
7	6.406	156.3
8	6.760	165.4

[a] See above table for operating conditions.

[b] The UV dose is based on the following equation:

$$\text{UV dose} = \frac{\text{log inactivation} - 0.326}{0.0389}$$

4. Compare the SCB test results to the values obtained from the linear regression equation and the PI equation.
   a. The two comparisons are presented in the following table:

Test	UV dose, mJ/cm^2 Predicted from regression equation	PI predicted from regression equation	Measured from spot check	Ratio spot-check/ predicted from regression equation	Ratio spot-check/ predicted PI from regression equation
1	111.9	98.4	120.2	1.07	1.22
2	111.9	98.4	115.1	1.03	1.17
3	111.9	98.4	110.3	0.99	1.12
4	111.9	98.4	105.7	0.94	1.07
5	127.7	112.3	110.0	0.86	0.98
6	139.5	122.8	135.8	0.97	1.11
7	155.0	136.4	156.3	1.01	1.15
8	176.3	155.2	165.4	0.94	1.07

   b. In comparing the SCB data to the regression equation it can be seen that the distribution of values is as would be expected, with a more or less equal distribution of values above and below the value obtained from the regression analysis.
   c. Based on the performance ratio, seven of the eight test results are above the predicted value of the PI, thus, the operation of the full-scale UV disinfection system is consistent with the design intent, as required by CDPH.
5. System adjustments for poor performance. In a situation in which more than one of the eight SCB test values lies below the PI curve, the following steps should be taken:
   a. Review the features of the installation, as discussed above, that may be leading to poor performance, correct any of the problems commonly encountered, and conduct a new SCB test.
   b. If the new test results are the same as the previous test, the UV system target UV dose set point must be adjusted or the system must be derated.
      i. Where the regulatory agency prefers not to modify the system dose equation, a site-specific target dose can be developed. The site-specific target dose can be computed using the following expression:

$$\text{Target UV dose} = \frac{\text{Design equation UV dose}}{\text{7th lowest 75\% PI spot check ratio}}$$

      The 7th lowest spot check ratio, based on the PI, is obtained as shown in column 5 in the above table. In this example the value is 0.94.
      ii. Alternatively, the system target UV dose can be derated using the following expression:

$$\text{UV dose}_{\text{Adj}} = \text{Design equation} \times \text{7th lowest 75\% PI spot check ratio}$$

      As above, 7th lowest spot check ratio, based on the PI, is 0.94.

Comment To avoid having to derate a UV system or change the target UV dose, it is imperative that careful attention be devoted to the design, installation, and operation of the UV disinfection system and its appurtenant facilities, especially the outlet control structure.

Troubleshooting UV Disinfection Systems

Problems associated with UV disinfection systems are related primarily to the inability to achieve permit limits. Some issues that must be considered when diagnosing problems associated with UV disinfection systems are discussed below.

UV Disinfection System Hydraulics. Perhaps one of the most serious problems encountered in the field is erratic or reduced inactivation performance due to poor system hydraulics. The most common hydraulic problems are related to (1) the creation of density currents that can cause the incoming water to move along the bottom or top of the UV lamp banks resulting in short circuiting, (2) inappropriate entry and exit conditions that can lead to the formation of eddy currents which ultimately create uneven velocity profiles that induce short circuiting, (3) the creation of dead spaces or zones within the reactor resulting in short circuiting, and (4) uneven flow distribution in systems with multiple channels leading to overloading in certain channels and underloading in others. The occurrence of short circuiting, channel overloading, and dead zones reduces the average contact time and leads to a decrease in UV dose and therefore compromises disinfection. When designing a UV system, the use of CFD modeling may be warranted to ensure hydraulic issues that could negatively impact disinfection performance are accounted for.

The principal hydraulic design features that can be used to improve system hydraulics in open channels include the use of (1) submerged perforated diffusers at the inlet of UV channel(s), (2) corner fillets in rectangular open channel systems with horizontal lamp placement, and (3) flow deflectors in open channel systems with vertical lamp placement. In rare cases, power input to mix the incoming flow may be necessary. Some of these corrective measures for open channel UV disinfection systems are illustrated on Fig. 12–46. Submerged perforated baffles should have an open area of about 4 to 6 percent of the cross-sectional area of the flow channel. Similar to open-channel systems, closed vessel UV systems may require similar design features to improve hydraulics through the reactors. Again, the use of CFD modeling may be of great value in studying the effect of various physical interventions in bringing about a more uniform approach velocity flow field (Sotirakos et al., 2013).

Biofilms on Walls of UV Channels and on UV Equipment. Another serious problem encountered with UV disinfection systems is the development of biofilms on the exposed surfaces of the UV reactor. The problem is especially serious in open channel systems covered with standard grating. It has been found that if the UV channels are exposed to any light, even very dim light, biofilms (typically fungal and filamentous bacteria) will develop on the exposed surfaces. The problem with biofilms is that they can harbor and effectively shield bacteria. When the clumped biofilms break away from the attachment surface, bacteria can be shielded as the clumps pass through the disinfection system. The best control measure is to completely cover the UV channels. Further, all concrete channels should be lined or coated to avoid the formation of bacterial colonies in the crevices and rough spots found in poured concrete. In addition, the channels can be cleaned and disinfected occasionally using hypochlorite, peracetic acid (see Sec. 12–8), or another suitable cleaning agent/disinfectant.

It should be noted that biofilm development can also occur in closed UV systems, but the severity is usually less, with the exception of UV systems in which medium-pressure high-intensity UV lamps are employed. Because medium-pressure high-intensity UV lamps emit some light in or near the visible light range (see Fig. 12–33) they can stimulate the growth of microorganisms on exposed surfaces. In some cases, growths approaching 300 mm in length have been found attached to the lamp support structure. The amount of

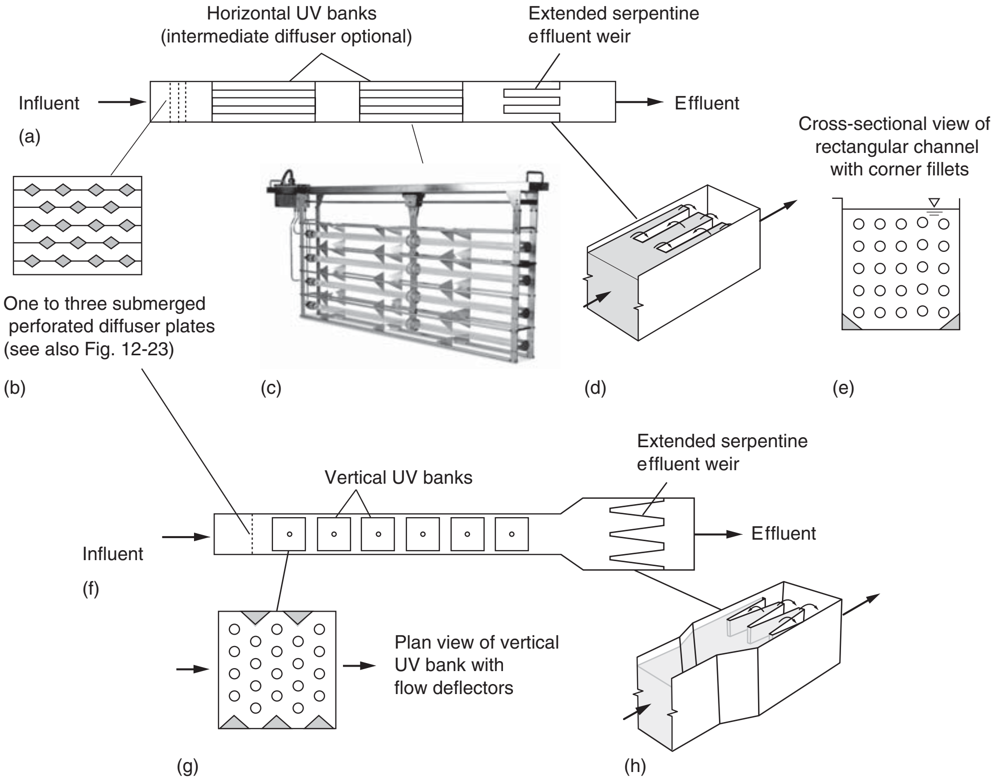


Figure 12–46

Typical examples of physical features that can be used to improve the performance of horizontal and vertical open UV reactors: (a) plan view of horizontal lamp UV system in channel with lining or coating, (b) perforated submerged diffuser plates to promote plug flow, (c) use of delta wings for enhanced internal mixing (courtesy of Calgon Carbon), (d) and (h) extended serpentine effluent weirs to promote plug flow, (e) elimination of dead space with corner fillets, (f) plan view of vertical lamp UV system in channel with lining or coating, and (g) use of baffle diffusers for enhanced internal mixing.

light emitted in the visible light range will vary with each type of lamp (i.e., manufacturer). Removal of these growths with a suitable disinfectant must be conducted on a periodic basis.

Overcoming the Impact of Particles by Increasing UV Intensity. It was thought at one time that the impact of particles on the performance of UV disinfection systems could be overcome by increasing the UV intensity. Unfortunately, it has been found that increasing the UV intensity tenfold has little effect on reducing the number of surviving particle-associated coliform bacteria because the absorption of UV irradiation by particles in wastewater is typically 10,000 times or more greater than the bulk liquid medium. Particles essentially block the transmission of UV light. Particles larger than a certain critical size (a function of the size of the target organism) will effectively shield the embedded microorganisms (Emerick et al., 1999; Emerick et al., 2000). Because the effectiveness of UV disinfection is governed primarily by the number of particles containing coliform bacteria, to improve the performance of a UV disinfection system, either the number of particles with associated coliform bacteria must be reduced (e.g., by modifying the treatment process mode of operation or by adding polymer to improve the performance of the secondary sedimentation facilities), or the particles themselves must be removed (e.g., by some form of filtration). Currently (ca. 2013), to meet the stringent total coliform bacteria requirements for body contact water reuse applications (i.e., equal to or less than 2.2 MPN/100 mL), some form of effluent filtration is required.

Effect of Treatment Processes on UV Performance. The number of particles with associated coliform bacteria, as well as their size, is another factor that will impact the performance of a UV disinfection system. As noted previously in Sec. 12–2, it has been observed that for activated sludge plants the number of particles with associated coliform organisms is a function of the SRT (see Fig. 12–5). Thus, both the mode of operation of the biological process and the design and operation of the secondary sedimentation facilities must be evaluated carefully, especially where an unfiltered effluent is to be UV irradiated. Even with effluent filtration, attention must be focused on the distribution of particle sizes in the filtered effluent (Darby et al., 1999; Emerick et al., 1999). Although the number of particle associated bacteria is reduced with long SRT values, it should be noted that the use of long SRT values leads to the formation of a larger number of particles for a given turbidity level. Dispersed particles are also difficult to filter and may pass through some filtration systems without violating turbidity limits, which, in turn, reduces the effectiveness of UV disinfection system.

Environmental Impacts of UV Radiation Disinfection

The environmental impacts associated with the use of UV disinfection for wastewater stem primarily from the fact that UV systems utilize much more electricity than other disinfection methods. To understand the carbon footprint of the system, the source of electricity for a UV system should be investigated. Because ultraviolet light is not a chemical agent, no toxic residuals are produced. However, certain chemical compounds may be altered by the ultraviolet irradiation. On the basis of the evidence to date, it appears that the compounds formed are harmless or are broken down into more innocuous forms at the dosages used for the disinfection of wastewater and reclaimed water (20 to 100 mJ/cm^2). Photooxidation, which does alter the structure of compounds, occurs above about 400 kJ/cm^2 range. Thus, the disinfection of wastewater with ultraviolet light is not considered to have any adverse environmental impacts. The impacts associated with some of the new very high-energy lamps, which may operate in the kilojoule range, is not known at present (ca. 2013).

12–10 DISINFECTION BY PASTEURIZATION

The process of heating food or water at a specified temperature and time for the purpose of killing microorganisms is known as *pasteurization*. The process was first demonstrated on April 20, 1862 in France by Pasteur and Bernard in response to a request by Emperor Napoleon III to save France's wine industry from what were called "diseases of wine" (Lewis and Heppell, 2000). The major contribution made by Pasteur was to define the exact time and temperature required to kill specific microorganisms, without affecting the taste of the wine. From the early beginnings, pasteurization is now used universally in the food industry to control pathogenic microorganisms. It is important to note that pasteurization is not intended to kill all microorganisms as compared to sterilization. Rather, it is intended to reduce the viable number of microorganisms present. Description of the pasteurization process, reported performance data, and regulatory requirements are discussed below.

Description of the Pasteurization Process

The operation of a pasteurization process is illustrated schematically on Fig. 12–47. As shown, effluent to be disinfected is introduced into the preheat reactor where heat from the

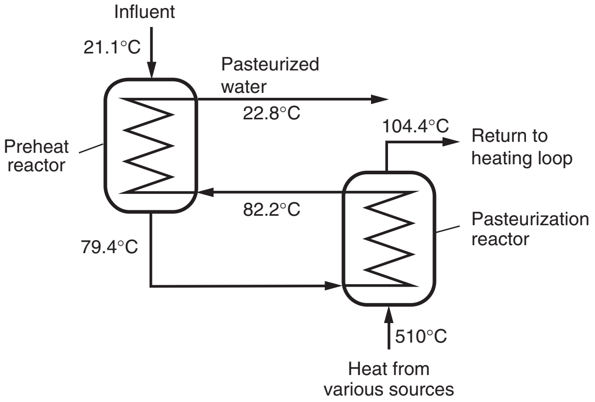

Figure 12–47

Definition sketch for the pasteurization process for the wastewater. (Adapted from Salveson et al., 2011.)

disinfected effluent is used to preheat the incoming effluent. The preheated effluent is then directed to the pasteurization reactor where heat from an external source is used to heat the preheated effluent to the desired temperature and where it is retained for a prescribed period of time. The external heat source can be from turbine exhaust, engine exhaust, waste gas burner exhaust, hot water, or from another suitable fluid. The reported temperature values shown on Fig. 12–47 are site specific and will depend on local conditions and the design of the heat exchange equipment.

Operationally, three different types of pasteurization are in use: (1) batch, (2) HTST (high-temperature short time) and (3) UHT (ultra-high temperature). Because of the large volumes required, batch pasteurization is only suitable for very small operations. Typical operational ranges for the three types of pasteurization are summarized in Table 12–34. The continuous flow HTST pasteurization process is used in most industrial operations and is the form used for the disinfection of treated wastewater. General operational data for the HTST process to achieve four-log inactivation of specific organism groups is presented in Table 12–35. The UHT pasteurization process, also known as flash pasteurization, is only used in more specialized applications.

Thermal Disinfection Kinetics

The disinfection performance of the pasteurization process depends on both temperature and holding time. As noted in Table 12–2, and as compared to other disinfection methods,

Table 12–34

General operating ranges for pasteurization technologies[a]

Pasteurization technology	Temperature		Time	Comments
	°C	°F		
Batch	62–64	144–147	30–35 min	Inactivates most vegetative bacterial calls including streptococci, staphylococci, and mycobacterium tuberculosis
High-temperature short time (HTST)	72–75	161–165	8–30s	Same effect as batch, but at much shorter times
Ultra-high temperature (UHT)	135–140	275–285	<1–5s	Lethal for most bacterial cells at even shorter times than HTST

[a] Adapted in part from Toder (2012), Hudson et al. (2003), Sorqvist (2003).

Table 12–35

General operating ranges for HTST pasteurization to achieve approximately 4-log inactivation of selected microorganisms

Microorganism	Temperature °C	Temperature °F	Time, s	Comments
Bacteria	72–77	161–170	6–16	
Protozoa	70–72	158–162	8–16	Essentially complete inactivation
Virus	80–85	176–185	10–30	
MS2 Coliphage	79–81	175–178	15–40	
Helminths	70–72	158–162	8–10	Essentially complete destruction

Various sources.

the high temperature is needed to denature the enzymes in the cell protoplasm and to alter the structure of the cell wall. The holding time is needed to complete the reaction within the cell and with the cell wall constituents. In a manner similar to chemical disinfection it has been observed that if the temperature is increased the time required to inactivate a given microorganism will decrease (Pflug et al., 2001).

First Order Kinetics. The microbial disinfection of microorganisms, at a specific temperature, can be modeled as a first order reaction as follows:

$$\frac{dN}{dt} = -kN \tag{12–70}$$

where N = the number of organisms surviving after time t
k = reaction rate constant, base e
t = the exposure time

The integrated form of Eq. (12–70) in base 10 is

$$N_t = N_o 10^{-Kt} \tag{12–71}$$

where N_t = the number of organisms remaining at time t
N_o = the initial number of organisms
K = reaction rate constant, base 10, Note K =0.4343k
t = time, s, min, h

The reaction rate constant, K, is given by

$$K = (\log N_o - \log N)/t \tag{12–72}$$

Heat Resistance Parameters. Two parameters, D and Z, are used commonly to describe the effectiveness of the pasteurization process (Goff, 2012; Pflug et al., 2001). The term D is a measure of the heat resistance of a given microorganism and corresponds to the time required to achieve 1-log of inactivation (i.e., 90 percent) at a given temperature T, as illustrated on Fig.12–48(a). Also known as the *decimal reduction time*, D, is given by the following expression:

$$D = 1/K = t/(\log N_o - \log N_t) \tag{12–73}$$

Using Eq. (12–73), Eq. (12–72) can be written as

$$N_t = N_o 10^{-t/D} \tag{12–74}$$

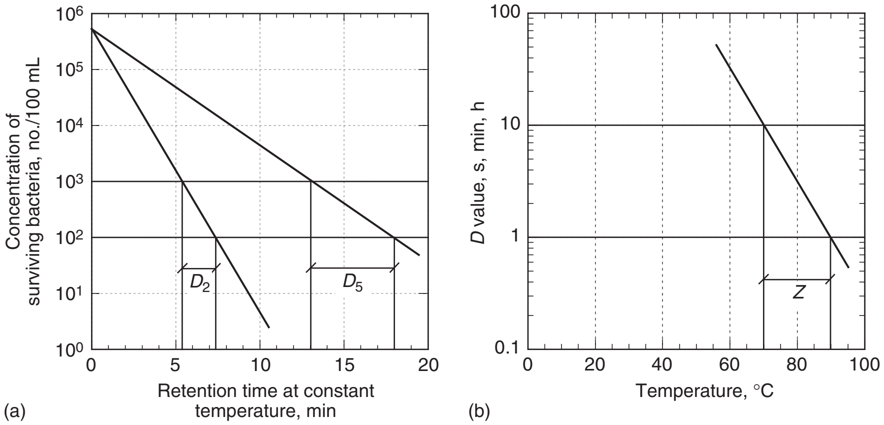

Figure 12–48

Definition sketches for the pasteurization process: (a) plot to determine the time, *D*, at constant temperature required to reduce the concentration of microorganisms by 1-log and (b) plot to determine, *Z*, the temperature increase required to reduce the *D* value by 1-log.

Each microorganism will have a specific value of D. It should be noted that the K and D values are only for a specific temperature. For example, at temperature T, an organism having a D value of 6 is less resistant than an organism with a D_T value of 10 [see Fig. 12–48(a)].

The term, Z, reflects the temperature dependence of D as illustrated on Fig. 12–48(b). The Z value corresponds to the temperature required to achieve 1-log change in the D value. The Z value is given by the following expression:

$$Z = (T_2 - T_1)/[\log(D_1) - \log(D_2)] \text{ or} \tag{12–75}$$

$$\log\left(\frac{D_1}{D_2}\right) = \frac{(T_2 - T_1)}{Z} \tag{12–76}$$

When D_1 and D_2 differ by one log, Eq. (12–76) reduces to

$$Z = (T_2 - T_1) \tag{12–77}$$

Using these two parameters, the heat resistance of a single microorganism can be quantified. Typical D and Z values for selected microorganisms are reported in Table 12–36. The values given in Table 12–36 are derived from a number of sources. The most extensive evaluation of D and Z values has been by Sorqvist (2003). Typical Z values for bacteria are in the range from 5 to 10. The application of the terms D and Z is illustrated in Example 12–17.

Non-Linear Inactivation. Although the equations for D and Z assume a more or less log-linear response, a number of researchers have observed both shoulder and tailing effects as described previously (see also Fig. 12–4). In general, the shoulder effect reflects the condition where the microorganism is less effected by temperature initially as compared to the subsequent linear inactivation phase. The tailing effect corresponds a period of reduced thermal destruction in which the response is less rapid than that that observed in the linear inactivation phase. In both cases, the effects are not understood completely (Hiatt, 1964). In addition, a number of other microorganisms such as spore forming bacteria *(B. anthracis and B. cereus)* exhibit a nonlinear response. Inactivation of spore-forming bacteria requires extremely high temperatures, especially if short contact times are to be used.

Table 12–36

Typical D and Z values for selected microorganisms[a]

	Temperature		*D*, s		*Z*, °C

[b] Computed *Z* values based on the typical *D* values given in column 5.

EXAMPLE 12–17 **Estimate Pasteurization Operating Conditions** Some new pasteurization equipment is to be installed to replace some existing equipment for the disinfection of an unknown strain of bacteria. The current equipment operates at a temperature of 65°C (150°F). The corresponding *D* and *Z* values for the bacteria are 10 s and 12°C, respectively. The initial bacterial count is 10^6 org/100 mL. If the new equipment is to operate at 77°C (170°F) for 4 s, what level of inactivation can be achieved? If the new equipment cannot be installed, what time would be required at a temperature of 65°C (150°F) to achieve 4 log removal?

Solution

1. Determine D_T at 77°C using Eq. (12–76).

$$\log\left(\frac{10.0\text{ s}}{D_2}\right) = \frac{(77 - 65)}{12} = 1.0$$

$$\left(\frac{10.0\text{ s}}{D_2}\right) = \text{inverse}\log(1.0) = 10.0$$

$D_2 = 10.0\text{ s}/10.0 = 1.0\text{ s}$

2. Determine the degree of inactivation using Eq. (12–73).

$$\log\left(\frac{N}{N_o}\right) = -4\text{s}/1.0\text{ s} = -4$$

Four-log inactivation can be achieved

3. Determine the time required to achieve a 4-log inactivation using the existing equipment. The required time can be estimated using Eq. (12–73).

$$\log\left(\frac{N}{N_o}\right) = -t/D_T$$

$$\log\left(\frac{N}{N_o}\right) = -4 = -t/10$$

$t = 4 \times 10 = 40\text{ s}$

Germicidal Effectiveness of Pasteurization

The literature on the thermal destruction of microorganisms in the food processing industry is vast. However, the literature on the disinfection of treated effluent is relatively limited. In a study completed recently, the use of UV and pasteurization were evaluated at pilot scale as possible replacements for the existing chlorine disinfection system. The secondary effluent was filtered. In the studies on pasteurization, conducted using proprietary equipment, contact times and temperatures were varied depending on the test organism (Salveson et al., 2011). Based on the test results for MS2 coliphage, it was found that within the range of times tested, contact time did not appear to be significant up to a temperature of about 73°C (163°F) (i.e., non-linear response). The temperature and time required to achieve a 4-log reduction of MS2 was on the order 80°C (176°F) and 7.7 s, respectively. These values are consistent with the values approved by the CDPH for pasteurization.

Regulatory Requirements

The CDPH has approved the use of the pasteurization process for the disinfection of treated effluent for Title 22 reuse applications. To achieve a 4-log virus reduction (based on MS2), the CDPH has set the temperature at 82°C (180°F) at a contact time of 10 s. For nonreuse applications where virus reduction is not needed, it may be possible to reduce the temperature to 74°C (165°F) and the time to 8 s. It is anticipated that these values will be revised as additional operational data are collected.

Application of Pasteurization for Disinfection

Pasteurization has been studied at a number of locations and has been found to have the lowest cost when compared to other disinfection technologies, and especially where waste heat is available (Salveson et al., 2011). A typical heat balance for the pasteurization process was shown previously on Fig. 12–47. The recovery of the heat from wastewater is another possibility that can be considered in the application of the pasteurization process. The survival of bacterial indicator species and bacteriophages in sludge and wastewater after thermal treatment has been studied (Moce-Uivina et al., 2003). The pasteurization of biosolids is considered further in Chap. 14.

PROBLEMS AND DISCUSSION TOPICS

12–1 Assuming Chick's law applies, determine the inactivation rate constant for total coliform for one of the following four treated effluents (sample to be selected by instructor). The effluent temperature was 20°C. If the activation energy for the disinfection reaction is 52 kJ/mole, determine the inactivation rate constant at 12°C.

	Time, min			
	Effluent sample			
Log of organisms remaining	1	2	3	4
8	0.0	0.0	0.0	0.0
7	1.8	5.5	3.8	2.6
6	3.6	11.5	8.0	5.5
5	5.6	17.5	12.3	8.0
4	7.4	23.5	16.5	11.0
3	9.2	20.9	20.9	13.9

12–2 Using the rate constant developed in Problem 12–1, determine the chlorine dose required to achieve a 99.99 percent inactivation of total coliform in 60 min at 15 and 25°C.

12–3 The following combined chlorine disinfection data were obtained in a series of laboratory tests performed on three different filtered activated sludge effluents:

	Residual fecal coliform count, no./100 mL		
	Test		
Combined chlorine CT, mg·min/L	1	2	3
0	10^6	10^6	10^6
50	10,000	199,500	316,000
100	10,200	31,600	63,000
200	126	800	4000
300	1	25	280
400		1	20
			1

a. Using these data, determine the value of the coefficient of specific lethality in Eq. (12–6) and the CT value to achieve a residual coliform count of 200/100 mL and 1000/100 mL.

b. Using the following data, determine the required volume in m^3 of a chlorine contact chamber designed to provide 60-min contact at the average winter flowrate. Using the equations developed in Part *a*, determine the minimum dosage required in mg/L to give the required kill for one of the test results given above (test condition to be selected by instructor). Assuming that the yearly chlorine requirement can be computed on the basis of the average flowrate for each of the two 6-mo periods, determine the minimum yearly chlorine requirement in kilograms.

Item	Unit	May-Oct	Nov-Apr
Average flowrate	m^3/d	20,000	26,000
Peak daily flowrate	m^3/d	40,000	52,000
Maximum permissible fecal coliform count in effluent	MPN/100 mL	200	1000

12–4 The following data were obtained for several filtered wastewater effluents. Using these data estimate the coefficients for the refined Collins-Selleck model [Eq. (12–27)] for wastewater number (to be selected by instructor).

	Time min			
	Wastewater number			
$-\log (N/N_o)$	1	2	3	4
1	2.1	6.9	2.9	3.5
2	4	15	5.9	8.1
3	7.1	36	12.3	18
4	13.6	80	24	40
5	21.5	190	55.5	90
6	42.3	430	115	200

Using the derived values, estimate the inactivation that could be achieved with a CT value of 30, 60, or 120 mg·min/L (value to be selected by instructor).

12–5 A consultant has proposed using chorine dosages of 15 and 8, 20 and 10, 30 and 20 mg/L during the summer and winter, respectively for effluent disinfection. If the effluent total coliform count before disinfection is 10^7/100 mL, estimate the final total coliform counts that can be achieved during the summer and winter with one of the dosage sets (to be selected by instructor).

1. Demand due to decay during chlorine contact = 2.0 mg/L
2. Required chlorine contact time = 45 min
3. Use the typical values given below for the coefficients.

   $b = 4.0$ and $n = 2.8$

12–6 The chlorine residuals measured when various dosages of chlorine were added to four different wastewater effluents are given below. For one of the effluents (to be selected by instructor), determine: (a) the breakpoint dosage and (b) the design dosage to obtain a free chlorine residual of 1, 2, or 3.5, mg/L (value to be selected by instructor).

	Residual, mg/L			
	Effluent number			
Dosage, mg/L	1	2	3	4
0	0	0	0	0
1	0	1	0	0
2	1	2	1	1
3	0.2	3	2	2
4	1	4	2.3	2.9
5	2	4.3	1.2	3.4
6	3	3.6	0.9	2.7
7		2.3	1.7	1.2

(*continued*)

Dosage, mg/L	1	2	3	4
8		0.7	2.7	1.2
9		0.7	3.7	2.1
10		1.7		3.1
11		2.8		4.1

12–7 Estimate the daily required chlorine dosage, the required alkalinity, if alkalinity will have to be added, and the resulting buildup of total dissolved solids when breakpoint chlorination is used for the seasonal control of nitrogen. Assume that the following data apply to this problem:

1. Plant flowrate = 4800 m^3/d
2. Effluent characteristics
   a. BOD = 15 mg/L
   b. Total suspended solids = 15 mg/L
   c. NH_3-N = 1, 1.25, or 1.5 mg/L (value to be selected by instructor)
   d. Alkalinity = 125, 145, or 165 mg/L as $CaCO_3$ (value to be selected by instructor)

12–8 Review the current literature and prepare an assessment of the use of chlorine gas versus sodium hypochlorite for the disinfection of treated wastewater. A minimum of 3 recent (after 2000) articles and/or reports should be cited in your assessment.

12–9 The following data were obtained from dye tracer studies of five different chlorine contact basins. Using these data, determine the mean hydraulic residence time and the corresponding variance, the t_{10} time, and the Morrill Dispersion Index and the volumetric efficiency for one of the basins (to be selected by instructor). How would the performance of the basin selected for analysis be classified according to the U.S. EPA guidelines?

12–10 Using the following dose response data for an enteric virus and the tracer data for four different chlorine contact basins, determine for one of the basins (to be selected by instructor) the expected effluent microorganism concentration based on the t_{10} and mean hydraulic residence times. Also estimate the chlorine residual that would be required to achieve 4 logs of removal with the existing basins.

Dose response data for enteric viruses

CT, mg/L·min[a]	Number of organisms remaining
0	10^7
100	$10^{6.2}$
200	$10^{5.4}$
400	$10^{3.8}$
600	$10^{2.1}$
800	$10^{0.6}$
1000	10^{-1}

[a] Combined chlorine residual = 6.0.

12–11 Determine the amount of sulfur dioxide (SO_2), sodium sulfite (Na_2SO_3), sodium bisulfite ($NaHSO_3$), sodium metabisulfite ($Na_2S_2O_5$), and activated carbon (C) that would be required per year to dechlorinate treated effluent containing a combined chlorine residual of 5.0, 6.5, 7.0, or 7.7 mg/L as Cl_2 (residual to be selected by instructor) from a plant with an average flowrate of 1500, 3300, 4600, or 7500 m^3/d (flowrate to be selected by instructor).

12–12 Estimate the immediate ozone demand and the first order decay equation for wastewater number (to be selected by instructor) using the following bench-scale steady-state and decay test data collected at 25°C. If the coefficient of specific lethality for the inactivation of a newly discovered microorganism with ozone is 0.15 L/mg·min, estimate the degree of inactivation that could be achieved at 15°C using an ozone contactor with 4 compartments following the injection of ozone. The theoretical detention time in each compartment is 3 min. Assume the activation energy for ozone for the new microorganism is 48 kJ/mole.

		Ozone residual, mg/L			
		Wastewater number			
Test	Ozone dose, mg/L	1	2	3	4
1	6		2.4	1.0	3.3
2	10	1.1	4.9	5.9	7.0
3	14	6.9	7.4	10.5	10.3
4	18	12.2	10.0	15.5	14.0
5	20	15.0	11.1	18.0	15.7

The corresponding decay data are:

	Ozone residual, mg/L			
	Wastewater number			
Time, min	1	2	3	4
0	3.8	2.8	2.0	3.25
5	2.25	1.4	1.37	2.3
10	1.35	0.72	0.95	1.65
15	0.82	0.37	0.67	1.19
20	0.50	0.19	0.46	0.84

12–13 Estimate the immediate ozone demand and the first order decay equation using the following bench-scale steady-state test data collected at 20°C. If a four-compartment ozone contactor, similar to the one shown on Fig. 12–31(a), is used, estimate the log reduction in *Cryptosporidium* that can be achieved at 5°C. Assume the activation energy for ozone for *Cryptosporidium* is 54 kJ/mole.

The steady-state test results are as follows.

Test	Ozone dose, mg/L	Ozone residual, mg/L
1	5	1.5
2	8	5
3	10	7.5
4	13	10.3
5	18	17.5

The corresponding decay data are:

Time, min	Ozone residual, mg/L
0	5
4	3
7	2.5
10	2

12–14 Given the following ozone decay test data, estimate the number of compartments that would be required in an ozone contactor to achieve 3-log reduction in *Cryptosporidium* based on test number (to be selected by instructor). Assume the theoretical detention time in each compartment is 3 min and the t_{10}/t for the reactor is 0.65.

	Ozone residual, mg/L			
	Test number			
Time, min	1	2	3	4
0	3.3	1.5	3.2	2.8
2	3.0		2.75	
4		1.0		2.1
6	2.0		1.8	
10		0.65		1.8
12	1.5		0.9	
16		0.3		1.6

12–15 Review the current literature and prepare an assessment of the use of ozone for the disinfection of treated wastewater. A minimum of three articles and/or reports dating back to 1995 should be cited in your assessment.

12–16 Review the current literature and prepare an assessment of the use of peracetic acid alone or in combination with other disinfectants. A minimum of three articles and/or reports dating back to 2000 should be cited in your assessment.

12–17 Given the following measurements and data for a collimated beam test, determine the average UV dose delivered to the sample and best estimate of the uncertainty associated with the measurement.

$I_m = 10 \pm 0.5$ mW/cm^2 (accuracy of meter ±7%)

$t = 30 \pm 1$ s

$R = 0.025$ (assumed to be the correct value)

$P_f = 0.94 \pm 0.02$

$\alpha = 0.065 \pm 0.005$ cm^{-1}

$d = 1 \pm 0.05$ cm

$L = 48 \pm 0.5$ cm

12–18 If the intensity of the UV irradiation measured at the water surface in a Petri dish is 12 mW/cm^2, determine the average UV intensity to which a sample will be exposed if the depth of water in the Petri dish is 10, 22, 14, 15, or 16 mm (water depth to be selected by instructor).

12–19 If the intensity of UV irradiation measured at the water surface in a Petri dish in Problem 12–18 is 8 mW/cm^2, and that the computed UV dose was based on a water depth of 10 mm. What would be the effect if the actual water depth in the Petri dish were 20 mm?

12–20 Determine the mean, the standard deviation, the 75 percent confidence interval, and the 75 percent prediction interval for following MS2 bacteriophage inactivation data, (test to be selected by instructor) obtained using a collimated beam device. What UV dose would be required to achieve a 4-log inactivation of MS2 based on the lower prediction interval of 75 percent?

	Log reduction, $-\log N/N_o$				
	Test number				
Applied UV dose, mJ/cm^2	1	2	3	4	5
20	0.9	1.7	1.4	1.1	1
40	1.7	3.3	2.6	2.2	1.8
60	2.4	5.2	4.1	3	2.8
80	3.5	6.5	5.1	4.3	3.7
100	4.3			5.5	4.7
120	4.9			6.2	5.4

12–21 In the latest edition of the NWRI UV Guidelines (NWRI, 2012), the standard dose response curve that should be used to evaluate reactor performance is given as

$$\text{UV dose} = \frac{\text{log inactivation} - 0.5464}{0.0368}$$

The dose response curve used in this chapter is:

$$\text{UV dose} = \frac{\text{log inactivation} - 0.326}{0.0389}$$

Compare the two curves for UV dosages of 20, 40, 60, 80, 100, and 120 mJ/cm^2 (dosages to be selected by instructor). Is the difference significant? Why is it reasonable to specify a standard curve that all equipment manufacturers should use to evaluate the performance of their equipment?

12–22 A UV reactor comprised of two banks with 4 lamps per bank was tested on two different reclaimed waters (1 and 2) at four flowrates using MS2 bacteriophage as the test organism. The transmittance for both wastewaters was 65 percent. The hydraulic loading rates were varied from 50 to 200 L/min·lamp. In conducting the test, each flowrate was tested randomly with respect to order. The measured inlet and outlet phage concentrations are as follows:

Flowrate, L/min	Replicate	Wastewater 1, phage/mL		Wastewater 2, phage/mL	
		Inlet	Outlet	Inlet	Outlet
200	1	9.65×10^6	3.80×10^1	1.05×10^7	2.19×10^2
200	2	1.00×10^7	3.98×10^1	6.98×10^6	1.54×10^2
200	3	1.15×10^7	3.72×10^2	1.15×10^7	1.70×10^2
400	1	1.00×10^7	1.95×10^3	1.00×10^7	3.75×10^2
400	2	1.29×10^7	1.55×10^3	1.23×10^7	3.62×10^2
400	3	9.55×10^6	1.77×10^3	1.12×10^7	3.08×10^2
600	1	1.23×10^7	1.12×10^3	1.20×10^7	1.32×10^4
600	2	1.05×10^7	9.33×10^3	1.05×10^7	1.05×10^4
600	3	1.25×10^6	8.91×10^3	9.55×10^6	9.95×10^3
800	1	1.13×10^7	4.79×10^4	1.03×10^7	5.95×10^4
800	2	1.08×10^7	8.35×10^4	1.19×10^7	1.00×10^5
800	3	8.95×10^6	6.61×10^4	1.11×10^7	7.68×10^4

Using the given data, for water 1 or 2 (water to be selected by instructor), develop design equations based on (1) the regression analysis, (2) the 75 percent prediction interval, and

(3) the 75 percent prediction interval taking into account lamp aging and fouling for a transmittance value of 72 percent. What is the maximum flowrate per lamp over which the UV system will deliver a dose of 50 mJ/cm^2? Assume the MS2 UV dose response curve given in Example 12–12 will be used for the analysis of the inactivation test results.

12–23 The following MS2 bacteriophage inactivation data were obtained for filtered wastewater with a transmittance of 55 percent at 254 nm with a UV pilot test unit comprised of 6 UV lamps in a single UV bank operated at various ballast settings. The reported inactivation test results are the average of triplicate samples. Determine the maximum flowrate, expressed as L/min·lamp, over which the UV disinfection system will deliver a dose of 100 mJ/cm^2 at a ballast setting of 100 percent, 80 mJ/cm^2 at a ballast setting of 80 percent, or 50 mJ/cm^2 at a ballast setting of 50 percent (ballast setting to be selected by instructor) taking into account lamp fouling and aging. Assume the lamp aging and fouling factor is 60 percent based on the regression equation developed for each ballast setting.

Flowrate, L/min	Ballast output, %	Log$_{10}$ MS2 bacteriophage inactivation
180	100	7.7559
180	80	6.7445
180	50	5.4219
400	100	6.3555
400	80	5.383
400	50	5.383
560	100	5.5775
560	80	4.7606
560	50	3.5547
732	100	5.0718
732	80	4.2549
732	50	3.2046

12–24 Using the data from Problem 12–23, develop the design curve based on the regression analysis taking into account flowrate and ballast settings. Plot the original data, the regression curve, and the 75 percent prediction interval.

12–25 Review the current literature and prepare an assessment of the use of low-pressure low-intensity versus low-pressure high-intensity UV disinfection systems for the disinfection of filtered secondary effluent. A minimum of 3 articles and/or reports dating back to 2005 should be cited in your assessment.

12–26 Using the D and Z values given in Table 12–36, determine whether the CDPH pasteurization requirements of 82°C for 10 s is sufficient to achieve a 4-log reduction in MS2 coliphage.

12–27 The following data were obtained from a pilot-plant pasteurization test. Using these data determine the D and Z values. If the temperature were increased to 68°C, how long would it take to achieve a 4-log reduction?

	Observed log reduction at indicated time		
Temp., °C	3 s	7 s	10 s
60	0.25	0.4	0.5
65	0.55	1.32	1.8
70	1.80	4.35	6.00

Processing and Treatment of Sludges

WORKING TERMINOLOGY

Term	Definition
Acid-gas digestion	A modified process of anaerobic digestion where the acid phase hydrolysis is separated from the gas producing phase for increased volatile solids reduction.
Aerobic digestion	Biological stabilization process operated in the presence of oxygen in which the biodegradable matter in primary and secondary sludge is oxidized to carbon dioxide and other end products.
Anaerobic digestion	Biological stabilization process operated in the absence of oxygen in which the biodegradable matter in primary and secondary sludge is converted to methane, carbon dioxide, and other end products.
Autothermal thermophilic aerobic digestion (ATAD)	An aerobic digestion process in which the microbes generate enough heat to maintain temperatures in the thermophilic range. When maintained for enough time to meet 40CFR 503 requirements, the process results in biosolids that are relatively pathogen free and meet Class A standards.
Biosolids	Sludge from wastewater treatment processes that has been stabilized to meet the criteria in the U.S. EPA's 40 CFR 503 regulations and, therefore, can be used beneficially.
Class A biosolids	Biosolids that contain less than 1000 most probable number (MPN)/g of fecal coliforms and less than 3 MPN/4g of Salmonella bacteria and meet one of six stabilization alternatives given in 40 CFR 503. The material also must meet the pollutant limits and vector attraction reduction requirements set forth in 40 CFR 503.
Class B biosolids	Biosolids that contain less than 2 million colony-forming units (CFU) or most probable number (MPN) of fecal coliforms per gram of dry biosolids. The material also must meet the pollutant limits and vector attraction reduction requirements set forth in 40 CFR 503.
Digestion	The process of biologically degrading organic matter in sludge, thereby reducing the concentrations of volatile solids and pathogens.
Disposition	Disposition is a term used to reflect disposal of biosolids or sludge for either beneficial or non-beneficial use due to the value of the material.
Dissolved air flotation	A clarification process in which small air bubbles become attached to flocculated material, float to the surface, and are removed by skimming. Heavier solids which settle are removed by mechanical scrapers.
Dual digestion	A two-stage digestion process wherein the first stage is aerobic thermophilic digestion and the second stage is mesophilic anaerobic digestion. High-purity oxygen has also been used for the first stage.
Grit	Sand, gravel, cinders, other heavy inorganic materials and also organic matter such as eggshells, bone chips, seeds, and coffee grounds.

Term	Definition
Humus	Sludge removed from trickling filters.
Mesophilic anaerobic digestion	Anaerobic digestion that occurs in a temperature range of 30 to 38°C (85 to 100°F).
Methanogenesis	The metabolic conversion of organic acids or hydrogen and carbon dioxide to methane.
Screenings	The material removed from a screening device.
Scum	Buoyant materials (e.g., grease, food waste, paper, and foam) often found floating on the surface of primary and secondary clarifiers and thickeners.
Sidestream	A portion of the wastewater flow that has been diverted from the main treatment process flow for specialized treatment.
Solids	A term often used as a replacement for sludges that have not been stabilized by physical, chemical or biological treatment. The term solids is not used as a substitute for sludge in this chapter. The mass of dry material in sludge is referred to as the solids content.
Sludge	Any material (i.e., sludge) produced during primary, secondary, or advanced wastewater treatment that has not undergone any process to reduce pathogens or vector attraction.
Stabilization	A treatment process designed to reduce the number of pathogens in sludge and to reduce the attraction of vectors as defined in the requirements of 40 CFR 503.
Thermal hydrolysis	A thermal conditioning process, utilizing high-pressure steam for pretreating dewatered sludge prior to anaerobic digestion, that hydrolyzes and reduces the viscosity of the sludge.
Thermophilic anaerobic digestion	Anaerobic digestion that occurs in a temperature range of 50 to 57°C (122 to 135°F).

The constituents removed and/or produced in wastewater treatment plants include screenings, grit, scum, sludge, and biosolids. The sludge and biosolids (formerly collectively called sludge) resulting from wastewater treatment processes are usually in the form of a liquid or semisolid liquid, which typically contains from 0.25 to 12 percent solids by weight, depending on the operations and processes used. In the United States, the term *biosolids*, as defined by the Water Environment Federation (WEF 2010a), refers to any sludge that has been stabilized to meet the criteria in the U.S. Environmental Protection Agency's 40 CFR 503 regulations and, therefore, can be used beneficially. The term *sludge* is only used before beneficial use criteria (discussed in Sec. 14–2) have been achieved. The term *sludge* is generally used in conjunction with a process descriptor, such as *primary sludge*, *enhanced primary sludge, waste activated sludge*, and *secondary sludge*. Although the terms solids and has been used as a substitute for sludge, to avoid confusion only the terms *sludge*, as defined above, and *biosolids* are used in this chapter and book.

Of the constituents removed by treatment, sludge is by far the largest in volume, and its processing, reuse, and disposition present perhaps the most complex problem in the field of wastewater treatment. For this reason, two chapters have been devoted to this subject. The disposition of grit and screenings is discussed in Chap. 5. The problems of dealing with sludge are complex because (1) sludge is composed largely of the substances responsible for the offensive character of untreated wastewater; (2) the portion of sludge produced from biological treatment requiring disposition is composed of the organic matter contained in the wastewater but in another form, and it, too, will decompose and become offensive; and (3) only a small part of sludge is solid matter.

The purpose of this chapter is to describe the principal processes and methods used for sludge processing and treatment as identified in Table 13–1. Resource recovery

Table 13–1

Sludge handling and processing methods

Handling or processing method	Function	See Sec.
Pumping	Transport of sludge and biosolids	13–4
Preliminary operation		13–5
Grinding	Particle size reduction	13–5
Screening	Removal of fibrous material	13–5
Degritting	Grit removal	13–5
Blending	Homogenization of sludge	13–5
Storage	Flow equalization	
Thickening		
Gravity thickening	Volume reduction	13–6
Flotation thickening	Volume reduction	13–6
Centrifugation	Volume reduction	13–6
Gravity belt thickening	Volume reduction	13–6
Rotary drum thickening	Volume reduction	13–6
Stabilization		
Alkaline stabilization	Stabilization	13–8
Anaerobic digestion	Stabilization, mass reduction, resource recovery	13–9
Aerobic digestion	Stabilization, mass reduction	13–10
Composting	Stabilization, product recovery	14–5
Heat drying	Stabilization, volume reduction, resource recovery	14–3
Conditioning	Improve dewatering	14–1
Dewatering		
Centrifuge	Volume reduction	14–2
Belt filter press	Volume reduction	14–2
Rotary press	Volume reduction	14–2
Screw press	Volume reduction	14–2
Filter press	Volume reduction	14–2
Advanced dewatering	Volume reduction and stabilization	14–2
Drying beds	Volume reduction	14–2
Reed beds	Storage and volume reduction	14–2
Lagoons	Storage and volume reduction	14–2
Advanced Thermal Oxidation	Volume and mass reduction, resource recovery	14–4
Application of biosolids to land	Beneficial use and disposition	14–10
Conveyance and storage	Transport and storage of sludge and biosolids	14–6

methods, also identified in Table 13–1, and the beneficial use of the biosolids is discussed in Chapter 14. To understand the various sludge handling and processing methods, the first two sections of this chapter are devoted to a discussion of the sources, characteristics, and quantities of sludge; the current regulatory environment; and a presentation of representative sludge-treatment process flow diagrams. Because the pumping of sludge is a fundamental part of wastewater treatment plant design, a separate discussion (Sec. 13–4) is devoted to sludge and scum pumping. The preliminary processing of sludge is discussed in Secs. 13–5 and 13–6. Stabilization of sludge is introduced in Sec. 13–7 and is divided into three subsequent sections for more detailed discussion: alkaline stabilization, anaerobic digestion, and aerobic digestion (see Secs. 13–8 through 13–10). Composting, also used for sludge stabilization after dewatering, is considered in Chap. 14.

13–1 SLUDGE SOURCES, CHARACTERISTICS, AND QUANTITIES

To design sludge processing, treatment, and disposition facilities properly, the sources, characteristics, and quantities of the sludge to be handled must be known. The method of primary and secondary treatment of wastewater has a significant impact on quantity and quality of the sludge produced. For example, using membrane bioreactors in secondary treatment produces sludge that is difficult to dewater and digest anaerobically, as compared to using a conventional waste activated sludge process. Stringent regulations for producing high quality effluent have an impact on the process used for secondary treatment, which in turn impact the quantity and quality of biosolids produced from sludge. For example, using biological nutrient removal (BNR) systems to meet stringent nutrient effluent quality produces lesser amount of sludge, but a sludge that is more difficult to process downstream by dewatering or digestion. The purpose of this section is to present background data and information on these topics that will serve as a basis for the material to be presented in the subsequent sections of this chapter.

Sources

The sources of sludge in a treatment plant vary according to the type of plant and its method of operation. The principal sources of sludge and the types generated are reported in Table 13–2. For example, in a complete mix activated sludge process, if the wasting of sludge is accomplished from the mixed liquor line or aeration chamber, the activated sludge

Table 13–2

Sources of sludge from conventional wastewater treatment plants[a]

Unit operation or process	Types of sludge	Remarks
Preaeration	Grit and scum	In some plants, scum removal facilities are not provided in preaeration tanks. If the preaeration tanks are not preceded by grit removal facilities, grit deposition may occur in preaeration tanks.
Primary sedimentation	Primary and scum	Quantities of sludge and scum depend upon the nature of the collection system and whether industrial wastes are discharged to the system.
Biological treatment	Secondary and scum	Suspended solids are produced by the biological conversion of BOD. Some form of thickening may be required to concentrate the waste sludge stream from biological treatment. Provision for scum removal from secondary settling tanks is a requirement of the U.S. EPA.

[a] The coarse material removed by screening and grit during preliminary treatment are considered in Chap. 5.

settling tank is not a source of sludge. On the other hand, if wasting is accomplished from the activated sludge return line, the activated sludge settling tank constitutes a source of sludge. Processes used for thickening, digesting, conditioning, and dewatering of sludge produced from primary and secondary settling tanks also constitute sources.

Characteristics

To treat and reuse the sludge produced from wastewater treatment plants in the most effective manner, it is important to know the characteristics of the sludge that will be processed. The characteristics vary depending on the origin of the sludge, the amount of aging that has taken place, and the type of processing to which the sludge has been subjected (see Table 13–3).

General Composition. Typical data on the chemical composition of sludges are reported in Table 13–4. Many of the chemical constituents, including nutrients, are important in considering the ultimate disposition of the processed sludge and the liquid removed during processing. The measurement of pH, alkalinity, and organic acid content

Table 13–3

Characteristics of sludge and biosolids produced during wastewater treatment

Type	Description
Scum/grease	Scum consists of the floatable materials skimmed from the surface of primary and secondary settling tanks. Scum may contain grease, vegetable and mineral oils, animal fats, waxes, soaps, food wastes, vegetable and fruit skins, hair, paper and cotton, cigarette tips, plastic materials, condoms, grit particles, and similar materials. The specific gravity of scum is less than 1.0 and usually around 0.95.
Primary sludge	Sludge from primary settling tanks is usually gray and slimy and, in most cases, has an extremely offensive odor. Primary sludge can be readily digested under suitable conditions of operation.
Sludge from chemical precipitation	Sludge from chemical precipitation with metal salts is usually dark in color, though its surface may be red if it contains much iron. Lime sludge is grayish brown. The odor of chemical sludge may be objectionable, but is not as bad as primary sludge. While chemical sludge is somewhat slimy, the hydrate of iron or aluminum in it makes it gelatinous. If the sludge is left in the tank, it undergoes decomposition similar to primary sludge, but at a slower rate. Substantial quantities of gas may be given off and the sludge density increased by long residence times in storage.
Activated sludge	Activated sludge generally has a brown flocculant appearance. If the color is dark, the sludge may be approaching a septic condition. If the color is lighter than usual, there may have been underaeration with a tendency for the sludge to settle slowly. Sludge in good condition has an inoffensive "earthy" odor. The sludge tends to become septic rapidly and then has a disagreeable odor of putrefaction. Activated sludge digests well aerobically, but not anaerobically.
Trickling filter sludge	Humus sludge from trickling filters is brownish, flocculant, and relatively inoffensive when fresh. It generally undergoes decomposition more slowly than other undigested sludges. When trickling filter sludge contains many worms, it may become inoffensive quickly. Trickling filter sludge digests readily.
Aerobically digested biosolids	Aerobically digested biosolids are brown to dark brown and have a flocculant appearance. The odor of aerobically digested sludge is not offensive; it is often characterized as musty. Well digested aerobic sludge dewaters easily on drying beds.
Anaerobically digested biosolids	Anaerobically digested biosolids are dark brown to black and contain an exceptionally large quantity of gas. When thoroughly digested, they are not offensive, the odor being relatively faint and like that of hot tar, burnt rubber, or sealing wax.

[a] The characteristics of the coarse material removed by screening and grit during preliminary treatment are considered in Chap. 5.

Table 13–4

Typical chemical composition of untreated primary and activated sludge[a]

Item	Untreated primary sludge Range	Untreated primary sludge Typical	Untreated activated sludge Range	Untreated activated sludge Typical
Total dry solids (TS),%	1–6	3	0.4–1.2	0.8
Volatile solids (% of TS)	60–85	75	60–85	70
Grease and fats (% of TS)	5–8	6	5–12	8
Protein (% of TS)	20–30	25	32–41	36
Nitrogen (N, % of TS)	1.5–4	2.5	2.4–5	3.8
Phosphorus (P_2O_5, % of TS)	0.8–2.8	1.6	2.8–11	5.5
Potash (K_2O, % of TS)	0–1	0.4	0.5–0.7	0.6
Cellulose (% of TS)	8–15	10	—	
Iron (not as sulfide)	2–4	2.5	—	
Silica (SiO_2, % of TS)	15–20	—	—	
pH	5–8	6	6.5–8	7.1
Alkalinity (mg/L as $CaCO_3$)	500–1500	600	580–1100	790
Organic acids (mg/L as HAc)	200–2000	500	1100–1700	1350
Energy content, kJ/kg VSS	23,000–29,000	25,000	19,000–23,000	20,000

Note: kJ/kg × 0.4303 = Btu/lb.

is important in process control of anaerobic digestion. The content of heavy metals, pesticides, and hydrocarbons has to be determined when incineration and land application methods are contemplated. The thermal content of sludge is important where a thermal reduction process such as incineration or gasification is considered.

Specific Constituents. Biosolids characteristics that affect their suitability for application to land and for beneficial use include organic content (usually measured as volatile solids), nutrients, pathogens, metals, and toxic organics. The fertilizer value of the biosolids, which should be evaluated where they are to be used as a soil conditioner, is based primarily on the content of nitrogen, phosphorus, and potassium (potash). Typical nutrient values of wastewater biosolids as compared to commercial fertilizers are reported in Table 13–5. In most land application systems, biosolids provide sufficient nutrients for

Table 13–5

Comparison of nutrient levels in commercial fertilizers and wastewater biosolids

Product	Nutrients, % Nitrogen	Nutrients, % Phosphorus	Nutrients, % Potassium
Fertilizers for typical agricultural use[a]	5	10	10
Typical values for stabilized wastewater biosolids (based on TS)[b]	3.3	2.3	0.3

[a] The concentrations of nutrients may vary widely depending upon the soil and crop needs.

[b] The concentrations of nutrients may vary depending on wastewater nutrient removal requirements.

Table 13–6

Typical metal content in wastewater solids[a]

Metal	Range of dry solids, mg/kg[b]
Arsenic[c]	1.18–49.2
Cadmium[c]	0.21–11.8
Chromium[c]	6.74–1160
Cobalt	0.87–290
Copper[c]	115–2580
Iron	1575–299,000
Lead[c]	5.81–450
Manganese	34.8–14,900
Mercury[c]	0.17–8.3
Molybdenum[c]	2.51–132

[c] Metals currently regulated under 40 CFR 503.

plant growth. In some applications, the phosphorus and potassium content may be low and require augmentation.

Trace elements are those inorganic chemical elements that, in very small quantities, can be essential or detrimental to plants and animals. The term "heavy metals" is used to denote several of the trace elements present in sludge and biosolids. Concentrations of heavy metals may vary widely, as indicated in Table 13–6. Due to successful implementation of pretreatment programs, quality of sludge and biosolids in terms regulated heavy metals improved significantly. For the application of biosolids to land, concentrations of heavy metals may limit the application rate and the useful life of the application site (see Sec. 14–10).

Quantities

Data on the quantities of sludge produced from various processes and operations are presented in Table 13–7. Although the data in Table 13–7 are useful as presented, it should be noted that the quantity of sludge produced would vary widely. Corresponding data on expected sludge concentrations from various processes are given in Table 13–8.

Quantity Variations. The quantity of semi-solid and solid material entering the wastewater treatment plant daily may be expected to fluctuate over a wide range. To ensure capacity capable of handling these variations, the following items must be considered in the design of sludge processing and disposition facilities (1) the average and maximum rates of sludge production, and (2) the potential storage capacity of the treatment units within the plant. The variation in daily quantity of sludge that may be expected in large cities is shown

Table 13–7

Typical data for the physical characteristics and quantities of sludge produced from various wastewater treatment operations and processes

Treatment operation or process	Specific gravity of solids	Specific Gravity of Sludge	Dry solids lb/10^3 gal		Dry solids kg/10^3 m^3	
			Range	Typical	Range	Typical
Primary sedimentation	1.4	1.02	0.9–1.4	1.25	110–170	150

on Fig. 13–1. The curve is characteristic of large cities having a number of large collection lines laid on flat slopes; even greater variations may be expected at small plants.

A limited quantity of sludge may be stored temporarily in the sedimentation and aeration tanks. Where digestion tanks with varying levels are used, their large storage capacity provides a substantial dampening effect on peak digested sludge loads. In sludge treatment systems where digestion is used, the design is usually based on maximum monthly loadings to provide a minimum of 15 d residence time during these maximum month loadings. Thus, based on average daily loadings, digesters have some sludge storage capacity. Where digestion is not used, the sludge treatment processes should be designed based on the inherent storage capacity available in the sludge handling system. For example, the mechanical dewatering system following gravity thickening could be based on the maximum 1 or 3 d sludge production. Certain components of the sludge processing system, such as sludge pumping and thickening, are sized to handle the maximum-day conditions.

Volume-Mass Relationships. The volume of sludge depends mainly on its water content and only slightly on the character of the solid matter. A 10 percent sludge, for example, contains 90 percent water by weight. If the solid matter is composed of fixed

Table 13–8

Expected solids concentrations from various treatment operations and processes

Operation or process application	Solids concentration, % dry solids Range	Solids concentration, % dry solids Typical
Primary settling tank		
Primary sludge	1–6	3
Primary sludge to a cyclone degritter	0.5–3	1.5

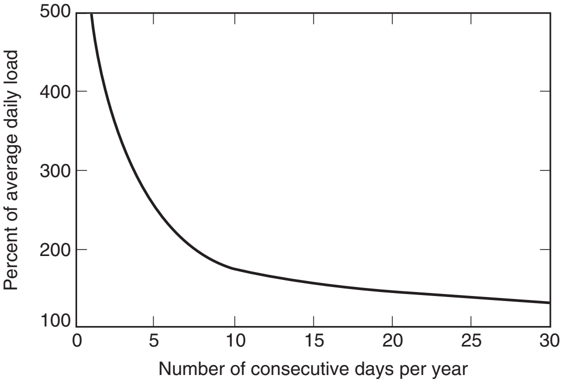
Figure 13–1

Peak sludge load as a function of the average daily load.



(mineral) and volatile (organic) solids, the specific gravity of all of the solid matter can be computed using Eq. (13–1).

$$\frac{W_s}{S_s\rho_w} = \frac{W_f}{S_f\rho_w} + \frac{W_v}{S_v\rho_w} \tag{13–1}$$

where W_s = weight of solids
S_s = specific gravity of solids
ρ_w = density of water
W_f = weight of fixed solids (mineral matter)
S_f = specific gravity of fixed solids
W_v = weight of volatile solids
S_v = specific gravity of volatile solids

Therefore, if one-third of the solid matter in a sludge containing 90 percent water is composed of fixed mineral solids with a specific gravity of 2.5, and two-thirds is composed of volatile solids with a specific gravity of 1.0, then the specific gravity of all solids S_s would be equal to 1.25, as follows:

$$\frac{1}{S_s} = \frac{0.33}{2.5} + \frac{0.67}{1.0} = 0.82$$

$$S_s = \frac{1}{0.82} = 1.25$$

If the specific gravity of the water is taken to be 1.0, the specific gravity of the sludge S_{sl} is 1.02, as follows:

$$\frac{1}{S_{sl}} = \frac{0.1}{1.25} + \frac{0.9}{1.0} = 0.98$$

$$S_{sl} = \frac{1}{0.98} = 1.02$$

The volume of sludge may be computed with the following expression:

$$V = \frac{M_s}{\rho_w S_s P_s} \tag{13–2}$$

where V = volume, m^3
M_s = mass of dry solids, kg
ρ_w = specific weight of water, 10^3 kg/m^3
S_{sl} = specific gravity of the sludge
P_s = percent solids expressed as a decimal

For approximate calculations for a given solids content, it is simple to remember that the volume varies inversely with the percent of solid matter contained in the sludge as given by

$$\frac{V_1}{V_2} = \frac{P_2}{P_1} \qquad \text{(approximate)}$$

Where V_1, V_2 = sludge volumes
P_1, P_2 = percent of solid matter

The application of these volume and weight relationships is illustrated in Example 13–1.

EXAMPLE 13–1 **Volume of Untreated and Digested Dewatered Sludge** Determine the liquid volume before and after digestion and dewatering and the percent reduction for 500 kg (dry basis) of primary sludge with the following characteristics:

	Primary	Digested and dewatered
Solids, %	5	20
Volatile matter, %	80	60 (destroyed)
Specific gravity of fixed solids	2.5	2.5
Specific gravity of volatile solids	≈1.0	≈1.0

Solution

1. Compute the average specific gravity of all the solids in the primary sludge using Eq. (13–1).

$$\frac{1}{S_s} = \frac{0.2}{2.5} + \frac{0.8}{1.0} = 0.88$$

$$S_s = \frac{1}{0.88} = 1.14 \quad \text{(primary solids)}$$

2. Compute the specific gravity of the primary sludge.

$$\frac{1}{S_{sl}} = \frac{0.05}{1.14} + \frac{0.95}{1} = 0.99$$

$$S_{sl} = \frac{1}{0.99} = 1.01$$

3. Compute the volume of the primary sludge using Eq. (13–2).

$$V = \frac{500\,\text{kg}}{(10^3\,\text{kg/m}^3)(1.01)(0.05)}$$
$$= 9.9\,\text{m}^3$$

4. Compute the percentage of volatile matter after digestion total volatile solids after digestion.

$$\text{Volatile matter, \%} = \frac{\text{total VS after digestion}}{\text{total TS after digestion}} \times 100$$

$$= \frac{(\text{VS Primary})M_s(1 - \text{VSR})}{M_s - M_s(\text{VS Primary})(\text{VSR})} \times 100$$

$$= \frac{(0.8)(500\text{ kg})(1 - 0.6)}{500\text{ kg} - 500\text{ kg}(0.8)(0.6)} \times 100 = 61.5\%$$

5. Compute the average specific gravity of all the solids in the digested sludge using Eq. (13–1).

$$\frac{1}{S_s} = \frac{0.385}{2.5} + \frac{0.615}{1.0} = 0.769$$

$$S_s = \frac{1}{0.769} = 1.30 \text{ (digested solids)}$$

6. Compute the specific gravity of the digested sludge (S_{ds}).

$$\frac{1}{S_{ds}} = \frac{0.20}{1.3} + \frac{0.80}{1} = 0.95$$

$$S_{ds} = \frac{1}{0.95} = 1.05$$

7. Compute the volume of digested sludge using Eq. (13–2).

$$V = \frac{500 \text{ kg} - 500\text{kg}(0.8)(0.6)}{(10^3 \text{ kg/m}^3)(1.05)(0.20)}$$
$$= 1.2\text{m}^3$$

8. Determine the percentage reduction in the sludge volume after digestion.

$$\text{Reduction} = \frac{(9.9 - 1.2) \text{ m}^3}{9.9 \text{ m}^3} \times 100 = 87.8\%$$

13–2 REGULATIONS FOR THE REUSE AND DISPOSITION OF SLUDGE IN THE UNITED STATES

In selecting the appropriate methods of sludge processing, reuse, and disposition, consideration must be given to the appropriate regulations. In the United States, regulations (40 CFR Part 503) were promulgated in 1993 by the U.S. Environmental Protection Agency (U.S. EPA) that established pollutant numerical limits and management practices for the reuse and disposition of sludge generated from the processing of municipal wastewater and septage (Federal Register, 1993). The regulations were designed to protect public health and the environment from any reasonably anticipated adverse effects of pollutants contained in the biosolids.

The regulations addressed by 40 CFR Part 503 cover specifically (1) land application of biosolids, (2) surface disposition of biosolids, (3) pathogen and vector reduction in treated biosolids, and (4) incineration. Each of these subjects is discussed below. The regulations directly affect selection of many of the processes used for sludge treatment, especially for sludge stabilization, i.e., alkaline stabilization, anaerobic digestion, aerobic digestion, and composting. In some cases, to achieve compliance, appropriate treatment requirements or methods are stipulated by the regulations. Additional discussion regarding regulations for applying biosolids on land is provided in Sec. 14–8.

Land Application

Land application relates to biosolids reuse and includes all forms of applying bulk or bagged biosolids to land for beneficial uses at agronomic rates, i.e., rates designed to provide the amount of nitrogen needed by crop or vegetation while minimizing the amount that passes below the root zone. The regulations establish two levels of biosolids quality with respect to heavy metals concentrations—pollutant ceiling and pollutant concentrations ("high" quality biosolids); two levels of quality with respect to pathogen densities—Class A and Class B; and two types of approaches for meeting vector attraction—biosolids processing or use of physical barriers. Vector attraction reduction decreases the potential for spreading infectious disease by vectors such as rodents, insects, and birds.

Surface Disposition

The surface disposition part of the Part 503 regulations applies to (1) dedicated surface disposition sites; (2) monofills, i.e., sludge-only landfills; (3) piles or mounds; and (4) impoundments or lagoons. Disposition sites and sludge placed on those sites for final disposition are addressed in the surface disposition rules. Surface disposition does not include placement of sludge for storage or treatment purposes. Where surface disposition sites do not have a liner or leachate collection system, limits are established for pollutants such as arsenic and nickel and vary based on the distance of the active surface disposition site boundary from the site property line (see Federal Register, 1993).

Pathogen and Vector Attraction Reduction

The 40 CFR Part 503 regulations divide the quality of biosolids into two categories, referred to as Class A and Class B (see requirements in Table 13–9,). Class A biosolids must meet specific criteria to ensure they are safe to be used by the general public and for nurseries, gardens, and golf courses. Class B biosolids have lesser treatment requirements than Class A, and typically are used for application to agricultural land and daily cover in a landfill.

In addition to meeting the requirements in Table 13–9, Class A biosolids must meet one of the following criteria:

- A fecal coliform density of less than 1000 MPN/g total dry solids
- Salmonella sp. density of less than 3 MPN/4 g total dry solids (3 MPN/4 g TS)

Bulk biosolids applied to lawns and home gardens or sold or given away in bags or other containers must meet the Class A criteria for pathogen reduction (see Table 13–9) and one of several vector attraction reduction processing options (see Table 13–10). Alternatively, biosolids can be treated by a prescribed process that reduces pathogens beyond detectable levels.

Class B pathogen requirements are the minimum level of pathogen reduction for land application and surface disposition. The only exception to achieving at least Class B level occurs when the sludge is placed in a surface disposition facility that is covered daily. Biosolids that do not qualify as Class B cannot be land applied. To meet Class B requirements, biosolids must be treated by a process that reduces but does not eliminate pathogens (see PSRP, also discussed below), or that must be tested to meet fecal coliform limits of less than 2.0×10^6 MPN/g TS or less than 2.0×10^6 CFU/g TS.

To meet pathogen and vector attraction reduction requirements, two levels of preapplication treatment are required and have been defined by the U.S. EPA as Processes to Further Reduce Pathogens (PFRP) and Processes to Significantly Reduce Pathogens (PSRP). These processes are defined in Tables 13–11 and 13–12. Because PSRPs reduce but do not eliminate pathogens, PSRP-treated biosolids still have the potential to transmit disease. Because PFRPs reduce pathogens below detectable levels, there are no pathogen-related restrictions for land application. Minimum frequency of monitoring, record-keeping, and reporting requirements must be met, however.

Table 13–9

Pathogen reduction alternatives[a]

Class A	Description
Alternative 1	Thermally Treated Sewage Sludge: Use one of four time-temperature regimes.
Alternative 2	Sewage Sludge Treated in a High pH-High Temperature Process: Specifies pH, temperature, and air-drying requirements.
Alternative 3	For Sewage Sludge Treated in Other Processes: Demonstrate that the process can reduce enteric viruses and viable helminth ova. Maintain operating conditions used in the demonstration.
Alternative 4	Sewage Sludge Treated in Unknown Processes: Demonstration of the process is unnecessary. Instead, test for pathogens—*Salmonella* sp. bacteria, enteric viruses, and viable helminth ova—at the time the sewage sludge is used or disposed, or is prepared for sale or give-away in a bag or other container for application to the land, or when prepared to meet the requirements in 503.10(b), (c), (e), or (f).
Alternative 5	Use of PFRP: Sewage sludge is treated in one of the processes to further reduce pathogens (PFRP).
Alternative 6	Use of a Process Equivalent to PFRP: Sewage sludge is treated in a process equivalent to one of the PFRPs, as determined by the permitting authority.
Class B	**Description**
Alternative 1	Monitoring of Indicator Organisms: Test for fecal coliform density as an indicator for all pathogens at the time of sewage sludge use or disposal.
Alternative 2	Use of PSRP: Sewage sludge is treated in one of the processes to significantly reduce pathogens (PSRP).
Alternative 3	Use of Processes Equivalent to PSRP: Sewage sludge is treated in a process equivalent to one of the PSRPs, as determined by the permitting authority.

[a] From US EPA (1992).

[b] In addition to meeting the requirements in one of the six alternatives listed below, fecal coliform or *Salmonella* spp. bacterial levels must meet specific densities at the time of sewage sludge use or disposal, when prepared for sale or give-away in a bag or other container for application to the land, or when prepared to meet the requirements in 503.10(b), (c), (e), or (f).

[c] The requirements in one of the three alternatives below must be met in addition to Class B site restrictions.

Incineration

Originally, the definition of a nonhazardous solid waste material included sludges from wastewater treatment and other secondary material being discarded. However, wastewater sludges were eventually exempted from being defined under the nonhazardous solid waste ruling and were instead covered under 40 *CFR* 503 regulations.

Resource Conservation and Recovery Act. Under the Resource Conservation and Recovery Act, in the Identification of Non-Hazardous Secondary Materials that are Solid Waste (published by the U.S. EPA on March 21, 2011), sludge is defined somewhat differently. If the secondary material (e.g., sludge) is being discarded, it falls under the solid waste definition. As such, the burning of sludges in sewage sludge incinerators (SSIs) would be considered discarding, and, thus, would fall under the “other discarded material” part of the solid waste definition. Accordingly, SSIs would be regulated under Sec. 129 of

Table 13–10

Vector attraction reduction[a]

Requirement	What is required?	Most appropriate for:
Option 1 503.33(b)(1)	At least 38 percent reduction in volatile solids during biosolids treatment	Biosolids processed by: Anaerobic biological treatment Aerobic biological treatment Chemical oxidation
Option 2 503.33(b)(2)	Less than 17 percent additional volatile solids loss during bench–scale anaerobic batch digestion of the biosolids for 40 additional d at 30 to 37°C (86 to 99°F)	Only for anaerobically digested biosolids
Option 3 503.33(b)(3)	Less than 15 percent additional volatile solids reduction during bench–scale aerobic batch digestion for 30 additional d at 20°C (68°F)	Only for aerobically digested biosolids with 2 percent or less solids—e.g., biosolids treated in extended aeration plants
Option 4 503.33(b)(4)	SOUR at 20°C (68°F) is 1.5 mg O_2/h·g total biosolids solids	Biosolids from aerobic processes (should not be used for composted sludges). Also for biosolids that has been deprived of oxygen for longer than 1 to 2 h
Option 5 503.33(b)(5)	Aerobic treatment of the biosolids for at least 14 d at over 40°C (104°F) with an average temperature of over 45°C (113°F)	Composted biosolids (Options 3 and 4 are likely to be easier to meet for biosolids from other aerobic processes)
Option 6 503.33(b)(6)	Addition of sufficient alkali to raise the pH to at least 12 at 25°C (77°F) and maintain a pH of 12 for 2 h and a pH of 11.5 for 22 more h	Alkali-treated biosolids (alkalies include lime, fly ash, kiln dust, and wood ash)
Option 7 503.33(b)(7)	Percent solids of 75 percent prior to mixing with other materials	Biosolids treated by an aerobic or anaerobic process (i.e., biosolids that do not contain unstabilized sludge generated in primary wastewater treatment)
Option 8 503.33(b)(8)	Percent solids of 90 percent prior to mixing with other materials	Biosolids that contain unstabilized sludge generated in primary wastewater treatment (e.g., any heat-dried sludges)
Option 9 503.33(b)(9)	Biosolids is injected into soil so that no significant amount of biosolids is present on the land surface 1 hour after injection, except Class A biosolids which must be injected within 8 h after the pathogen reduction process	Liquid biosolids applied to the land. Domestic septage applied to agricultural land, a forest, or a reclamation site
Option 10 503.33(b)(10)	Biosolids is incorporated into the soil within 6 h after application to land. Class A biosolids must be applied to the land surface within 8 h after the pathogen reduction process, and must be incorporated within 6 h after application	Biosolids applied to the land. Domestic septage applied to agricultural land, forest, or a reclamation site

[a] From U.S. EPA (1992).

the Clean Air Act, instead of how they have been regulated historically, under Sec. 112 of the Clean Air Act through Part 503 biosolids regulations.

Clean Air Act. Section 129 of the Clean Air Act requires the U.S. EPA to develop standards for solid waste combustion processes. As a result, the U.S. EPA was required to develop new source performance standards (NSPSs) and emission guidelines (EGs) for sewage sludge incineration units (SSIs). The new standards and emission guidelines were finalized by the U.S. EPA on February 21, 2011 and published in the Federal Register on March 21, 2011.

Table 13–11

Regulatory definition of processes to further reduce pathogens (PFRP)[a]

Process	Definition
Composting	Using either within-vessel or static aerated pile composting, the temperature of the biosolids is maintained at 55°C or higher for 3 d. Using windrow composting, the temperature of the wastewater sludge is maintained at 55°C or higher for 15 d or longer. During this period, a minimum of five windrow turnings is required.
Heat drying	Dewatered biosolids are dried by direct or indirect contact with hot gases to reduce the moisture content to 10 percent or lower. Either the temperature of biosolids particles exceed 80°C or the wet bulb temperature of the gas stream in contact with the biosolids as the biosolids leave the dryer exceeds 80°C.
Heat treatment	Liquid biosolids are heated to a temperature of 180°C or higher for 30 min.
Thermophilic aerobic digestion	Liquid biosolids are agitated with air or oxygen to maintain aerobic conditions, and the MCRT is 10 d at 55 to 60°C.
Beta ray irradiation	Biosolids are irradiated with beta rays from an accelerator at dosages of at least 1.0 megarad (Mrad) at room temperature (approximately 20°C).
Gamma ray irradiation	Biosolids are irradiated with gamma rays from certain isotopes such as 60 Cobalt or 135 Cesium at dosages of at least 1.0 Mrad at room temperature (approximately 20°C).
Pasteurization	The temperature of the biosolids is maintained at 70°C or higher for at least 30 min.

[a] Federal Register (1993).

Table 13–12

Regulatory definition of processes to significantly reduce pathogens (PSRP)[a]

Process	Definition
Aerobic digestion	Biosolids are agitated with air or oxygen to maintain aerobic conditions for a MCRT and temperature between 40 d at 20°C and 60 d at 15°C.
Air drying	Biosolids are dried on sand beds or on paved or unpaved basins for a minimum of 3 mo. During 2 of the 3 mo, the ambient average daily temperature exceeds 0°C.
Anaerobic digestion	Biosolids are treated in the absence of air between an MCRT of 15 d at temperatures of 35 to 55°C and an MCRT of 60 d at a temperature of 20°C. Times and temperatures between these endpoints may be calculated by linear interpolation.
Composting	Using either within-vessel, static aerated pile, or windrow composting, the temperature of the biosolids is raised to 40°C or higher for 5 d. For 4 h during the 5 d period, the temperature in the compost pile should exceed 55°C.
Lime stabilization	Sufficient lime is added to raise the pH of the biosolids to pH 12 and maintained for 2 h of contact.

[a] Federal Register (1993).

Emission Guidelines and New Source Performance Standards. The new rule requires facilities to meet the maximum achievable control technology (MACT) limits. The MACT standards for existing units were based on the best performing 12 percent of the existing units, while MACT standards for new or "modified" units are based on the "best controlled similar unit." MACT standards have been set for nine pollutants. These pollutants are: cadmium (Cd), lead (Pb), mercury (Hg), particulate matter (PM), carbon monoxide (CO), hydrogen chloride (HCl), sulfur dioxide (SO_2), nitrogen oxides (NOx), and dioxins and furans (PCDD/PCDF).

The new SSI rules and emission guidelines contain standards for existing and new multiple-hearth furnaces (MHFs) and fluidized bed incinerators (FBIs). This rule stipulates that all SSIs will require Title V operating permits, annual operator training, annual stack testing and/or continuous emissions monitoring systems, recordkeeping requirements, and establishment of operating limits. For new or modified SSIs, the proposed MACT limits are set as a composite of the best emissions performance from the best SSIs tested. For new SSIs, owners or operators are required to conduct a siting analysis prior to construction. This analysis would include site specific analysis of air pollution control alternatives to minimize the environmental and health impacts to the maximum extent practicable. Details regarding air pollution controls are discussed in Sec. 14–6 in Chap.14.

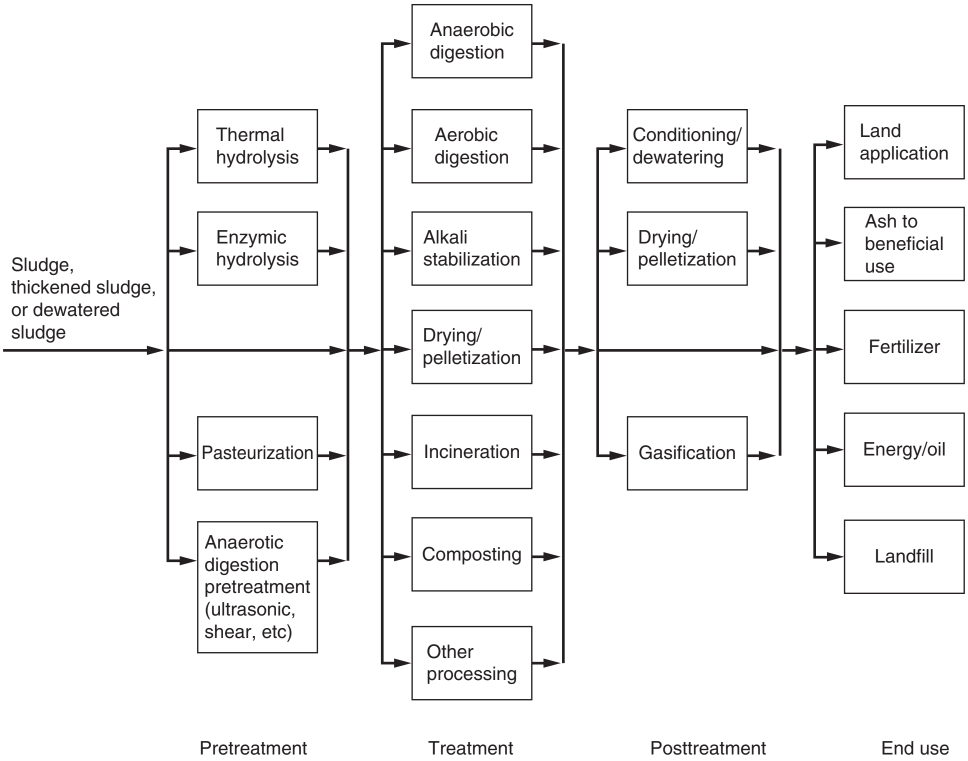
Clean Water Act. Under the 503 regulations, the requirements for biosolids incineration are still applicable. There is some overlap between the 503 regulations and the Clean Air Act Section 129 MACT based EGs and NSPSs, but they differ significantly due to the different approaches used to develop each set of rules. The 503 regulations are based on a risk based approach and aim to avoid adverse impacts. Limits are based partially on maximum allowable concentrations of pollutants within the feed biosolids coupled with stack monitoring of total hydrocarbons (or carbon monoxide) and operational standards to ensure good combustion and emissions performance. However, the MACT rules are technology based and set the limits relative to the best performing incinerator units within their class (ie. MHF or FBI). These limits are expressed as maximum concentrations of pollutants in the incinerator flue gases. The methods of measurement and media in which the concentrations are measured are entirely different and are not directly comparable to the 503 regulations. In practical application, the MACT emission requirements are much more stringent than previously required under Part 503 and they will generally dictate the required emission performance levels for both new and existing incinerators. For the time being, both sets of rules apply with overlapping requirements leading to duplicate sampling by operators of both the feed biosolids and the flue gases.

13–3 SLUDGE PROCESSING FLOW DIAGRAMS

A generalized flow diagram incorporating the unit operations and processes to be discussed in this chapter and chapter 14 is presented on Fig. 13–2. As shown, an almost infinite number of combinations are possible. In practice, the most commonly used process flow diagram for sludge processing involves biological treatment. Typical flow diagrams incorporating biological processing are presented on Fig. 13–3. Thickeners may be used depending upon the source of sludge and the method of sludge stabilization, dewatering, and disposition. Following biological digestion, any of the several methods shown may be used to dewater the sludge; the choice depends on economic evaluation, beneficial use requirements, and local conditions. In instances where biological stabilization is not used, dewatered sludge undergoes thermal decomposition, in either multiple-hearth or fluidized-bed incinerators. Furthermore, unstabilized dewatered cake can be dried, alkaline stabilized, or hauled to a landfill.

Figure 13–2

Generalized sludge processing flow diagram.



13–4 SLUDGE AND SCUM PUMPING

Sludge produced in wastewater treatment plants must be conveyed from point to point in the plant in conditions ranging from a watery sludge or scum to a thick sludge. Sludge may also be pumped off-site for long distances for treatment and disposition. For each type of sludge and pumping application, a different type of pump may be needed (see Table 13–13).

Pumps

Pumps used most frequently to convey sludge include the plunger, progressive cavity, hose, solids handling centrifugal (screw centrifugals and traditional “non-clog designs), recessed impeller, diaphragm, high-pressure piston diaphragm, and rotary lobe types. Other types of pumps such as hydraulic piston slurry pumps have also been used to pump sludge. Chopper pumps are used extensively for pumping scum containing rags, plastics, and other fibrous materials that require shredding. The advantages and disadvantages of each type of pump are summarized in Table 13–14.

Plunger Pumps. Plunger pumps [see Fig. 13–4(a)] have been used frequently for sludge applications, especially primary sludges, and have proved to be quite satisfactory. The advantages of plunger pumps are as follows:

1. Pulsating action of simplex and also duplex pumps tends to concentrate the sludge in the hoppers ahead of the pumps and resuspend solids in pipelines when pumping at low velocities.
2. They are suitable for suction lifts up to 3 m (10 ft) and are self-priming.

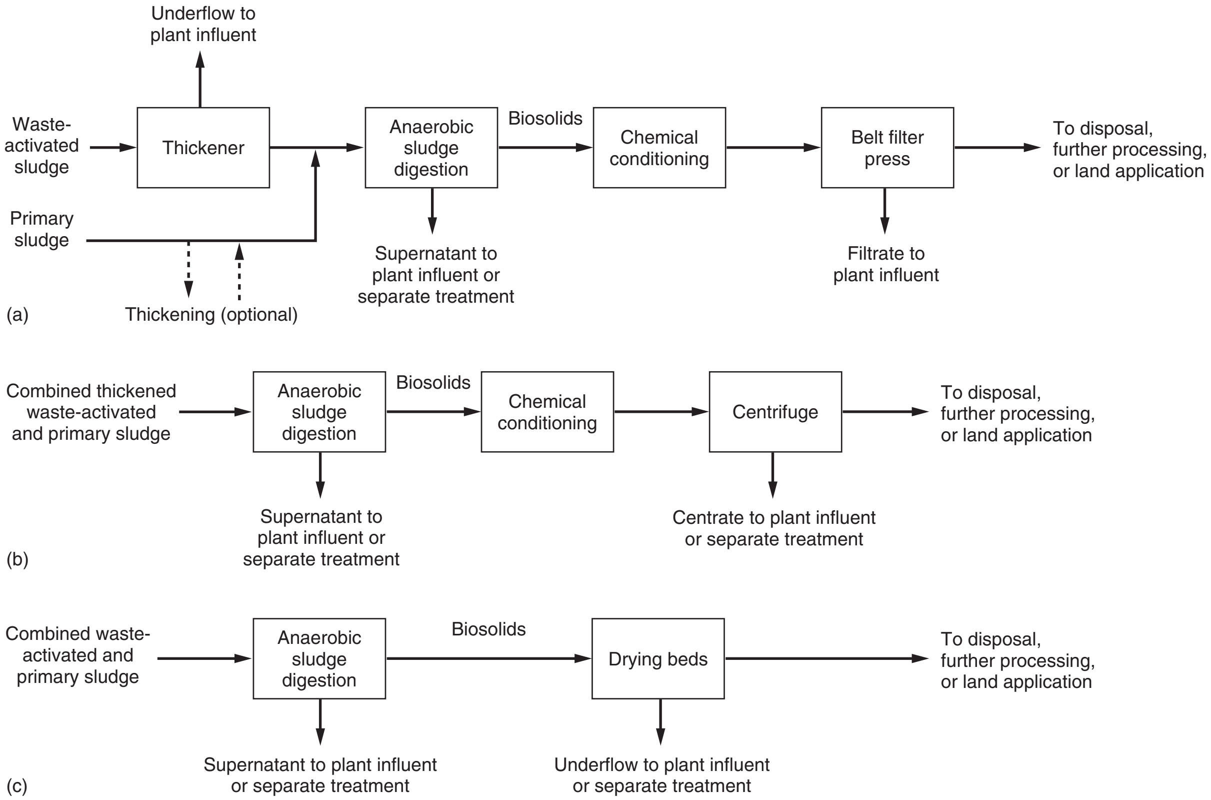


Figure 13–3

Typical sludge treatment flow diagrams with biological digestion and three different sludge dewatering processes: (a) belt filterpress, (b) centrifuge, (c) drying bed. In some plants, flows that are to be returned to the headworks are stored in equalization basins for return to the treatment process during the early morning hours when the plant load is reduced.

3. Low pumping rates can be used with large port openings.
4. Positive delivery is provided unless some object prevents the ball checks valves from seating.
5. They have constant but adjustable capacity, regardless of large variations in pumping head.
6. Discharge pressure limitations are approximately 10 to 11 bar (150 to 165 $lb_f/in.^2$).
7. Heavy sludge concentrations may be pumped if the equipment is designed for the load conditions.

Plunger pumps come with one, two, or three plungers (called simplex, duplex, or triplex units) with capacities of 2.5 to 3.8 L/s (40 to 60 gal/min) per plunger, and larger models are available. Pump speeds should be between 40 and 50 strokes per min. Because grease accumulations in sludge lines cause a progressive increase in head with use, heavier duty pumps should be designed for a minimum head of 6.9 bar (100 $lb_f/in.^2$). Capacity is decreased in constant speed pumps by shortening the stroke of the plunger; however, the pumps seem to operate more satisfactorily at or near full stroke. For this reason, many pumps are provided with variable-speed drives for speed control of capacity. A plunger pump differs from a centrifugal or recessed impeller pump in that its

Table 13–13

Application of pumps to types of sludge and biosolids[a]

Type of sludge or solids	Applicable pump	Comment
Ground screenings	Pumping screenings should be avoided	Pneumatic ejectors may be used.
Grit	Torque flow centrifugal	The abrasive character of grit and the presence of rags make grit difficult to handle. Hardened casings and impellers should be used for torque flow pumps. Pneumatic ejectors may also be used.
Scum	Plunger, progressive cavity, diaphragm, centrifugal, chopper	Scum is often pumped by the sludge pumps; valves are manipulated in the scum and sludge lines to permit this. In larger plants separate scum pumps are used. Scum mixers are often used to ensure homogeneity prior to pumping. Pneumatic ejectors may also be used.
Primary sludge	Plunger, centrifugal torque flow, diaphragm, progressive cavity, rotary lobe, chopper, hose	In most cases, it is desirable to obtain as concentrated a sludge as practicable from primary sedimentation tanks, usually by collecting the sludge in hoppers and pumping intermittently, allowing the sludge to collect and consolidate between pumping periods. The character of untreated primary sludge will vary considerably, depending on the characteristics of the solids in the wastewater, and the types of treatment units and their efficiency. Where biological treatment follows, the quantity of sludge from (1) waste activated sludge (2) humus sludge from settling tanks following trickling filters, (3) overflow liquors from digestion tanks, (4) and centrate or filtrate return from dewatering operations will also affect the sludge characteristics. In many cases, the character of the sludge is not suitable for the use of conventional nonclog centrifugal pumps. Where sludge contains rags, chopper pumps may be used.
Chemical precipitation	Same as for primary sludge	The precipitate may contain large amounts of inorganic constituents depending on the type and amount of chemicals used.
Trickling filter humus	Nonclog and torque flow centrifugal, progressive cavity, plunger, diaphragm	Humus is usually of homogenous character and can be easily pumped.
Return or waste activated sludge	Nonclog and torque flow centrifugal, progressive cavity, diaphragm	Sludge is dilute and contains only fine solids so that nonclog pumps may be used. For nonclog pumps, slow speeds are recommended to minimize the breakup of flocculent particles.
Thickened or concentrated sludge	Plunger, progressive cavity, diaphragm, high pressure piston, rotary lobe, hose	Positive displacement pumps are most applicable for concentrated sludge because of their ability to generate movement of the sludge mass. Torque flow pumps may be used but may require the addition of flushing or dilution facilities.
Digested biosolids	Plunger, torque flow centrifugal, progressive cavity, diaphragm, high pressure piston, rotary lobe	Well digested biosolids are homogenous, containing 2 to 5 percent total solids and a quantity of gas bubbles. Poorly digested biosolids may be difficult to handle. If good screening and grit removal are provided, nonclog centrifugal pumps may be considered.

Table 13–14

Advantages and disadvantages of various types of sludge pumps[a]

Type of Pump	Advantages	Disadvantages
Plunger	• Can pump heavy sludge concentrations (up to 15 percent) • Self-priming and can handle suction lifts up to 3 m (10 ft) • Constant but adjustable capacity regardless of variations in head • Cost-effective choice for flowrates up to 30 L/s (500 gal/min) and heads up to 60 m (200 ft) • Pulsating action of simplex and duplex pumps sometimes helps to concentrate sludge in hoppers ahead of pumps and resuspended solids in pipelines when pumping at low velocities • High Pressure Capacity	• Low efficiency • High maintenance if operated continuously • Depending on downstream processes, pulsating flow may not be acceptable
Progressing Cavity	• Provides a relatively smooth flow • Pumps greater than 3 L/s (50 gal/min) capacity can pass solids of about 20 mm (0.8 in.) in size • Easily controlled flowrates • Minimal pulsation • Relatively simple operation • Stator/rotor tends to act as a check valve, thus preventing backflow through pump. An external check valve may not be required	• Stator will burn out if pump is operated dry; needs a run dry protection system • Smaller pumps usually require grinders to prevent clogging • Power cost escalates when pumping heavy sludge • Grit in sludge may cause excessive stator wear • Seals and water required typically
Diaphragm	• Pulsating action may help to concentrate sludge in hoppers ahead of pumps and resuspend solids in pipelines when pumping at low velocities • Self-priming with suction lifts up to 3 m (10 ft) • Can pump grit with relatively minimum wear • Relatively simple operation	• Depending on downstream processes, pulsating flow may not be acceptable • Requires a source of compressed air • Operation may be excessively noisy • Low head and efficiency • High maintenance if operated continuously
Centrifugal Nonclog (mixed flow)	• Has high volume and excellent efficiency for activated sludge pumping applications • Relatively low cost	• Not recommended for other sludge pumping applications because of potential clogging due to rags and other debris
Recessed Impeller	• Because of recessed impeller design, pump can pass large solids and grit • Can pump digested sludges up to approximately 4%	• Low efficiency-about 5 to 20 percent lower than standard nonclog pumps • Limited to raw sludge with solid concentrations of 2.5 percent or less • Abrasion-resistant impellers cannot be trimmed to modify pumping characteristics
Chopper	• Reduces clogging of pump suction • May eliminate need for grinder or comminutor • Can handle higher sludge concentrations than nonclog pumps	• Relatively low efficiency-efficiency ranges from about 40 to 60 percent • Requires a level of maintenance similar to grinders
Rotary Lobe	• Provides a relatively smooth flow • Does not require a check valve in most applications with low to moderate discharge static heads • Able to run dry for short period of time without significant damage Low speed and low maintenance	• Because of close tolerances between rotating lobes, grit will cause excessive wear, thus reducing pumping efficiency • Fluid pumped must act as a lubricant • Cost of pumping increases with volume
Peristalic Hose	• Has self-priming capabilities • Because it is a positive-displacement pump, it is capable of metering flow • Relatively simple to maintain • Can pump sludge with abrasive grit	• Depending on downstream processes, pulsating flow may not be acceptable • High starting torque (two to three times running torque) • Replacement hoses may be expensive
High-pressure pistion	• Can be used to pump thickened sludge long distances • Can pump at rates of 30 L/s (500 gal/min) at pressures up to 13,800 kPa (2000 $\text{lb}_f/\text{in.}^2$) • Can run dry without major damage • Unobstructed internal flow path; can pass large solids	• High Capital Cost • Requires skilled maintenance personnel

discharge is pulsing due to the action of a piston; consequently, the actual flow while sludge is moving in the pipeline is greater than average pumping capacity. The headloss calculations, therefore, must be based on the peak pulsating flow rather than the design flow. The factors given in Table 13–15 can be used to account for the actual peak pulsating or instantaneous flow.

Table 13–15

Factors for computing peak pulsating flowrate when using plunger pumps

Type of plunger pump	Actual pulsating peak flowrate
Simplex	3.1 × design flowrate
Duplex	1.55 × design flowrate
Triplex	1.2 × design flowrate

Progressive Cavity Pumps. The progressive cavity pump [see Fig. 13–4(b) and (c)] has been used successfully on almost all types of sludges. The pump is composed of a single-threaded rotor that operates with a minimum of clearance in a double-threaded helix elastomer stator. A volume or "cavity" moves progressively from suction to discharge when the rotor turns. The pump is self-priming at suction lifts up to 8.5 m (28 ft), but it must not be operated dry or it will burn out the elastomer stator. Progressive cavity pumps are available in capacities up to 126 L/s (2000 gal/min) and may be operated at discharge heads of 48 bar (720 $lb_f/in.^2$) with sludge. This type of pump requires oversizing to meet system conditions over the life of the of equipment. For example, if a 9.5 L/s (150 gal/min) pump is required the pump selection should be sized for an additional 50 percent or a pump sized for 14.25 L/s (225 gal/min). Speed for sludge applications should be limited to approximately 250 rev/min. For sludges and for systems feeding dewatering equipment, a grinder normally precedes these pumps. The pumps are expensive to maintain because of wear of the rotors and stators, particularly in primary sludge pumping applications where grit is present. For primary sludge applications consideration should be given to recessed impeller pumps. Advantages of the pumps are (1) the flowrates are controlled easily using variable speed drives, (2) pulsation is minimal, and (3) operation is relatively simple.

Centrifugal Pumps. Centrifugal pumps of solids handling or "non-clog" design [see Fig. 13–4(d)] are commonly used to pump activated sludge. In centrifugal pumping applications, the problem is choosing the proper number and capacity to accommodate the typical wide range of flowrates required. At any given speed, centrifugal pumps operate well only if the pumping head is within a relatively narrow range; the variable nature of sludge, however, causes pumping heads to change. The selected pumps must have sufficient clearance to pass the solids without clogging and have a small enough capacity to avoid pumping a sludge diluted by large quantities of wastewater overlying the sludge blanket. Throttling the discharge to reduce the capacity is impractical because of frequent stoppages; hence it is absolutely essential that these pumps be equipped with variable-speed drives. Centrifugal pumps of special design: recessed impeller and "chopper" type pumps have been used for pumping primary sludge.

Recessed impeller pumps [see Figs. 13–4(e) and (f)] have impellers that are fully recessed and are very effective in conveying sludge and higher sludge concentrations than the solids handling centrifugal pumps. The size of particles that can be handled is limited only by the diameter of the suction or discharge openings. The rotating impeller develops a vortex in the sludge so that the main propulsive force is the liquid itself. Most of the fluid does not actually pass through the vanes of the impeller, thereby minimizing abrasive contact; however, pumps used in sludge service are recommended to have nickel or chrome abrasion-resistant volute and impellers. The pumps can operate only over a narrow head range at a given speed, so the system operating conditions must be evaluated carefully. Variable speed control is recommended where the pumps are expected to operate over a wide range of head conditions. For high-pressure applications, multiple pumps may be used, connected together in series.

Chopper-type pumps have a cutter knife attached to a non-clog impeller that agitates and breaks up large solids that tend to block the pump suction. Incoming sludge is chopped by sharpened impeller blades that turn across the cutter bar. Chopper pumps are manufactured in sizes up to 380 L/s (6000 gal/min) in both horizontal and vertical dry pit configurations as well as submersible configurations.

Slow-speed centrifugal and mixed-flow pumps are commonly used for returning activated sludge to the aeration tanks. Screw pumps are also being used for this service especially where pumps are required to have a large turndown. Screw centrifugal pumps tend to have less clogging issues for these applications.

Diaphragm Pumps. Diaphragm pumps use a flexible membrane that is pushed and pulled to contract and enlarge an enclosed cavity [see Fig. 13–4(g) and (h)]. Flow is directed through this cavity by check valves, which may be either ball or flap type. The capacity of a diaphragm pump is altered by changing either the length of the diaphragm stroke or the number of strokes per minute. Pump capacity can be increased and flow pulsations smoothed out by providing two pump chambers and using both strokes of the diaphragm for pumping. Diaphragm pumps are relatively low capacity and low head; the largest available air diaphragm pump delivers 14 L/s (220 gal/min) against 15 m (50 ft) of head.

High-Pressure Piston Diaphragm Pumps. High-pressure piston pumps are used in high-pressure applications such as pumping sludge long distances. Several types of piston pumps have been developed for high-pressure applications and are similar in action to plunger pumps. The high-pressure piston pumps use separate power pistons or membranes or diaphragms to separate the drive mechanisms from contacting the sludge. A schematic of a piston pump is shown on Fig 13–4(i). A view of a duplex piston pump is shown on Fig. 13–4(j). Advantages of these types of pumps are (1) they can pump relatively small flowrates at high pressures, up to 13.8 bar (note 1 bar = 100 kPa) (200 $\text{lb}_f/\text{in.}^2$), (2) large solids up to the discharge pipe diameter can be passed, (3) a range of sludge concentrations can be handled, and (4) the pumping can be accomplished in a single stage. The pumps, however, are very expensive.

Rotary Lobe Pumps. Rotary lobe pumps [see Fig. 13–4(k) and (l)] are positive displacement pumps in which two rotating synchronous lobes push the fluid through the pump. Rotational speed and shearing stresses are low. For sludge pumping, lobes are made of hard metal or hard rubber. This type of pump requires oversizing to meet system conditions over the life of the of equipment. For example if a 9.5 L/s (150 gal/min) pump is required the pump selection should be sized for an additional 50 percent or a pump sized for 14.25 L/s (225 gal/min). Speed for sludge applications should be limited to approximately 250 to 300 rev/min depending on the abrasiveness of the sludge. An advantage cited for the rotary lobe pump is that lobe replacement is less costly than rotor, and stator replacement for progressive cavity pumps and the space required for installation is less. Rotary lobe pumps, like other positive-displacement pumps, must be protected against pipeline obstructions.

Hose Pumps. Peristaltic hose pumps [see Fig. 13–4(m)] have also been used for pumping sludge. The pump works by alternately compressing and relaxing a specially designed resilient but reinforced hose. The hose is compressed between the inner wall of the pump housing and the compression shoes on the rotor. A lubricant is used to reduce heat and wear on the hose. The pumped sludge only comes in contact with the inner wall of the hose, which cushions entrained abrasives during compression. The pumps are available in capacities ranging from 36 to 1250 L/min (10 to 330 gal/min). As a positive-displacement pump, the pump output is directly proportional to speed at either high or low discharge pressures. The primary disadvantages of the hose pump are the pulsating flow, hose wear, and the relatively high cost of hose replacement.

Headloss Determination

The headloss encountered in the pumping of sludge depends on the flow properties (rheology) of sludge, the pipe diameter, and the flow velocity. It has been observed that headlosses increase with increased solids content, increased volatile content, and lower temperatures. When the percent volatile matter multiplied by the percent solids exceeds 600, difficulties may be encountered in pumping sludge.

Water, oil, and most other fluids are "Newtonian," which means that the pressure drop is proportional to the velocity and viscosity under laminar flow conditions. As the velocity increases past a critical value, the flow becomes turbulent. Dilute sludges such as unconcentrated activated and trickling-filter sludges behave similar to water. Concentrated wastewater sludges, however, are non-Newtonian fluids. The pressure drop under laminar conditions for non-Newtonian fluids is not proportional to flow, so the viscosity is not a constant. Special procedures may be used to determine headloss under laminar-flow conditions, and the velocity at which turbulent flow begins. In this section both the simplified approach of calculating headloss and a method using the sludge rheology will be discussed.

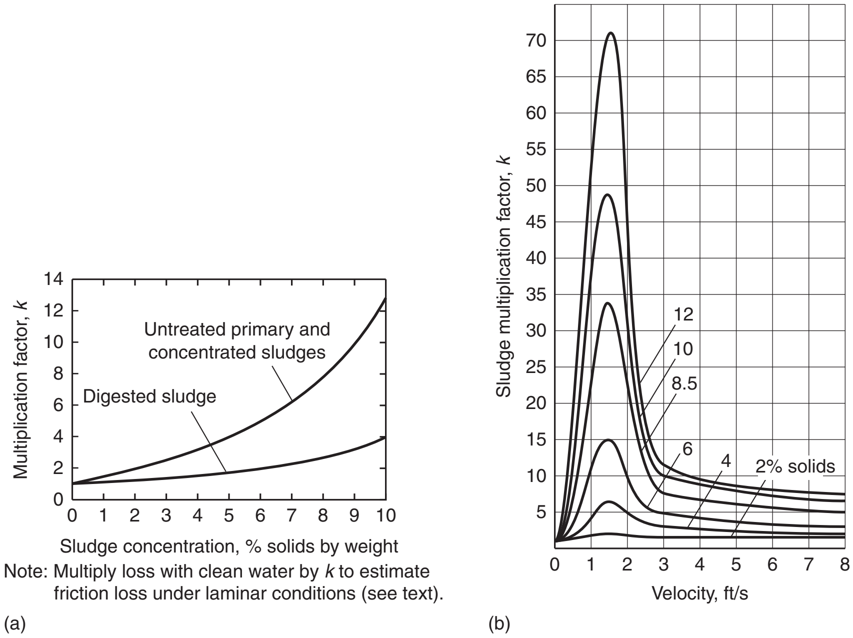
The headloss in pumping unconcentrated activated and trickling-filter sludges may be from 10 to 25 percent greater than for water. Primary, digested, and concentrated sludges at low velocities may exhibit a plastic-flow phenomenon in which a definite pressure is required to overcome resistance and start flow. The resistance then increases approximately with the first power of the velocity throughout the laminar range of flow, which extends to about 1.1 m/s (3.5 ft/s), the lower critical velocity. Above the higher critical velocity at about 1.4 m/s (4.5 ft/s), the flow may be considered turbulent. In the turbulent range, the losses for well-digested sludge may be more than two to three times the losses for water. The losses for primary and concentrated sludges, especially those conditioned with polymer, and scum may be considerably greater. The risk of underestimating the headloss also increases as the piping distance and sludge concentration increases. Where possible, particularly in long-distance sludge pumping, hydraulic studies should be conducted to confirm the ranges of headloss characteristics.

Simplified Headloss Computations. Relatively simple procedures are used to compute headloss for short sludge pipelines. The accuracy of these procedures may be adequate, especially at sludge solids concentrations less than 3 percent by weight. To determine the headloss, the factor k is obtained from Fig. 13–5(a) for a given solids content and type of sludge. The headloss when pumping sludge is computed by multiplying the headloss of water, determined by using the Darcy-Weisbach, Hazen-Williams, or Manning equations, by k. The values given on Fig. 13–5(a) should be used only when (1) velocities are at least 0.8 m/s (2.5 ft/s), (2) velocities do not exceed 2.4 m/s (8 ft/s), (3) thixotropic behavior is not considered, and (4) the pipe is not obstructed by grease or other materials.

Another approximate method makes use of empirical multiplication factor charts [see Fig. 13–5(b)]. The approximate method involves only velocity and percent solids consideration. Usually, the consistency of untreated primary sludge changes during pumping. At first, the most concentrated sludge is pumped. When most of the sludge has been pumped, the pump must handle a dilute sludge that has essentially the same hydraulic characteristics as water. The change in characteristics causes a centrifugal pump to operate farther out

Figure 13–5

Headloss multiplication factors: (a) for different sludge types and concentrations (b) for different pipeline velocities and sludge concentrations.



Note: Multiply loss with clean water by *k* to estimate friction loss under laminar conditions (see text).

on its head-capacity curve, beyond the areas of best efficiency. The pump motor should be sized for the additional load, and a variable-speed drive should be considered to reduce the flow under changing sludge characteristics. If the pump motor is not sized for the maximum load when pumping water at top speed, it is likely to be overloaded or damaged if the overload devices do not function or are set too high.

To determine the operating speeds and motor power required for a centrifugal pump handling sludge, system curves should be computed (1) for the most dense sludge anticipated with design friction factor, (2) for average conditions, and (3) for water with a new pipe friction factor to cover the full anticipated range of the pumping system. The curves should be plotted on a graph of the pump curves for a range of available speeds. The maximum and minimum speeds required of a particular pump are obtained from the intersection of the pump head-capacity curves with the system curves at the desired capacity. Where the maximum speed head-capacity curve intersects the system curve for water determines the power required. In constructing the system curves for sludge for velocities from 0 to 1.1 m/s (3.5 ft/s), the headloss can be considered constant at the figure computed for 1.1 m/s (3.5 ft/s). The intersection of the pump curves with the system curve for average conditions can be used to estimate hours of operations, average speed, and power costs.

Because the usual flow formulas cannot be used in the plastic and laminar range, judgment and experience must be relied upon. In this range, capacities will be small, and plunger, progressive cavity, or rotary-lobe pumps should be used with ample head and capacity as recommended previously.

Application of Rheology to Headloss Computations. For pumping sludge over long distances, an alternative method of computing headloss characteristics has been developed based on the flow properties of the sludge. A method of computing headloss for laminar flow conditions was derived originally by Babbitt and Caldwell (1939), based on the results of experimental and theoretical studies. Additional studies have been performed for the transition from laminar to turbulent flow (Mulbarger et al., 1981;

U.S. EPA, 1979) and are summarized in Sanks et al. (1998). Long-distance pumping of mixtures of untreated (raw) primary and secondary sludge is discussed by Carthew et al. (1983). The approach used in those studies for turbulent flow, which is of critical importance for long pipelines, is described below. For laminar and transitional flow, computational procedures described in Sanks et al. (1998) are recommended.

As stated previously, water, oil, and most other common fluids are "Newtonian," which means the pressure drop is directly proportional to the velocity and viscosity under laminar-flow conditions. As the velocity increases past a critical value, the flow becomes turbulent. The transition from laminar to turbulent flow depends on the Reynolds number, which is inversely proportional to the fluid viscosity. Wastewater sludge, however, is a non-Newtonian fluid. The pressure drop under laminar conditions is not proportional to flow, so the viscosity is not a constant. The precise Reynolds number at which turbulent-flow characteristics are encountered is uncertain for sludges.

Sludge has been found to behave much like a Bingham plastic, a substance with a straight-line relationship between shear stress and flow only after flow begins. A Bingham plastic is described by two constants: the yield stress s_y and the coefficient of rigidity η. Typical ranges of values for yield stress and coefficient of rigidity are shown on Figs. 13–6(a) and (b). If the two constants can be determined, the pressure drop over a wide range of velocities can be obtained using ordinary equations for water and the use of Fig. 13–6(c). As observed on Figs. 13–6(a) and (b), published data quantifying yield stress and the coefficient of rigidity values for wastewater sludges are highly variable. Pilot studies should be conducted to determine the rheological data for specific applications. Procedures for developing yield stress and the coefficient of rigidity using a pipeline viscometer and rotational viscometer are also given by Carthew et al. (1983).

Two dimensionless numbers can be used to determine the pressure drop due to friction for sludge: Reynolds number and Hedstrom number. Reynolds number is calculated by using the following expression:

$$N_R = \frac{\rho v D}{\eta} \qquad \text{SI units} \tag{13–3a}$$

$$N_R = \frac{\gamma v D}{\eta} \qquad \text{U.S. customary units} \tag{13–3b}$$

where N_R = Reynolds number, dimensionless

ρ = density of sludge, kg/m^3

γ = specific weight of sludge, lb/ft^3

v = average velocity, m/s (f/s)

D = diameter of pipe, m (ft)

η = coefficient of rigidity, kg/m·s (lb/ft·s)

Hedstrom number, which is reviewed by Hill et al. (1986), is calculated as follows:

$$H_e = \frac{D^2 s_y \rho}{\eta^2} \qquad \text{SI units} \tag{13–4a}$$

$$H_e = \frac{D^2 s_y g_c \gamma}{\eta^2} \qquad \text{U.S. customary units} \tag{13–4b}$$

where H_e = Hedstrom number, dimensionless

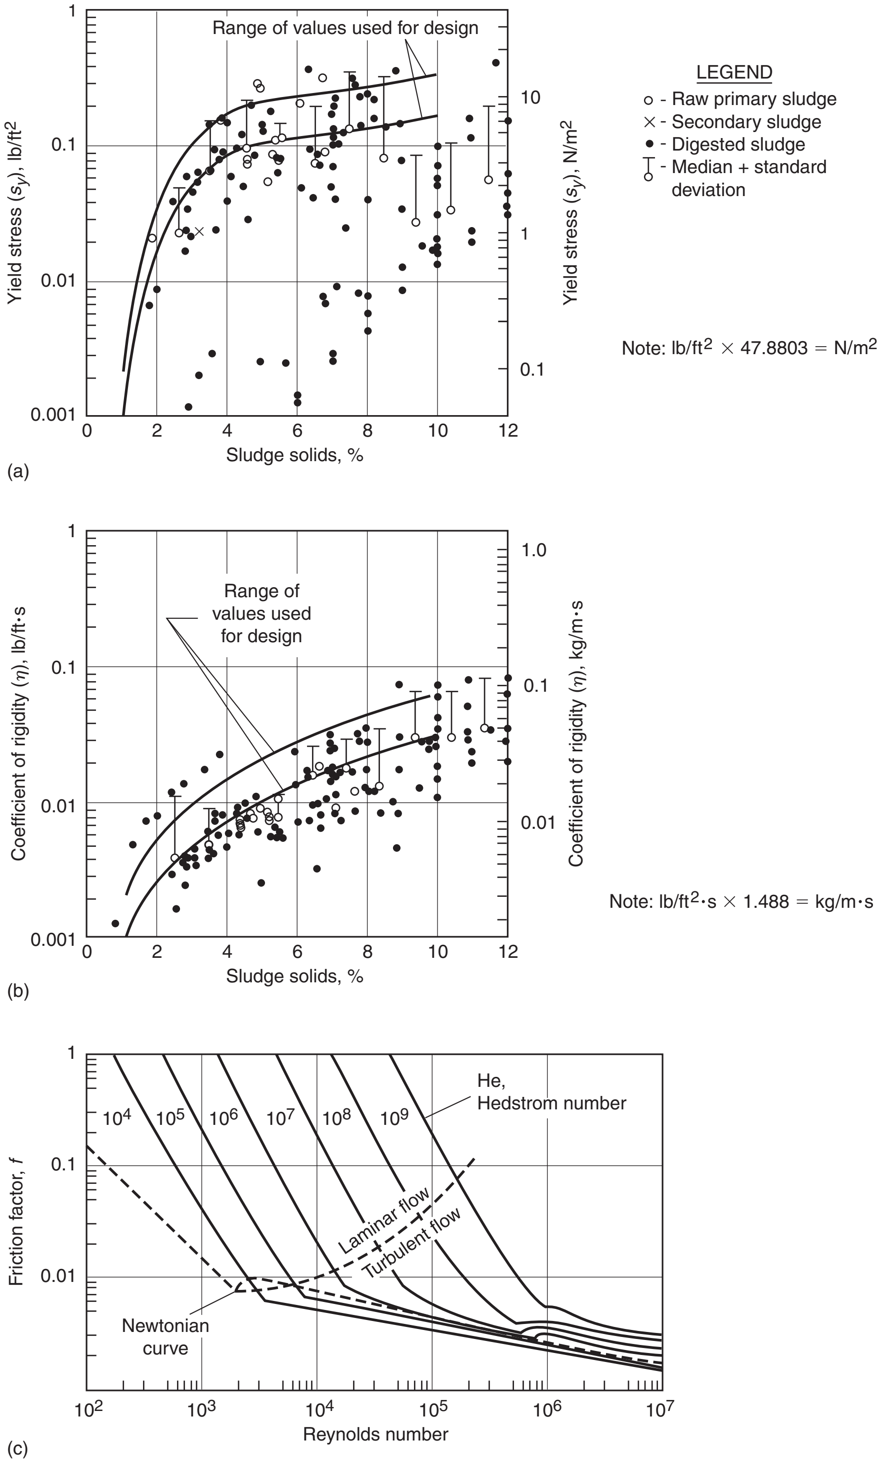
s_y = yield stress, N/m^2 (lb$_f$/ft^2)

g_c = 32.2 lb$_m$·ft/lb$_f$·s^2

Other terms are as defined previously.

Figure 13–6

Curves for computing pipeline headloss by the sludge rheology method: (a) yield stress vs. percent sludge solids, (b) coefficient of rigidity vs. percent sludge solids, and (c) friction factor for sludge analyzed as a Bingham plastic. (Adapted from Carthew et al., 1983.)



Note: lb/ft^2 × 47.8803 = N/m^2

Note: lb/ft^2·s × 1.488 = kg/m·s

Using the calculated Reynolds number and the Hedstrom number, the friction factor f can be determined from Fig. 13–6(c). The pressure drop for turbulent conditions can then be calculated from the following relationship:

$$\Delta p = \frac{2f\rho L v^2}{D} \qquad \text{SI units} \tag{13–5a}$$

$$\Delta p = \frac{2f\gamma L v^2}{g_c D} \qquad \text{U.S. customary units} \tag{13–5b}$$

where Δp = pressure drop due to friction, N/m^2 (lb$_f$/ft^2)
f = friction factor [from Fig. 13–6(c)]
L = length of pipeline, m (ft)
Other terms are as defined previously.

In using Eqs. (13–3), (13–4), and (13–5), it should be noted that the Reynolds number is not the same as the Reynolds number based on viscosity. In plastic flow, an effective viscosity may be defined, but it is variable and can be much greater than the coefficient of rigidity. Consequently, the two Reynolds numbers can differ greatly. The friction factor *f* will usually differ significantly from the *f* values reported in standard hydraulic texts for clear water, which may be four times the values used on Fig. 13–6(c). These equations apply to the entire range of laminar and turbulent flows, except that Fig. 13–6(c) does not allow for pipe roughness. To allow for pipe roughness, if customary water formulas for headloss result in a higher pressure drop than computed with Eq. (13–5), then roughness is dominant, the flow is fully turbulent, and the pressure drop given by the water headloss formula will be reasonably accurate. A safety factor on the order of 1.5 is recommended for worst-case design conditions (Mulbarger et al., 1981). The use of Eqs. (13–3), (13–4), and (13–5) is illustrated in Example 13–2.

EXAMPLE 13–2 **Computation of Headloss Using Sludge Rheology** Calculate the headloss in a 250-mm-diameter pipeline 10,000 m long conveying untreated (raw) sludge at an average flowrate 0.04 m^3/s. Determine also if the flow is turbulent. By testing, the following sludge rheology data were found:

Yield stress s_y = 1.3 N/m^2

Coefficient of rigidity η = 0.035 kg/m·s

Specific gravity = 1.01

Solution

1. Calculate the pipeflow velocity.
   a. Determine the pipe cross-sectional area.

$$A = \pi \times \frac{D^2}{4} = 3.14\frac{(0.25\text{ m})^2}{4} = 0.49\text{ m}^2$$

   b. Determine velocity.

$$v = \frac{Q}{A} = \frac{(0.04\text{ m}^3/\text{s})}{0.049\text{ m}^2} = 0.82\text{ m/s}$$

2. Compute sludge specific weight.

$$\rho = 1000\text{ kg/m}^3 \times 1.01 = 1010\text{ kg/m}^3$$

3. Compute Reynolds number using Eq. (13–3).

$$N_R = \frac{\rho v D}{\eta} = \frac{(1010\ \text{kg/m}^3)(0.82\ \text{m/s})(0.25\ \text{m})}{(0.035\ \text{kg/m·s})} = 5.92 \times 10^3$$

4. Compute Hedstrom number using Eq. (13–4).

$$H_e = \frac{D s_y \rho}{\eta^2} = \frac{(0.25\ \text{m})^2(1.3\ \text{N/m}^2)(1010\ \text{kg/m}^3)}{(0.035\ \text{kg/m·s})^2} = 6.70 \times 10^4$$

5. Determine friction factor f from Fig. 13–6(c) using the computed Reynolds and Hedstrom numbers.

$f = 0.007$

Note, on Fig. 13–6c, that the flow is in the turbulent zone.

6. Compute pressure drop using Eq. (13–5).

$$\Delta p = \frac{2 f \rho L v^2}{D} = \frac{2(0.007)(1010\ \text{kg/m}^3)(10{,}000\ \text{m})(0.82\ \text{m/s})^2}{0.25\ \text{m}}$$

$$= 380{,}309\ \text{kg/m·s}^2\ (\text{N/m}^2 \text{ or Pa})$$

Convert to meters of water.

$$\Delta p = \frac{380{,}309\ \text{kg/m·s}^2}{(10^3\ \text{kg/m}^3)(9.81\ \text{m/s}^2)} = 38.8\ \text{m}$$

Comment In this example, only one set of rheology data was used. In actual design, test data should be used for a range of probable conditions so that a family of headloss curves can be developed for the range of operating conditions. In addition, appropriate safety factors should be used for worst-case conditions. Comparison of the headloss to the headloss for water using the Hazen-Williams formula is left as a homework problem.

Sludge Piping

In wastewater treatment plants, conventional sludge piping should not be smaller than 150 mm (6 in.) in diameter although smaller-diameter glass-lined pipe has been used successfully. Sludge piping may not need to be larger than 200 mm (8 in.), unless the velocity exceeds 1.5 to 1.8 m/s (5 to 6 ft/s), in which case the pipe is sized to maintain that velocity. Gravity sludge withdrawal lines should not be less than 200 mm (8 in.) in diameter. It is common practice to install a number of cleanouts in the form of plugged tees or crosses instead of elbows so that the lines can be rodded if necessary. Pump connections should not be smaller than 100 mm (4 in.) in diameter.

A liberal number of hose gates should be installed in the piping, and an ample supply of high-pressure flushing water should be available for clearing stoppages. The flushing water should be plant effluent. The flushing water system should have a capacity of not less than 0.010 m^3/s (150 gal/min) at 500 kN/m^2 ($\sim$70 $\text{lb}_\text{f}/\text{in.}^2$). In large plants with larger piping, a greater capacity should be available, and the available pressure should be increased to 700 kN/m^2 (100 $\text{lb}_\text{f}/\text{in.}^2$).

Grease has a tendency to coat the inside of piping used for transporting primary sludge and scum. Grease accumulation is more of a problem in large plants than in small ones. The coating results in a decrease in effective diameter and a large increase in pumping head. For this reason, low capacity positive-displacement pumps are designed for heads greatly in excess of the theoretical head. Centrifugal pumps, with their larger capacity, usually pump a more dilute sludge, often containing some wastewater, and head buildup due to grease accumulations appears to occur more slowly. In some plants, provisions have been made for melting the grease by circulating hot water, steam, or digester supernatant through the main sludge lines.

In treatment plants, friction losses are low because the pipe runs are short; consequently, there is little difficulty in providing an ample safety factor. In the design of long sludge lines, however, special design features should be considered including (1) providing two pipes unless a single pipe can be shut down for several days without causing problems; (2) providing for external corrosion and pipe loads; (3) adding facilities for applying dilution water for flushing the line; (4) providing means to insert a pipe cleaner; (5) including provisions for steam injection, especially in cold climates and where excessive grease accumulation occurs; (6) providing air relief and blowoff valves for the high and low points, respectively, and (7) considering the potential effects of waterhammer. A discussion of waterhammer in force mains is provided in the companion volume to this text (Metcalf & Eddy, 1981).

13–5 PRELIMINARY SLUDGE PROCESSING OPERATIONS

Grinding, degritting, blending, and storage of sludge is necessary to provide a relatively constant, homogeneous feed to subsequent processing facilities. Blending and storage can be accomplished either in a single unit designed to do both or separately in other plant components. Screening of raw sludge or digested biosolids is sometimes required in reuse applications for the removal of plastics, rags, and other material. Each of these preliminary operations is discussed in this section.

Grinding

Sludge grinding is a process in which large and stringy material contained in sludge is cut or sheared into small particles to prevent clogging or wrapping around rotating equipment. A typical sludge grinder installation is shown on Fig. 13–7. Some of the processes that must be preceded by sludge grinders and the purposes of grinding are reported in Table 13–16. Grinders historically have required high maintenance, but newer designs of slow-speed grinders have been more durable and reliable. These designs include improved bearings and seals, hardened steel cutters, overload sensors, and mechanisms that reverse the cutter rotation to clear obstructions or shut down the unit if the obstruction cannot be cleared.

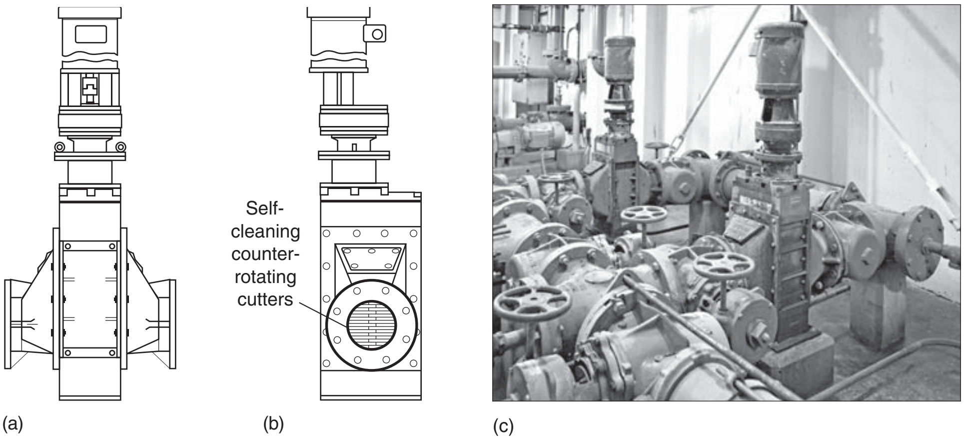


Figure 13–7

Typical inline sludge grinder: (a) side view, (b) end view, and (c) view of typical installation [(a) and (b) adapted from Franklin Miller].

Table 13–16

Operations or processes requiring the grinding of sludge and biosolids

Operation or process	Purpose of grinding
Pumping with progressive cavity pumps	Prevent clogging and reduce wear
Solid bowl centrifuges	Prevent clogging. Large solid bowl units generally can handle larger particles and may not require sludge or biosolids grinding
Belt filter press	Prevent clogging of the sludge or biosolids distribution system, prevent warping of rollers, and provide more uniform dewatering

Screening

Because raw wastewater screens can allow significant quantities of solid material to pass through, sludge screening is an alternative to grinding. Screening is advantageous in that nuisance material is removed from the sludge stream. Step screens, shown on Fig. 5–4(c) in Chap. 5, can be used for the removal of fine solids from septage and primary sludge. Screen openings normally range from 3 to 6 mm (0.12 to 0.24 in.), although openings up to 10 mm (0.4 in.) can be used.

Another type of sludge screen is an inline screen that can be installed in a pipeline (see Fig. 13–8). The screen removes material by passing the flow stream through a screen with 3 to 10-mm (0.12 to 0.4-in.) openings although 5 mm (0.2 in.) is the typical size for wastewater sludges. Material captured by the screen moves by a screw conveyor into a press or compaction zone where it is dewatered and compacted. Material is ejected from the press zone when sufficient solids build up to overcome the force on the unit's discharge cone. Screening solids concentrations range from 30 to 50 percent. Allowable operating pressure is reported to be 100 kPa (14 $lb_f/in.^2$) (Arakaki et al., 1998). The screened sludge is diluted and may require thickening.

Degritting

In some plants where separate grit removal facilities are not used ahead of the primary sedimentation tanks, or where the grit removal facilities are not adequate to handle peak

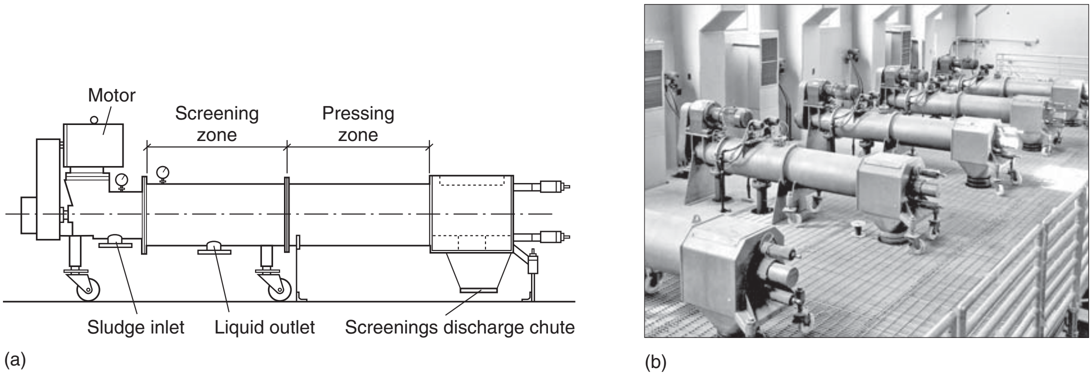

Figure 13–8

Sludge screenings press: (a) schematic and (b) view of a large installation (courtesy of the City of San Diego, CA).

Table 13–17

Grit removal efficiency using cyclone degritters for primary sludge[a]

Primary sludge concentration, % total solids	Mesh of removal[b]
1	150
2	100
3	65
4	28–35

[a] For a 300 mm (12 in.) hydrocyclone at 42 kN/m^2 (6 lb$_f$/in.^{2} gage) at 13 L/s (200 gal/min).

[b] About 95 percent or more of indicated particle size is removed.

Note: Normal design range is for 1 to 1.5 percent sludge.

flows and peak grit loads, it may be necessary to remove the grit before further processing of the sludge. Where further thickening of the primary sludge is desired, a practical consideration is sludge degritting. The most effective method of degritting sludge is through the application of centrifugal forces in a flowing system to achieve separation of the grit particles from the organic sludge. Such separation is achieved through the use of cyclone degritters, which have no moving parts. The sludge is applied tangential to a cylindrical feed section, thus imparting a centrifugal force. The heavier grit particles move to the outside of the cylinder section and are discharged through a conical feed section. The organic sludge is discharged through a separate outlet. The efficiency of the cyclone degritter is affected by pressure and by the concentration of the organics in the sludge. To obtain effective grit separation, the sludge must be relatively dilute, 1 to 2 percent TS. As the sludge concentration increases, the particle size that can be removed decreases. The general relationship between sludge concentration and effectiveness of removal for primary sludges is shown in Table 13–17.

Blending

Sludge is generated in primary, secondary, and advanced wastewater treatment processes. Primary sludge consists of settleable solids carried in the raw wastewater. Secondary sludge consists of biological solids as well as additional settleable solids. Sludge produced in the advanced wastewater may consist of biological and chemical solids. Sludge is blended to produce a uniform mixture to downstream operations and processes. Uniform mixtures are most important in short-detention-time systems, such as sludge dewatering, heat treatment, and incineration. Provision of well-blended sludge with consistent characteristics to these treatment units will enhance greatly plant operability and performance.

Sludge from primary, secondary, and advanced processes can be blended in several ways:

1. *In primary settling tanks*. Secondary or tertiary sludges can be returned to the primary settling tanks where they will mix and co-settle with the primary sludge.
2. *In pipes*. Blending in pipes requires careful control of sludge sources and feed rates to ensure the proper blend. Without careful control, wide variations in sludge consistency may be expected.
3. *In sludge-processing facilities with long detention times*. Aerobic and anaerobic digesters (complete-mix type) can blend the feed sludges uniformly.
4. *In a separate blending tank*. This practice provides the best opportunity to control the quality of the blended sludges.

In treatment plants of less than 0.05 m^3/s (1 Mgal/d) capacity, blending is accomplished usually in the primary settling tanks. In large facilities, optimum efficiency is achieved by separately thickening sludges before blending.

Storage

Storage should be provided to minimize fluctuations in the rate of sludge and biosolids production and to allow sludge to accumulate during periods when subsequent processing facilities are not operating, e.g., night shifts, weekends, and periods of unscheduled equipment downtime. Sludge and biosolids storage is particularly important in providing a uniform feed rate ahead of the following processes: mechanical dewatering, lime stabilization, heat drying, and thermal reduction.

Short-term sludge and biosolids storage may be accomplished in wastewater settling tanks or in thickening tanks. Long-term sludge and biosolids storage may be accomplished in stabilization processes with long detention times, e.g., aerobic and anaerobic digestion, or in specially designed separate tanks. In small installations, sludge is usually stored in the settling tanks and digesters. In large installations that do not use aerobic and anaerobic digestion, sludge is often stored in separate blending and storage tanks. Such tanks may be sized to retain the sludge for a period of several hours to a few days. If sludge or biosolids is stored longer than 2 to 3 d, it will deteriorate, become odorous, and be more difficult to dewater. The determination of the required storage volume is illustrated in Example 13–3. Sludge or biosolids is often aerated to prevent septicity and to promote mixing. Mechanical mixing may be necessary to assure complete blending of the sludge. Chlorine, iron salts, potassium permanganate, and hydrogen peroxide have been used with limited success to limit or control septicity and to control the odors from sludge storage and blending tanks. In cases where sludge storage occurs in enclosed tanks, ventilation should be provided along with appropriate odor-control technologies such as chemical scrubbers or biofilters (see Chap. 15).

EXAMPLE 13–3 **Determination of Volume Required for Sludge Storage** Assume that the yearly average rate of sludge production from an activated sludge treatment plant is 12,000 kg/d. Develop a curve of sustained sludge mass loading rates that can be used to determine the size of sludge-storage facilities required with various downstream sludge-processing units. Then, using the developed curve, determine the volume required for sludge storage, assuming that sludge accumulated for 7 d is to be processed in 5 working d, and that sludge accumulated for 14 d is to be processed in 10 working d. Note that the 5- and 10-d work periods correspond to 1 and 2 wk, respectively, assuming that certain sludge-processing facilities, such as belt-filter presses, will not be operated on the weekends.

Solution

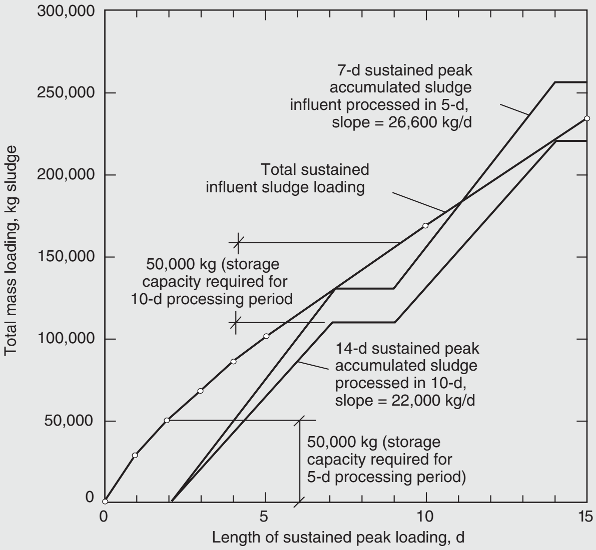
1. Develop a curve of sustained sludge mass loadings.
    a. Because no information is specified, it will be assumed that the sustained sludge production will mirror the sustained BOD plant loadings given on Fig. 3–13(a) and used in Example 3–7.
    b. Set up an appropriate computation table and compute the values necessary to plot the curve.

Length of sustained peak, d (1)	Peaking factor[a] (2)	Peak sludge mass loading, kg/d (3)	Total sustained loading, kg[b] (4)
1	2.4	28,800	28,800
2	2.1	25,200	50,400
3	1.9	22,800	68,400
4	1.8	21,600	86,400
5	1.7	20,400	102,000
10	1.4	16,800	168,000
15	1.3	15,600	234,000
365	1.0	12,000	

[a] From Fig. 3–13(a).

[b] Total mass produced for the corresponding sustained period given in col. 1.

c. Plot the sustained sludge loading curve (see following figure).



2. Determine the sludge storage volume required for the stated operating conditions.
   a. Determine the daily rate at which sludge must be processed to handle the 7-d sustained peak (from figure) in 5 working d.

$$\text{kg/d} = \frac{133{,}000}{5\,\text{d}} = 26{,}600\,\text{kg/d}$$

   b. Determine the daily rate at which sludge must be processed to handle the 14-d sustained peak (from figure) in 10 working d.

$$\text{kg/d} = \frac{220{,}000}{10\,\text{d}} = 22{,}000\,\text{kg/d}$$

c. Assuming that the sludge storage facilities are empty on Friday just before the weekend, plot on the figure the average daily rate at which sludge must be processed during the 5- and 10-d periods.

d. From the figure, the required storage capacity in pounds of sludge is
   i. Capacity based on 5 working d = 50,000 kg
   ii. Capacity based on 10 working d = 50,000 kg

Comment The downstream processing equipment can now be sized using the daily rate at which sludge must be processed. For example, if the number of kilograms per hour that can be processed with a belt-filter press is known, then the size and number of units can be computed from the number of shifts to be used per day and the assumed value of the actual working hours per shift. In sizing equipment, a trade-off analysis should always be performed between the cost of storage and processing facilities versus labor costs (for both one shift and two shifts) to determine the most cost-effective combination.

13–6 THICKENING

The solids content of primary, activated, trickling filter, or mixed sludge (i.e., primary plus waste activated) varies considerably, depending on the characteristics of the sludge, the sludge removal and pumping facilities, and the method of operation. Representative values of percent total solids from various treatment operations or processes were shown previously in Table 13–8. Thickening is a procedure used to increase the solids content of sludge by removing a portion of the liquid fraction. To illustrate, if waste activated sludge which is typically pumped from secondary settling tanks with a content of 0.8 percent, can be thickened to a content of 4 percent solids, then a five-fold decrease in sludge volume is achieved. Thickening is generally accomplished by physical means, including co-settling, gravity settling, flotation, centrifugation, gravity belt, and rotary drum. Typical sludge-thickening methods are described in Table 13–18.

Application

The volume reduction obtained by sludge concentration is beneficial to subsequent treatment processes, such as digestion, dewatering, and drying from the following standpoints: (1) capacity of tanks and equipment required, (2) quantity of chemicals required for sludge conditioning, and (3) amount of heat required by digesters and amount of auxiliary fuel required for heat drying.

For large facilities where sludge must be transported a significant distance, such as to a separate plant for processing, a reduction in sludge volume may result in a reduction of pipe size and pumping costs. For smaller facilities, the requirements of a minimum practicable pipe size and minimum velocity may necessitate pumping of significant volumes of wastewater in addition to sludge, thereby diminishing the value of volume reduction. Volume reduction is very desirable when liquid sludge is transported by tank trucks for direct application to land as a soil conditioner.

Sludge thickening is achieved at all wastewater treatment plants in some manner—in the primary clarifiers, in sludge digestion facilities, or in specially designed separate units. If separate units are used, the recycled flows are returned normally to the wastewater treatment facilities. In treatment plants of less than 4000 m^3/d (~1 Mgal/d) capacity, separate sludge thickening is seldom practiced. In small plants, gravity thickening is accomplished in the primary settling tank or in the sludge-digestion units, or both. In larger treatment

Table 13–18
Occurrence of thickening methods in sludge processing

Method	Type of sludge	Frequency of use and relative success
Gravity, co-settling in clarifier	Primary and waste activated	Occasional use; may negatively impact the effectiveness of the primary clarifier
Gravity, thickening in separate tank	Untreated primary	Commonly used with excellent results. Sometimes used with hydrocyclone degritting of sludge
	Untreated primary and waste activated	Often used. For small plants, generally satisfactory results with sludge concentrations in the range of 4 to 6 percent. For large plants, results are marginal. Can be odorous in warm weather
	Waste activated	Seldom used; poor solids concentration (2 to 3 percent)
Dissolved air flotation	Untreated primary and waste activated	Limited use; results similar to gravity thickeners
	Waste activated	Commonly used, but use is decreasing because of high operating cost; good results (3.5 to 5 percent solids concentration)
Solid bowl centrifuge	Waste activated	Often used in medium to large plants; good results (4 to 6 percent solids concentration)
Gravity belt thickener	Waste activated	Often used; good results (3 to 6 percent solids concentration)
Rotary drum thickener	Waste activated	Limited use; good results (5 to 9 percent solids concentration)

facilities, the additional costs of separate sludge thickening are often justified by the improved control over the thickening process and the higher concentrations attainable.

Description and Design of Thickeners

The following discussion is intended to introduce the reader to the operations used for the thickening of sludges. Because most of the equipment is mechanical, the primary concern is with its proper application to meet a given treatment objective rather than with the theory of mechanical design. In designing thickening facilities, it is important to (1) provide adequate capacity to meet peak demands and (2) prevent septicity, with its attendant odor problems, during the thickening process. The six methods of thickening discussed in this section are (1) co-settling thickening, (2) gravity, (3) dissolved air flotation, (4) centrifugal, (5) gravity belt, and (6) rotary drum.

Co-settling Thickening. Primary clarifiers are often used to thicken sludge for downstream processing. To thicken sludge, a sludge blanket must be created to consolidate the sludge without allowing the clarified water to be pulled through. Often, sludge retention times of 12 to 24 h or more are maintained in clarifiers to achieve thickened sludge concentration levels in the clarifier underflow. Excessive retention of sludge in the clarifier can cause septic conditions and gasification, and reduce the levels of TSS and BOD removal. Typical effects of sludge blanket retention on TSS removal are illustrated on Fig. 13–9.

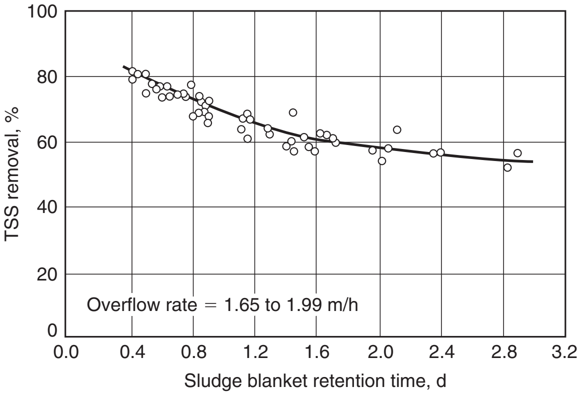


Figure 13–9

Effect of sludge blanket retention time on TSS removal for co-thickening of primary sludge (Albertson and Walz, 1997).

Successful thickening of sludge in primary clarifiers has been achieved by a combination of the following: (1) using one clarifier in a bank of clarifiers for co-settling thickening; dilute sludge underflow (less than 1 percent solids) from the other clarifiers is discharged to the thickening clarifier, (2) maintaining the sludge inventory for about 6 to 12 h, and (3) providing for the addition of coagulating chemicals such as polymer and ferric chloride to condition the sludge to enhance settling. The need for chemical addition depends upon the clarifier overflow rates. Underflow sludge concentrations on the order of 3 to over 5 percent have been reported (Albertson and Walz, 1997). By controlling the sludge blanket within the above sludge retention parameters, clarifier removal rates are enhanced, and sludge thickening is achieved. A schematic diagram of the co-settling thickening system is shown on Fig. 13–10.

Gravity Thickening. Gravity thickening is one of the most common methods used and is accomplished in a tank similar in design to a conventional sedimentation tank. Normally, a circular tank is used, and dilute sludge is fed to a center feed well. The feed sludge is allowed to settle and compact, and the thickened sludge is withdrawn from the conical tank bottom. Conventional sludge collecting mechanisms with deep trusses (see Fig. 13–11) or vertical pickets stir the sludge gently, thereby opening up channels for water to escape and promoting densification. The supernatant flow that results is drawn off and returned to either the primary settling tank, the influent of the treatment plant, or a return flow treatment process. The thickened sludge is pumped to the digesters or dewatering equipment as required; thus, storage space must be provided for the sludge. As indicated in Table 13–18,

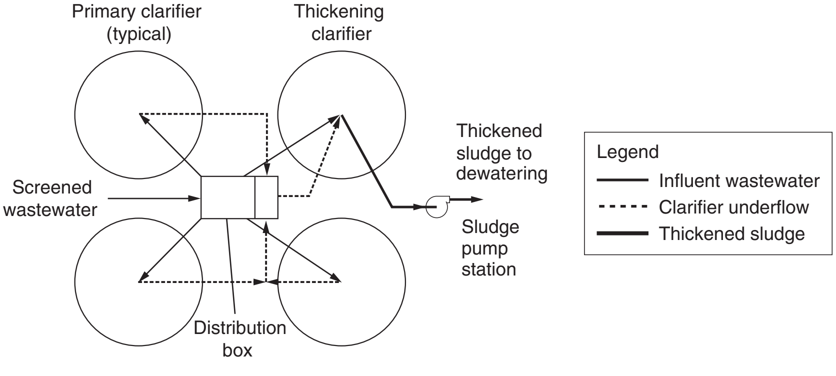

Figure 13–10

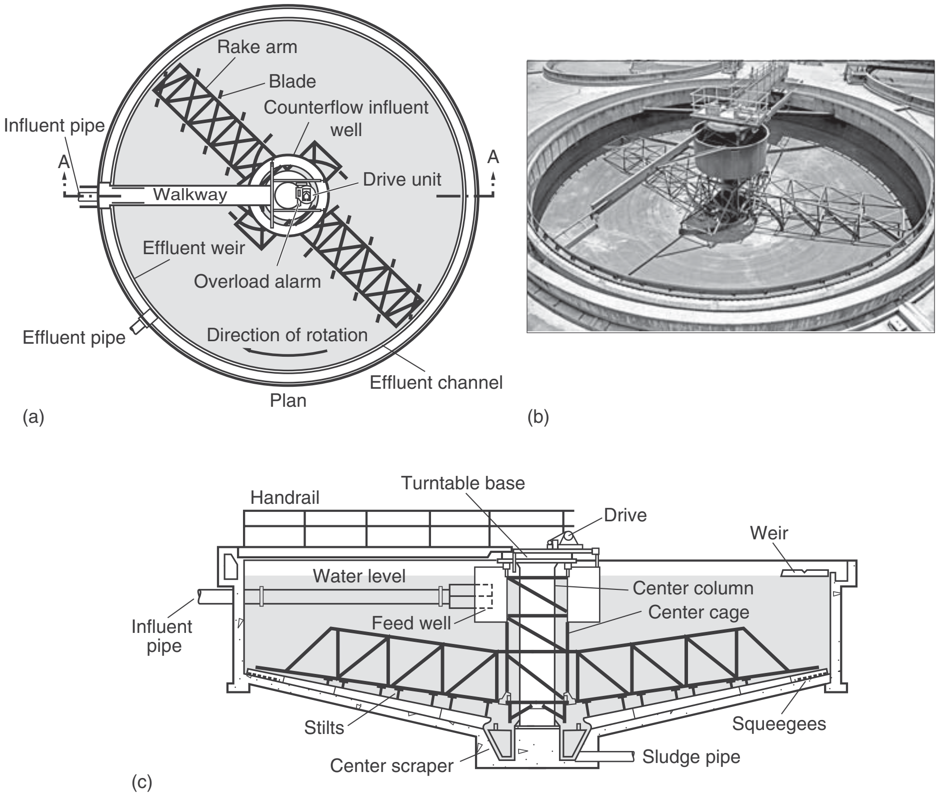
Schematic diagram of a sludge co-thickening system.

Figure 13–11

Schematic diagram of a gravity thickener: (a) plan and (b) section.



gravity thickening is most effective on primary sludge. Gravity thickeners are designed on the basis of solids loading and thickener overflow rate. Typical solids loadings based on existing data are reported in Table 13–19. Recommended maximum hydraulic overflow rates range from 15.5 to 31 $m^3/m^2{\cdot}d$ (380 to 760 $gal/ft^2{\cdot}d$) for primary sludges, 4 to 8 $m^3/m^2{\cdot}d$ (100 to 200 $gal/ft^2{\cdot}d$) for waste activated sludge, and 6 to 12 $m^3/m^2{\cdot}d$ (150 to 300 $gal/ft^2{\cdot}d$) for combined primary and waste activated sludge (WEF, 1980). High hydraulic loadings can cause excessive solids carryover. Conversely, low hydraulic loadings can cause septic conditions and odors, and floating sludge can result.

Provisions for dilution water and occasional chlorine addition are frequently included to improve process performance by maintaining the hydraulic loading. Polymer addition is frequently provided. To maintain aerobic conditions in gravity thickeners, especially when wastewater is warm (22 to 28°C), provisions should be included for adding up to 24 to 30 $m^3/m^2{\cdot}d$ (600 to 750 $gal/ft^2{\cdot}d$) of dilution water (final effluent) to the thickening tank. The dilution water may also remove certain soluble organic and inorganic compounds that consume large amounts of conditioning chemicals used in dewatering. Dilution water that is part of supernatant returned and recycled to the liquid process must be considered in process design.

Because the thickening characteristics of wastewater sludge can vary considerably, it is desirable to design a thickening facility using criteria based on a testing program. Testing programs that can be used include batch settling tests, bench-scale settling tests, and pilot-scale testing. The latter method is recommended wherever possible because data can be obtained from a variety of operating parameters. Test methods are described in WEF (2010a).

Table 13–19

Typical concentrations of unthickened and thickened sludges and solids loadings for gravity thickeners[a]

Type of sludge or biosolids	Solids concentration, %		Solids loading	
	Unthickened	Thickened	lb/ft²·d	kg/m²·d
Separate				
Primary sludge	1–6	3–10	20–30	100–150
Trickling filter humus sludge	1–4	3–6	8–10	40–50
Rotating biological contactor	1–3.5	2–5	7–10	35–50
Air–activated sludge	0.5–1.5	2–3	4–8	20–40
High–purity oxygen activated sludge	0.5–1.5	2–3	4–8	20–40
Extended aeration activated sludge	0.2–1.0	2–3	5–8	25–40
Anaerobically digested primary sludge from primary digester	8	12	25	120
Combined				
Primary and trickling filter humus sludge	1–6	3–9	12–20	60–100
Primary and rotating biological contactor	1–6	3–8	10–18	50–90
Primary and waste activated sludge	0.5–1.5	2–6	5–14	25–70
	2.5–4.0	4–7	8–16	40–80
Waste activated sludge and trickling filter humus sludge	0.5–2.5	2–4	4–8	20–40
Anaerobically digested primary and waste activated sludge	4	8	14	70
Chemical sludge:				
High lime	3–4.5	12–15	24–60	120–300
Low lime	3–4.5	10–12	10–30	50–150
Iron	0.5–1.5	3–4	2–10	10–50

[a] Adapted from WEF (2010a).

In operation, a sludge blanket is maintained on the bottom of the thickener to aid in concentrating the sludge. An operating variable is the sludge volume ratio, which is the volume of the sludge blanket held in the thickener divided by the volume of the thickened sludge removed daily. Values of the sludge volume ratio normally range between 0.5 and 20 d; the lower values are required during warm weather. Alternatively, sludge blanket depth should be measured. Blanket depths may range from 0.5 to 2.5 m (2 to 8 ft); shallower depths are maintained in the warmer months.

EXAMPLE 13–4 **Design a Gravity Thickener for Combined Primary and Waste Activated Sludge** Design a gravity thickener for a wastewater treatment plant having primary and waste activated sludge with the following characteristics:

Type of sludge	Specific gravity	Solids, %	Flowrate, m^3/d
Average design conditions:			
Primary sludge	1.03	3.3	400
Waste activated	1.005	0.2	2250
Peak design conditions:			
Primary sludge	1.03	3.4	420
Waste activated	1.005	0.23	2500

Solution

1. Compute the dry solids at peak design conditions.
   a. Primary sludge

$$\text{kg/d dry solids} = (420\ \text{m}^3/\text{d})(1.03)(0.034\ \text{g/g})(10^3\ \text{kg/m}^3)$$
$$= 14{,}708\ \text{kg/d}$$

   b. Waste activated sludge

$$\text{kg/d dry solids} = (2500\ \text{m}^3/\text{d})(1.005)(0.0023\ \text{g/g})(10^3\ \text{kg/m}^3)$$
$$= 5779\ \text{kg/d}$$

   c. Combined sludge mass = 14,708 + 5779 = 20,487 kg/d
   d. Combined sludge flowrate = 2,500 + 420 = 2,920 m^3/d

2 Compute solids concentration of the combined sludge, assuming the specific gravity of the combined sludge is 1.02.

$$\%\ \text{solids} = \frac{(20{,}487\ \text{kg/d})}{(2920\ \text{m}^3/\text{d})(1.02)(10^3\ \text{kg/m}^3)} \times 100 = 0.69\%$$

3. Compute surface area based on solids loading rate. Because the sludge concentration is between 0.5 and 1.5%, select a solids loading rate of 50 $kg/m^2 \cdot d$ from Table 13–19.

$$\text{Area} = \frac{(20{,}487\ \text{kg/d})}{(50\ \text{kg/m}^2 \cdot \text{d})} = 409.7\ \text{m}^2$$

4. Compute hydraulic loading rate.

$$\text{Hydraulic loading} = \frac{(2920\ \text{m}^3/\text{d})}{409.7\ \text{m}^2} = 7.13\ \text{m}^3/\text{m}^2 \cdot \text{d}$$

5. Compute diameter of thickener; assume two thickeners.

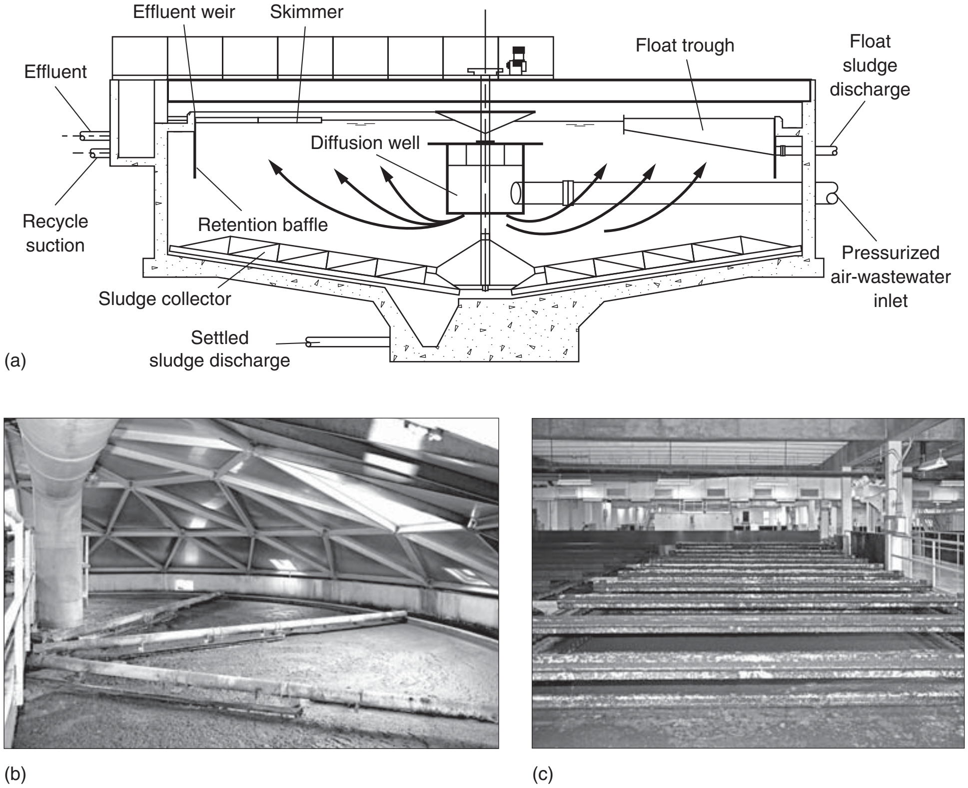
$$\text{Diameter} = \sqrt{\frac{4 \times 409.7\ \text{m}^2}{2 \times \pi}} = 16.15\ \text{m}$$

Comment The hydraulic loading rate of 7.13 $m^3/m^2 \cdot d$ at peak design flow is at the lower end of the recommended rate. To prevent septicity and odors, dilution water should be provided. Calculation of the dilution water requirements for average design flow is a homework problem. The thickener size of 16.15 m is within the maximum size of 20 m customarily recommended by thickener equipment manufacturers for use in municipal wastewater treatment. In actual design, round the thickener diameter to the nearest 0.5 m, or, in this case, 16 m.

Flotation Thickening. In dissolved air flotation, air is introduced into a solution that is being held at an elevated pressure. A typical unit used for thickening waste activated sludge is shown on Fig. 13–12. When the solution is depressurized, the dissolved air is released as finely divided bubbles carrying the sludge to the top, where it is removed.

Figure 13–12

Typical dissolved air flotation unit used for thickening waste activated sludge: (a) cross-section through typical circular flotation unit, (b) view inside covered circular flotation unit, and (c) view inside building containing rectangular flotation units.



Flotation thickening is used most efficiently for waste sludges from suspended-growth biological treatment processes, such as the activated sludge process or the suspended growth nitrification process. Other sludges such as primary sludge, trickling filter humus, aerobically digested sludge, and sludges containing metal salts from chemical treatment have been flotation thickened. In locations where freezing is a problem or where odor control is of concern, flotation thickeners are normally enclosed in a building.

The float solids concentration that can be obtained by flotation thickening of waste activated sludge is influenced primarily by the air-to-solids ratio, sludge characteristics (in particular the sludge volume index, SVI), solids loading rate, and polymer application. Although float solids concentrations have ranged historically between 3 and 6 percent by weight, float solids concentration is difficult to predict during the design stage without bench-scale or pilot-plant testing. The air-to-solids ratio is probably the most important factor affecting performance of the flotation thickener, and is defined as the weight ratio of air available for flotation to the solids to be floated in the feed stream. The air-to-solids ratio at which float solids are maximized varies from 2 to 4 percent. The SVI is also important because better thickening performance has been reported when the SVI is less than 200, using nominal polymer dosages. At high SVIs, the float concentration deteriorates and high polymer dosages are required.

Higher loadings can be used with dissolved air flotation thickeners than are permissible with gravity thickeners, because of the rapid separation of solids from the wastewater. Flotation thickeners typically are designed for the solids loadings given in Table 13–20. For design without the benefit of pilot studies, the minimum loadings should be used. The higher solids loadings generally result in lower concentrations of thickened sludge.

Table 13–20

Typical solids loadings for dissolved air flotation units[a,b]

	Loading, lb/ft²·h		Loading, kg/m²·h	
Type of sludge	**Without chemical addition**	**With chemicals**	**Without chemical addition**	**With chemicals**
Air activated sludge:				
Mixed Liquor	0.25–0.6	Up to 2	1.2–3	Up to 10
Settled	0.5–0.8	Up to 2	2.4–4	Up to 10
High purity oxygen activated sludge	0.6–0.8	Up to 2	3–4	Up to 10
Trickling filter humus sludge	0.6–0.8	Up to 2	3–4	Up to 10
Primary + air activated sludge	0.6–0.8	Up to 2	3–6	Up to 10
Primary + trickling filter humus sludge	0.83–1.25	Up to 2	4–6	Up to 10
Primary sludge only	0.83–1.25	Up to 2.5	4–6	Up to 12.5

[a] Adapted, in part, from U.S. EPA (1979) and WEF (2010a).

[b] Loading rates necessary to produce a minimum 4 percent solids concentration in the float.

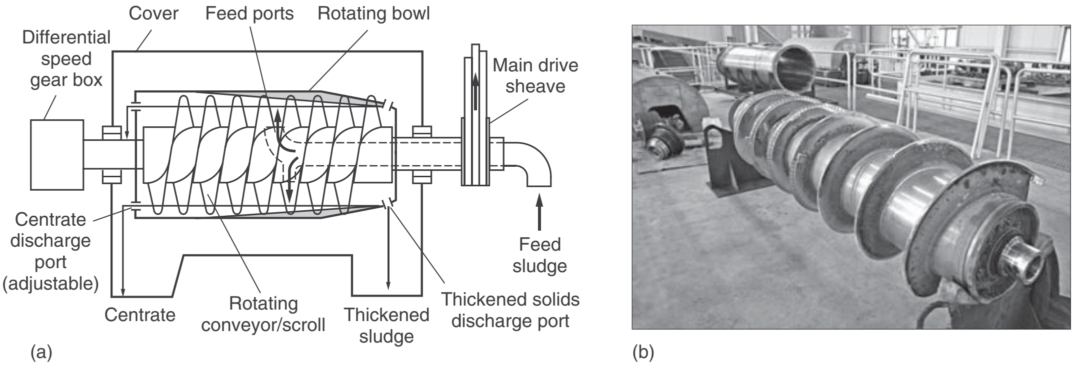
Operational difficulties may arise when the solids loading rate exceeds approximately 10 kg/m²·h (2.0 lb/ft²·h). The increased amount of float created at high solids loading necessitates continuous skimming, often at high skimming speeds.

Primary tank effluent or plant effluent is recommended as the source of air-charged water rather than flotation tank effluent, except when chemical aids are used, because of the possibility of fouling the air-pressure system with solids. The use of polymers as flotation aids is effective in increasing the solids recovery in the floated sludge from 85 to 98 or 99 percent, and in reducing the recycle loads. Polymer dosages for thickening waste activated sludge are 2 to 5 kg of dry polymer per tonne of dry solids (4 to 10 lb/ton).

Centrifugal Thickening. Centrifuges are used both to thicken and to dewater sludges. As indicated in Table 13–18, their application in thickening is limited normally to waste activated sludge. Thickening by centrifugation involves the settling of sludge particles under the influence of centrifugal forces. The basic type of centrifuge used for sludge thickening is the solid bowl centrifuge (see Fig. 13–13).

The solid-bowl centrifuge consists of a long bowl, normally mounted horizontally and tapered at one end. Sludge is introduced into the unit continuously, and the solids concentrate on the periphery. An internal helical scroll, spinning at a slightly different speed, moves the accumulated sludge toward the tapered end where additional solids concentration occurs and the thickened sludge is discharged.

Under normal conditions, thickening can be accomplished by centrifugal thickening without polymer addition. Maintenance and power costs for the centrifugal thickening process, however, can be substantial. Therefore, the process is usually attractive only at facilities larger than 0.2 m³/s (5 Mgal/d), where space is limited and skilled operators are available, or for sludges that are difficult to thicken by more conventional means. Many systems are designed with standby polymer systems for use to improve system performance. Polymer dosages for thickening waste activated sludge range from 0 to 4 kg of dry polymer per 1 tonne of dry solids (0 to 8 lb/ton).



(a)

(b)

Figure 13–13

Centrifuge used for sludge thickening: (a) schematic, and (b) scroll rotor removed for maintenance.

The performance of a centrifuge is often quantified by the concentration achieved in the thickened sludge product and the TSS recovery (sometimes termed "capture"). The recovery is calculated as the thickened dry solids as a percentage of the feed solids. Using the commonly measured solids concentrations, the recovery is calculated by the following expression (WEF, 2010a):

$$R = \frac{\text{TSS}_P(\text{TSS}_F - \text{TSS}_C)}{\text{TSS}_F(\text{TSS}_P - \text{TSS}_C)} \times 100 \tag{13–6}$$

where R = recovery, percent
TSS_P = total suspended solids concentration in thickened product, percent by weight
TSS_F = total suspended solids concentration in feed, percent by weight
TSS_C = total suspended solids concentration in centrate, percent by weight

For a constant feed concentration, the percent recovery increases as the concentration of solids in the centrate decreases. In concentrating sludge solids, recovery is important because with a higher recovery lesser amounts of biodegradable solids are returned to the treatment process for further treatment. In developing a mass balance for the treatment plant, return flows (also termed sidestream flows) from thickening, stabilization, and dewatering processes must be taken into account (see Sec. 14–7).

The principal operational variables include the following: (1) characteristics of the feed sludge (its water holding structure and the sludge volume index); (2) rotational speed; (3) hydraulic loading rate; (4) depth of the liquid pool in the bowl; (5) differential speed of the screw conveyor; and (6) polymer conditioning to improve the performance. Because the interrelationships of these variables will be different in each location, specific design recommendations are not available; in fact, bench-scale or pilot-plant tests are recommended.

Gravity Belt Thickening. The development of gravity belt thickeners stemmed from the application of belt presses for sludge dewatering. In belt-press dewatering, particularly for sludges having solids concentrations less than 2 percent, effective thickening occurred in the gravity drainage section of the press. The equipment developed for thickening consists of a gravity belt that moves over rollers driven by a variable-speed drive unit (see Fig. 13–14). The sludge is conditioned with polymer and fed into a feed/distribution box at one end, where the sludge is distributed evenly across the width of the moving belt. The water drains through the belt as the concentrating sludge is carried toward the discharge

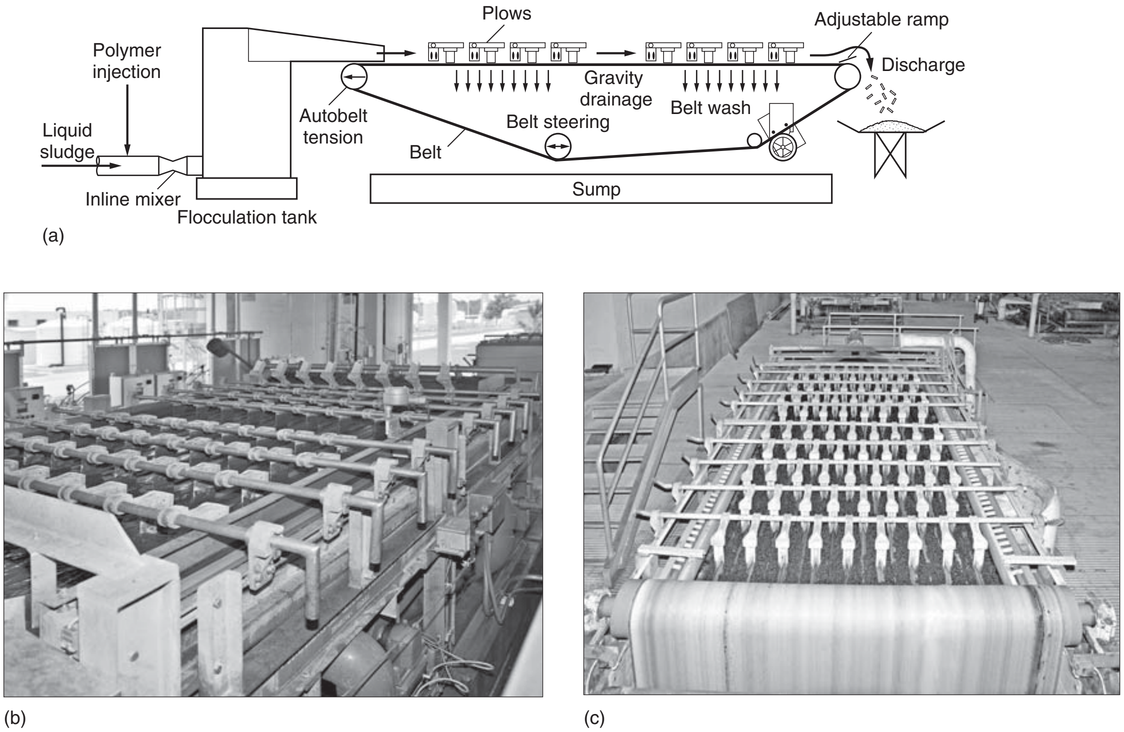


Figure 13–14

Gravity belt thickener: (a) schematic diagram (courtesy of Ashbrook Corporation), (b) top view of sludge plows used to aid the dewatering process, and (c) top view of gravity belt thickener viewed from the discharge end.

end of the thickener. The sludge is ridged and furrowed by a series of plow blades placed along the travel of the belt [see Fig. 13–14(b)], allowing the water released from the sludge to pass through the belt. After the thickened sludge is removed [see Fig. 13–14(c)], the belt travels through a wash cycle. The gravity-belt thickener has been used for thickening waste activated sludge, anaerobically and aerobically digested sludge, and some industrial sludges. Polymer addition is required. Testing is recommended to verify that the sludge can be thickened at typical polymer dosages.

Typical hydraulic loading rates for gravity-belt thickeners are given in Table 13–21. In lieu of pilot-plant data, a value of 800 L/m·min (64 gal/ft·min) is suggested as a design value;

Table 13–21

Typical hydraulic loading rates for gravity belt thickeners[a,b]

Belt size (effective dewatering width), m	Hydraulic loading range	
	gal/min	L/s
1.0	100–250	6.7–16
1.5	150–375	9.5–24
2.0	200–500	12.7–32
3.0	300–750	18–47

[a] Assumes 0.5 to 1.0 percent feed solids for municipal sludges. Variations in sludge density, belt porosity, polymer reaction rate, and belt speed will act to increase or decrease the rates of flow for any given size belt.

[b] Adapted from WEF (2010a).

Figure 13–15

Rotary drum thickener. (Courtesy of Parkson Corporation.)

the higher the feed rate, the greater the operator attention required to maintain stable operation. Solids loading rates range on the order of 200 to 600 kg/m·h (135 to 400 lb/ft^2·h). Systems are often designed for a maximum of 4 to 7 percent thickened solids. Solids capture typically ranges between 90 and 98 percent (WEF, 2010a). Polymer dosages for thickening waste activated sludge range from 3 to 7 kg of dry polymer per tonne of dry solids (6 to 14 lb/ton).

Rotary Drum Thickening. Rotary media-covered drums are also used to thicken sludges. A rotary drum thickening system consists of a conditioning system (including a polymer feed system) and rotating cylindrical screens (see Fig. 13–15). Polymer is mixed with dilute sludge in the mixing and conditioning drum. The conditioned sludge is then passed to rotating screen drums, which separate the flocculated solids from the water. Thickened sludge rolls out the end of the drums, while separated water decants through the screens. Some designs also allow coupling of the rotary drum unit to a belt filter press for combination thickening and dewatering.

Rotary drum thickeners can be used as a prethickening step before belt-press dewatering and are typically used in small- to medium-sized plants for waste activated sludge thickening. The addition of large amounts of polymer for conditioning can be of concern because of floc sensitivity and shear potential in the rotating drum (WEF, 2010a). Rotary drum thickeners are available in capacities up to 24 L/s (400 gal/min). Typical performance data for rotary drum thickeners are given in Table 13–22.

Table 13–22

Typical Performance ranges for rotary drum thickeners for sludge and biosolids[a]

Type of feed	Feed, % TS	Water removed, %	Thickened solids, %	Solids recovery, %
Untreated sludge				
Primary	3.0–6.0	40–75	7–9	93–98
WAS[b]	0.5–1.0	70–90	4–9	93–99
Primary + WAS	2.0–4.0	50	5–9	93–98
Anaerobically digested biosolids	2.5–5.0	50	5–9	90–98
Aerobically digested biosolids	0.8–2.0	70–80	4–6	90–98

[b] WAS = waste activated sludge.

13–7 INTRODUCTION TO SLUDGE STABILIZATION

Sludge is stabilized to (1) reduce pathogens, (2) eliminate offensive odors, and (3) inhibit, reduce, or eliminate the potential for putrefaction. The success in achieving these objectives is related to the effects of the stabilization operation or process on the volatile or organic fraction of the sludge. Survival of pathogens, release of odors, and putrefaction occur when microorganisms are allowed to flourish in the organic fraction of the sludge. The means to eliminate these nuisance conditions is mainly related to the biological reduction of the volatile content and the addition of chemicals to the sludge or biosolids to render them unsuitable for the survival of microorganisms.

Stabilization is not practiced at all wastewater treatment plants, but it is used by an overwhelming majority of plants ranging in size from small to very large. In addition to the health and aesthetic reasons cited above, stabilization can result for volume reduction, production of usable gas (methane), and improved sludge dewaterability.

The principal methods used for stabilization of sludge are (1) alkaline stabilization, usually with lime; (2) anaerobic digestion; (3) aerobic digestion; and (4) composting. These processes are generally defined in Table 13–23. Each of the processes, with the exception of

Table 13–23

Description of sludge stabilization processes

Process	Description	Comments
Alkaline stabilization	Addition of an alkaline material, usually lime, to maintain a high pH level to effect the destruction of pathogenic organisms.	An advantage of alkaline stabilization is that a rich soil-like product results with substantially reduced pathogens. A disadvantage is that the product mass is increased by the addition of the alkaline material. Some alkaline stabilization processes are capable of producing a Class A sludge.
Anaerobic digestion	The biological conversion of organic matter by fermentation in a heated reactor to produce methane gas and carbon dioxide. Fermentation occurs in the absence of oxygen.	Methane gas can be used beneficially for the generation of heat or electricity. The resulting biosolids may be suitable for land application. The process requires skilled operation as it may be susceptible to upsets and recovery is slow.
Aerobic digestion	The biological conversion of organic matter in the presence of air (or oxygen), usually in an open-top tank.	Process is much simpler to operate than an anaerobic digester, but no usable gas is produced. The process is energy-intensive because of the power requirements necessary for mixing and oxygen transfer.
Autothermal thermophilic digestion	Process is similar to aerobic digestion except higher amounts of oxygen are added to accelerate the conversion of organic matter. Process operates at temperatures of 40 to 80 °C, autothermally in an insulated tank.	Process is capable of producing a Class A sludge. Skilled operators are required and the process is a high energy user (to produce air or oxygen).
Composting	The biological conversion of solid organic matter in an enclosed reactor or in windrows or piles.	A variety of sludge or biosolids can be composted. Composting requires the addition of a bulking agent to provide an environment suitable for biological activity. Volume of compost produced is usually greater than the volume of wastewater sludge being composted. Class A or Class B sludge can be produced. Odor control is very important as process is odorous.

Table 13–24

Relative degree of attenuation achieved with various sludge stabilization processes[a]

Process	Degree of attenuation		
	Pathogens	Putrefaction	Odor potential
Alkaline stabilization	Good	Fair	Fair
Anaerobic digestion	Fair	Good	Good
Advanced anaerobic digestion	Excellent	Good	Good
Aerobic digestion	Fair	Good	Good
Autothermal thermophilic digestion (ATAD)	Excellent	Good	Good
Composting	Good	Good	Fair to good

[a] Adapted in part from WEF (2010a).

composting which is considered in Chap. 14, is discussed in more detail in the following sections, and their ability to mitigate or stabilize the effects related to pathogens, putrefaction, and odors is given in Table 13–24. Heat treatment and the addition of oxidizing chemicals, processes that seldom are used in the United States for stabilization, are not included in this text. For information about these processes please refer to Metcalf & Eddy (1991).

When designing a stabilization process, it is important to consider the sludge quantity to be treated, the integration of the stabilization process with the other treatment units, and the objectives of the stabilization process. The objectives of the stabilization process are often affected by existing or pending regulations. If sludge is to be applied on land, pathogen reduction has to be considered. The effect of regulations on application of biosolids to land is discussed in Sec. 14–8.

13–8 ALKALINE STABILIZATION

A method used to eliminate nuisance conditions in sludge involves the use of an alkaline material to render the sludge unsuitable for the survival of microorganisms. In the lime stabilization process, lime is added to untreated sludge in sufficient quantity to raise the pH to 12 or higher. The high pH creates an environment that halts or substantially retards the microbial reactions that can otherwise lead to odor production and vector attraction. The sludge will not putrefy, create odors, or pose a health hazard so long as the pH is maintained at this level. However, high ammonia odor levels have been observed during lime stabilization. The process can also inactivate virus, bacteria, and other microorganisms present. Advantages and disadvantages of alkaline stabilization are summarized in Table 13–25.

Chemical Reactions in Lime Stabilization

The lime stabilization process involves a variety of chemical reactions that alter the chemical composition of the sludge. The following simplified equations are illustrative of the types of reactions that may occur (WEF, 2010a):
Calcium

$$\mathrm{Ca^{2+} + 2HCO_3^- + CaO \rightarrow 2CaCO_3 + H_2O} \qquad (13\text{–}7)$$

Phosphorus

$$\mathrm{2PO_4^{3+} + 6H^+ + 3CaO \rightarrow Ca_3(PO_4)_2 + 3H_2O} \qquad (13\text{–}8)$$

Table 13–25

Advantages and disadvantages of alkaline stabilization[a]

Advantages	Disadvantages
1. Well proven process 2. Product is suitable for a variety of uses that are consistent with the EPA's national beneficial reuse policy 3. Simple technology requiring few special skills for reliable operation 4. Easy to construct of readily available parts 5. Small footprint 6. Flexible operation, easily started and stopped 7. Can produce Class A or Class B biosolids	1. The resulting product is not suitable for use on all soil, especially high alkaline soils 2. The volume of material to be managed and moved off-site is increased by approximately 15 to 50 percent in comparison with other stabilization techniques, such as digestion. The increased volume results in higher transportation costs when material is moved off-site 3. Potential for odor generation both at the processing and end use site due to ammonia and TMA release 4. Potential for dust production 5. The nitrogen content in the final product is lower than that in several other biosolids products because of ammonia volatilization. In addition, available phosphorous can be reduced through the formation of calcium phosphate

[a] Adapted, in part, from EPA (2000).

Carbon dioxide

$$CO_2 + CaO \rightarrow CaCO_3 \tag{13–9}$$

Reactions with organic contaminants:
Acids:

$$R\text{COOH} + \text{CaO} \rightarrow R\text{COOCaOH} \tag{13–10}$$

Fats:

$$\text{Fat} + \text{Ca(OH)}_2 \rightarrow \text{glycerol} + \text{fatty acids} \tag{13–11}$$

Other reactions also occur, such as the hydrolysis of polymers, especially polymeric carbohydrates and proteins, and the hydrolysis of ammonia from amino acids.

Initially, lime addition raises the pH of the sludge. Then, reactions occur such as those in the above equations. If insufficient lime is added, the pH decreases as the reactions take place. Therefore, excess lime is required.

Biological activity produces compounds, such as carbon dioxide and organic acids, that react with lime. If biological activity in the sludge being stabilized is not sufficiently inhibited, these compounds will be produced, reducing the pH and resulting in inadequate stabilization. Many odorous, volatile off-gases are also produced, especially ammonia, which require collection and treatment in odor-control systems such as chemical scrubbers or biofilters (see Chap. 16). Other odorous material such as trimethyl amine (TMA) is generated from the degradation of conditioning polymers during lime stabilization (Dentel et al., 2005).

Heat Generation

If quicklime, CaO (or any compound high in quicklime), is added to sludge, it initially reacts with water to form hydrated lime. This reaction is exothermic and releases approximately

64 kJ/g·mole (2.75×10^4 Btu/lb·mole) (WEF, 2010a). The reaction between quicklime and carbon dioxide is also exothermic, releasing approximately 180 kJ/g·mole (7.8×10^4 Btu/lb·mole). These reactions can result in substantial temperature rise (see discussion of lime posttreatment).

Application of Alkaline Stabilization Processes

Three methods of alkaline stabilization are commonly used: (1) addition of lime to sludge prior to dewatering, termed "lime pretreatment," (2) the addition of lime to sludge after dewatering, or "lime posttreatment," and (3) advanced alkaline stabilization technologies. Either hydrated lime, $Ca(OH)_2$, or quicklime is used most commonly for lime stabilization. Fly ash, cement kiln dust, and carbide lime have also been used as a substitute for lime in some cases.

Lime Pretreatment. Pretreatment (before dewatering) of liquid sludge with lime has been used for either (1) the direct application of liquid sludge to land, or (2) combining benefits of sludge conditioning and stabilization prior to dewatering. In the former case, large quantities of liquid sludge have to be transported to land disposition sites, which limits utilization of lime pretreatment of sludge to small treatment plants. When pretreatment is used prior to dewatering, dewatering has been accomplished using a pressure-type filter press and/or screw press. Lime pretreatment is seldom used with centrifuges or belt filter presses because of abrasive wear and scaling problems.

Lime pretreatment of liquid sludge requires more lime per unit weight of sludge processed than that necessary for dewatering. The higher lime dose is needed to attain the required pH because of the chemical demand of the liquid. In addition, sufficient contact time must be provided before dewatering so as to provide a high level of pathogen kill. The recommended design objective is to maintain the pH above 12 for about 2 h to ensure pathogen destruction (the minimum U.S. EPA criterion for lime stabilization), and to provide enough residual alkalinity so that the pH does not drop below 11 for several days. The lime dosage required varies with the type of sludge and solids concentration. Typical dosages are reported in Table 13–26. Generally, as the percent solids concentration increases, the required lime dose decreases. Testing should be performed for specific applications to determine the actual dosage requirements.

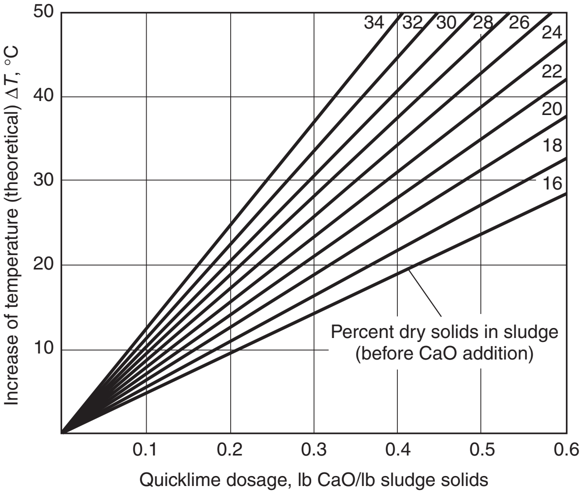
Table 13–26

Typical lime dosages for pretreatment sludge stabilization[a]

	Solids concentration, %		Lime dosage[b] lb $Ca(OH)_2$/ton dry solids		Lime dosage[b] g $Ca(OH)_2$/kg dry solids	
Type of sludge	**Range**	**Average**	**Range**	**Average**	**Range**	**Average**
Primary	3–6	4.3	120–340	240	60–170	120
Waste activated	1–1.5	1.3	420–860	600	210–430	300
Septage	1–4.5	2.7	180–1020	400	90–510	200

[a] Adapted from WEF, (1995a).

[b] Amount of $Ca(OH)_2$ required to maintain a pH of 12 for 30 min.



Note: In practice, higher temperature values are expected. 1.8 (°C) + 32 = °F

Figure 13–16

Theoretical temperature increase in post-lime stabilized sludge using quicklime (Roediger, 1987).

Because lime stabilization does not destroy the organics necessary for bacterial growth, the sludge must be treated with an excess of lime or used beneficially before the pH drops significantly. An excess dosage of lime may range up to 1.5 times the amount needed to maintain the initial pH of 12. Reasons for pH drop could be due to generation of carbon dioxide and organic acids from degradation of organic material in the sludge. The dissolution of carbon dioxide in the air could be another reason for pH decay. For additional details about pH decay following lime stabilization, WEF (1995a) is recommended.

Lime Posttreatment. In lime posttreatment, quicklime is mixed with dewatered sludge in a pugmill, paddle mixer, or screw conveyor to raise the pH of the mixture. Quicklime is used because the exothermic reaction of quicklime and water can raise the temperature of the mixture above 50°C, sufficient to inactivate worm eggs. The theoretical temperature increase by the addition of quicklime is illustrated on Fig. 13–16.

Lime posttreatment is more common than lime pretreatment and has several significant advantages when compared to lime pretreatment: (1) dry lime can be used; therefore, no additional water and equipment is needed for hydrated lime; (2) there are no special requirements for dewatering; and (3) scaling problems and associated maintenance problems of lime-sludge dewatering equipment are eliminated. Adequate mixing is critical for a posttreatment stabilization system so as to avoid pockets of putrescible material. A lime posttreatment stabilization system consists typically of a dry lime feed system, dewatered sludge cake conveyor, and a lime-sludge mixer (see Fig. 13–17). Good mixing is especially important to ensure contact between lime and small particles of sludge. When the lime and sludge are well mixed, the resulting mixture has a crumbly texture, which allows it to be stored for long periods or easily distributed on land by a conventional manure spreader. A potential disadvantage of lime posttreatment may be the release of odorous gases, specifically trimethyl amine (Novak, 2001; Dentel, 2005).

Advanced Alkaline Stabilization Technologies. Alkaline stabilization using materials other than lime is used by a number of municipalities. Most of the technologies that rely on additives, such as cement kiln dust, lime kiln dust, or fly ash, are modifications of conventional dry lime stabilization. The most common modifications include the addition

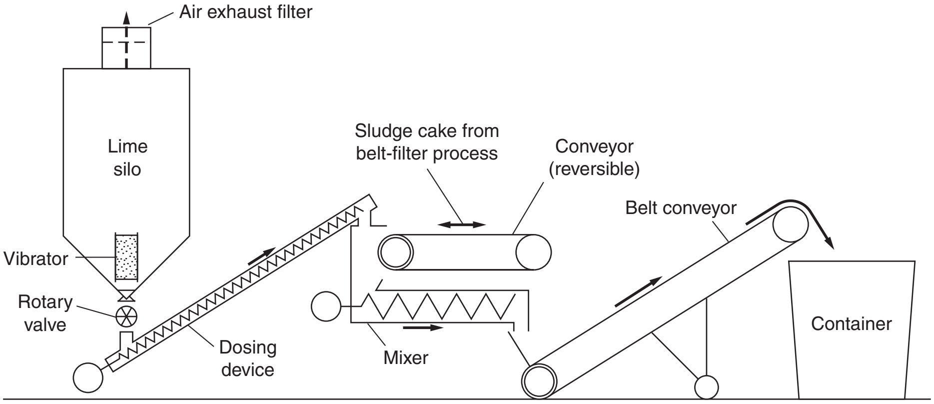


Figure 13–17

Typical lime posttreatment system. (From Roediger Pittsburgh.)

of other chemicals, a higher chemical dose, and supplemental drying. These processes alter the characteristics of the feed material and, depending on the process, may increase product stability, decrease odor potential, and provide product enhancement. To utilize these technologies, dewatered sludge is required.

Pasteurization may be accomplished by the exothermic reaction of quicklime with water to achieve a process temperature of 70°C and maintain it for more than 30 min. Other sources of energy can be used to aid in increasing the temperature generated from the exothermic chemical reaction. For example, the pasteurization system marketed by RDP Company uses electricity to generate heat for raising the temperature to the required degree. N-Viro International Corporation markets an advanced alkaline stabilization system combined with drying. To meet Class A biosolids criteria, the pasteurization reaction must be carried out under carefully controlled and monitored mixing and temperature conditions to ensure uniform treatment and inactivation of pathogens by the heat generated during the reaction. The process produces a soil-like material that is not subject to liquefaction under mechanical stress. Several other process variations of advanced alkaline stabilization are available, some of which are proprietary. Additional information may be found in WEF (2010a) and WEF (2012).

13–9 ANAEROBIC DIGESTION

Anaerobic digestion is among the oldest processes used for the stabilization of sludge. As described in Chap. 10, anaerobic digestion involves the decomposition of organic matter and reduction of inorganic matter (principally sulfate) in the absence of molecular oxygen. The major applications of anaerobic digestion are in the stabilization of concentrated sludges produced from the treatment of municipal and industrial wastewater. Great progress has been made in the fundamental understanding and control of the process, the sizing of tanks, and the design and application of equipment. Because of the emphasis on energy conservation and recovery and the desire to obtain beneficial use of wastewater biosolids, anaerobic digestion continues to be the dominant process for stabilizing sludge. Furthermore, anaerobic digestion of municipal wastewater sludge can, in many cases, produce sufficient digester gas to meet most of the energy needs for plant operation. An aerial view of a large digester installation is shown on Fig. 13–18.

In this section, a brief review is provided of process fundamentals followed by discussions of mesophilic anaerobic digestion, the most common basic process used; thermophilic digestion; and phased digestion. Phased digestion covers many of the new developments in anaerobic digestion.

Figure 13–18

Aerial view of several large anaerobic digesters at Boston, MA.

Process Fundamentals

As described in Chap. 7, the three types of chemical and biochemical reactions that occur in anaerobic digestion are hydrolysis; fermentation, also called acidogenesis (the formation of soluble organic compounds and short-chain organic acids); and methanogenesis (the bacterial conversion of organic acids into methane and carbon dioxide). Important environmental factors in the anaerobic digestion process are (1) solids retention time, (2) hydraulic retention time, (3) temperature, (4) alkalinity, (5) pH, (6) the presence of inhibitory substances, i.e., toxic materials, and (7) the bioavailability of nutrients and trace metals. The first three factors are important in process selection and are discussed in this section. Alkalinity is a function of feed solids and is important in controlling the digestion process. The effects of pH and inhibitory substances are discussed in Chaps. 7 and 10. The presence of nutrients and trace metals necessary for biological growth is described in Sec. 10–2 in Chap. 10.

Solids and Hydraulic Retention Times. Anaerobic digester sizing is based on providing sufficient residence time in well-mixed reactors to allow significant destruction of volatile suspended solids (VSS) to occur. Sizing criteria that have been used are (1) solids retention time SRT, the average time the solids are held in the digestion process, and (2) the hydraulic retention time τ, the average time the liquid is held in the digestion process. For soluble substrates, the SRT can be determined by dividing the mass of solids in the reactor (M) by the mass of solids removed daily (M/d). The hydraulic retention time τ is equal to the volume of liquid in the reactor (m^3) divided by the quantity of biosolids removed (m^3/d). For digestion systems without recycle, SRT $= \tau$.

The three reactions (hydrolysis, fermentation, and methanogenesis) are directly related to SRT (or τ). An increase or decrease in SRT results in an increase or decrease in the extent of each reaction. There is a minimum SRT for each reaction. If the SRT is less than the minimum SRT, bacteria cannot grow rapidly enough and the digestion process will fail eventually (WEF, 2010a).

Temperature. As discussed in Sec. 7–5, temperature not only influences the metabolic activities of the microbial population but also has a profound effect on such factors as gas transfer rates and the settling characteristics of biological sludges. In anaerobic digestion, temperature is important in determining the rate of digestion, particularly the rates of hydrolysis and methane formation. The minimum SRT required to achieve a given amount of VSS destruction is based on the design operating temperature. Most anaerobic digestion systems are designed to operate in the mesophilic temperature range, between 30 and 38°C (85 and 100°F). Other systems are designed for operation in the thermophilic temperature range of 50 to 57°C (122 to 135°F). Newly developed systems, as discussed in a latter part of this section, use a combination of mesophilic and thermophilic digestion in separate stages.

While selection of the design operating temperatures is important, maintaining a stable operating temperature is more important because the bacteria, especially the methane formers, are sensitive to temperature changes. Generally, temperature changes greater than 1°C/d affect process performance, and thus changes less than 0.5°C/d are recommended (WEF, 2010a).

Alkalinity. Calcium, magnesium, and ammonium bicarbonates are examples of buffering substances found in a digester. The digestion process produces ammonium bicarbonate from the breakdown of protein in the raw sludge feed; the others are found in the feed sludge. The concentration of alkalinity in a digester is, to a great extent, proportional to the solids feed concentration. A well-established digester has a total alkalinity of 2000 to 5000 mg/L.

The principal consumer of alkalinity in a digester is carbon dioxide, and not volatile fatty acids as is commonly believed (Speece, 2001). Carbon dioxide is produced in the fermentation and methanogenesis phases of the digestion process (see Sec. 7–12 in Chap. 7). Due to the partial pressure of gas in a digester, the carbon dioxide solubilizes and forms carbonic acid, which consumes alkalinity. The carbon dioxide concentration in the digester gas is, therefore, reflective of the alkalinity requirements. Volatile fatty acids are intermediate products from the acid phase of digestion and consume alkalinity. Volatile acids in digesters range from 50 to 300 mg/L. The ratio of volatile acids to the alkalinity is a parameter that is used to monitor the health of the digestion process and should be monitored closely. The volatile acids to alkalinity ratio for well-established digesters should fall between 0.05 to 0.25 with a 0.1 value indicating a good buffering capacity. Supplemental alkalinity can be supplied by the addition of sodium bicarbonate, lime, or sodium carbonate.

Description of Mesophilic Anaerobic Digestion Processes

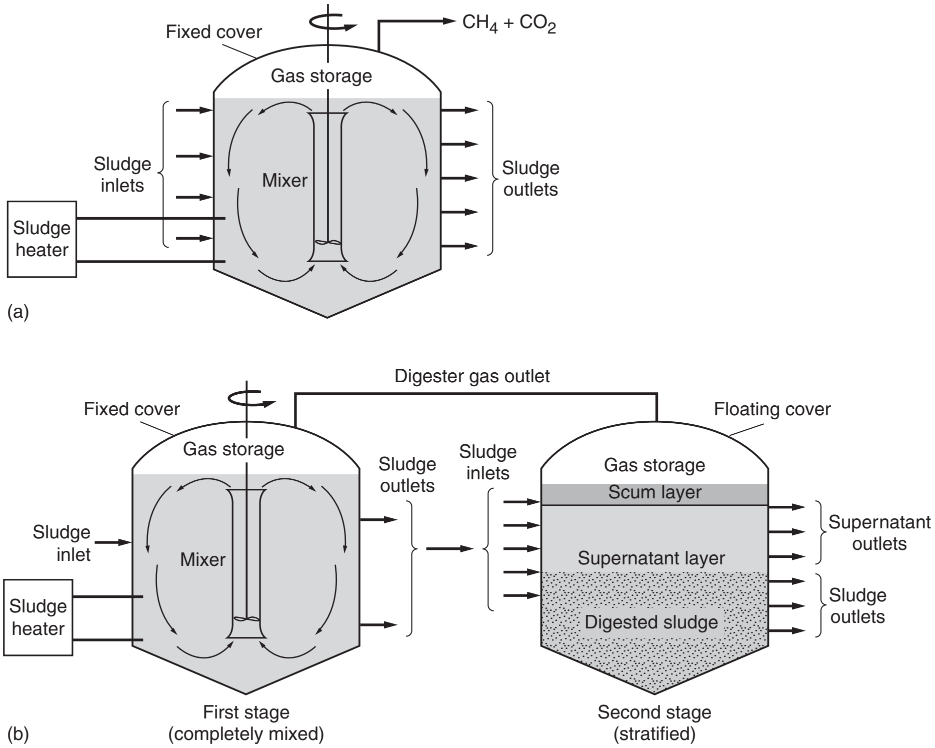
The operation and physical facilities for mesophilic anaerobic digestion in single-stage high-rate, two-stage, and separate digesters for primary sludge and waste activated sludge are described in this section. Standard-rate, sometimes called low-rate, digestion is seldom used for digester design (because of the large tank volume required and the lack of adequate mixing) and is not covered in this text. For information about standard-rate digestion, the reader is referred to the third edition of this text (Metcalf & Eddy, 1991) and WEF (1998). The processes described below normally operate in the mesophilic range; high-rate digesters also operate in the thermophilic range. Thermophilic digestion is discussed at the end of the section.

Single-Stage High-Rate Digestion. Heating, auxiliary mixing, uniform feeding, and thickening of the feed stream characterize the single-stage high-rate digestion process. The sludge is mixed by one of many systems such as gas recirculation, pumping, or draft-tube mixers (separation of scum and supernatant does not take place), and sludge is heated to achieve optimum digestion rates [see Fig. 13–19(a)].

Uniform feeding is very important, and sludge should be pumped to the digester continuously or on a 30-min to 2-h time cycle to help maintain constant conditions in

Figure 13–19

Schematic d diagram of typical anaerobic digesters (a) high-rate and (b) two-stage.



the reactor. In digesters fed on a daily cycle of 8 or 24 h, it is important to withdraw digested sludge from the digester before adding the feed sludge, because the pathogen kill is significantly greater when compared to using the feed sludge to displace the waste sludge (Speece, 2001). Because there is no supernatant separation in the high-rate digester, and the total solids are reduced by 45 to 50 percent and given off as gas, the digested sludge is about half as concentrated as the untreated sludge feed. Digestion tanks may have fixed roofs or floating covers (see subsequent discussion of digester types). Any or all of the floating covers may be of the gas holder type, which provides excess gas storage capacity. Alternatively, gas may be stored in a separate low-pressure gas holder or compressed and stored under pressure.

Two-Stage Digestion. Two-stage digestion, which was frequently used in the past, is seldom used in modern digester design. In two-stage digestion, a high-rate digester is coupled in series with a second tank [see Fig. 13–19(b)]. The first tank is used for digestion and is heated and equipped with mixing facilities. The second tank is usually unheated and used principally for storage. The tanks may be identical, in which case either one may be the primary. Tanks may have fixed roofs or floating covers, the same as single-stage digestion. In other cases, the second tank may be an open tank or a sludge lagoon. In the case of an open second digester some methane would escape if digestion continued leading to increased carbon footprint of the processes. Two-stage digestion of the type described above is seldom used, mainly because of the expense of building a large tank that is not fully utilized and because the second tank was of negligible benefit, operationally.

Because anaerobically digested biosolids may not settle well, the supernatant withdrawn from the second-stage tank may contain high concentrations of suspended solids. Reasons for poor settling characteristics include incomplete digestion in the primary digester (which generates gases in the secondary digester and causes floating solids) and fine-sized solids that have poor settling characteristics. Supernatant returned to the liquid processing system could cause upset conditions and might require separate treatment. Where two-stage digestion is used, return flows from the second tank must be accounted for in the solids mass balance. Less than 10 percent of the gas generated comes from the second stage.

In some installations, the second stage is a heated and mixed reactor to achieve further stabilization prior to dewatering or other subsequent processing. Additional discussion is provided later in this section on two-phase mesophilic digestion that provides more effective utilization of tank capacity.

Separate Sludge Digestion. Most wastewater treatment plants employing anaerobic digestion use a single digester for the digestion of a mixture of primary and biological sludge. The solid-liquid separation of digested primary sludge, however, is downgraded by even small additions of biological sludge, particularly activated sludge. The rate of reaction under anaerobic conditions is also slowed slightly. In separate sludge digestion, the digestion of primary and biological sludges is accomplished in separate tanks. Reasons cited for separate digestion include (1) the excellent dewatering characteristics of the digested primary sludge are maintained, (2) the digestion process is specifically tailored to the sludge being treated, and (3) optimum process control conditions can be maintained. Design criteria and performance data for the separate anaerobic digestion of biological sludges, however, are very limited. In some cases, especially where biological phosphorus removal is practiced, biological sludge is digested aerobically instead of anaerobically to prevent resolubilization of the phosphorus under anaerobic conditions. Separate sludge digestion is not currently a common practice at most plants.

Process Design for Mesophilic Anaerobic Digestion

Ideally, the design of anaerobic sludge digestion processes should be based on an understanding of the fundamental principles of biochemistry and microbiology discussed in Chap. 7 in Sec. 7–12. Because these principles have not been appreciated fully in the past, a number of empirical methods have also been used in the design of digesters. The purpose of the following discussion is to illustrate the various methods that have been used to design single-stage, high-rate digesters in terms of size. These methods are based on (1) solids retention time, (2) the use of volumetric loading factors, (3) volatile solids destruction, (4) observed volume reduction, and (5) loading factors based on population.

Solids Retention Time. Digester design based on SRT involves application of the principles discussed in Chaps. 7 and 10. To review briefly, the respiration and oxidation end products of anaerobic digestion are methane gas and carbon dioxide. The quantity of methane gas can be calculated using Eq. (13–12):

$$V_{CH_4} = (0.35)[(S_o - S)(Q)(1\,\text{kg}/10^3\,\text{g}) - 1.42P_x] \tag{13–12}$$

where V_{CH_4} = volume of methane produced at standard conditions (0°C and 1 atm), m^3/d

0.35 = theoretical conversion factor for the amount of methane produced, m^3, from the conversion of 1 kg of bCOD at 0°C (conversion factor at 35°C = 0.40, see Example 7–10 in Chap. 7)

Q = flowrate, m^3/d

S_o = bCOD in influent, g/m^3

S = bCOD in effluent, g/m^3

P_x = net mass of cell tissue produced per day, kg/d

Table 13–27

Suggested solids retention times for use in the design of complete-mix anaerobic digesters[a]

Operating temperature, °C	SRT (minimum)	SRT_{des}
18	11	28
24	8	20
30	6	14
35	4	10
40	4	10

[a] From McCarty (1964) and (1968).

Note: 1.8 (°C) + 32 = °F.

The theoretical conversion factor for the amount of methane produced from the conversion of 1 g of bCOD is derived in Sec. 7–12 in Chap. 7. For a complete-mix high-rate digester without recycle, the mass of biological solids synthesized daily, P_x, can be estimated using Eq. (13–13).

$$P_x = \frac{YQ(S_o - S)(1\ \text{kg}/10^3\ \text{g})}{1 + b(\text{SRT})} \tag{13–13}$$

where Y = yield coefficient, g VSS/g bCOD
b = endogenous coefficient, d^{-1} (typical values range from 0.02 to 0.04)
SRT = solids retention time, d
other terms as defined previously

For a complete-mix digester, the SRT is the same as the hydraulic retention time τ.

Typical anaerobic reaction values for Y and b are given in Table 10–13 in Chap. 10 and range from 0.05 to 0.10 and 0.01 to 0.04, respectively. Typical values for SRT at various temperatures are reported in Table 13–27. In practice for high-rate digestion, however, values for SRTs range from 15 to 20 d. Grady, Daigger, and Lim (1999) observed that (1) a lower SRT limit of 10 days at a temperature of 35°C is sufficient to ensure an adequate safety factor against a washout of the menthanogenic population, and (2) incremental changes in volatile solids destruction are relatively small for SRT values above 15 d at 35°C. In selecting the design SRT for anaerobic digestion, peak hydraulic loading must be considered. The peak loading can be estimated by combining poor thickener performance with the maximum sustained plant loading expected during seven continuous days during the design period (U.S. EPA, 1979). The application of Eqs. (13–12) and (13–13) in the process design of a high-rate digester is illustrated in Example 13–5.

EXAMPLE 13–5 Estimating Single-stage, High-rate Digester Volume and Performance

Estimate the size of digester required for primary sludge from a primary clarifier designed for 38,000 m^3/d (10 Mgal/d) of wastewater. Check the volumetric loading and the amount of gas produced. The influent wastewater BOD and TSS concentrations are 400 and 300 mg/L, respectively. The primary clarifier achieves 35 percent BOD removal and 50 percent TSS removal. Assume that the primary sludge contains about 95 percent moisture and has a specific gravity of 1.02. Other pertinent design assumptions are as follows:

1. The hydraulic regime of the reactor is complete-mix.
2. τ = SRT = 15 d at 35°C (see Table 13–27).

3. Efficiency of waste utilization (solids conversion) E = 0.70.
4. The sludge contains adequate nitrogen and phosphorus for biological growth.
5. $Y = 0.08$ kg VSS/kg bCOD utilized and $b = 0.03\ \text{d}^{-1}$.
6. Constants are for a temperature of 35°C.
7. Digester gas is 65 percent methane.

Solution

1. Determine the daily sludge mass and volume using Eq. (13–2).

$$\text{Sludge mass} = \frac{(38{,}000\ \text{m}^3/\text{d})(300\ \text{g/m}^3)(0.5)}{(10^3\ \text{g}/1\ \text{kg})} = 5700\ \text{kg/d}$$

$$\text{Sludge volume} = \frac{(5700\ \text{kg/d})}{1.02(10^3\ \text{kg/m}^3)(0.05)} = 111.8\ \text{m}^3/\text{d}$$

2. Determine the bCOD loading.

$$\text{bCOD loading} = (0.35)(400\ \text{g/m}^3)(38{,}000\ \text{m}^3/\text{d})(1\ \text{kg}/10^3\ \text{g}) = 5320\ \text{kg/d}$$

3. Compute the digester volume.

$$\tau = \frac{V}{Q}$$

$$V = Q\tau = (111.8\ \text{m}^3/\text{d})(15\text{d}) = 1677\text{m}^3$$

4. Compute the volumetric loading.

$$\frac{(\text{kg bCOD/d})}{\text{m}^3} = \frac{(5320\ \text{kg/d})}{1677\ \text{m}^3} = 3.17\ \text{kg/m}^3{\cdot}\text{d}$$

5. Compute the quantity of volatile solids produced per day using Eq. (13–13).

$$P_x = \frac{YQ(S_o - S)(10^3\ \text{g/kg})^{-1}}{1 + b(\text{SRT})}$$

$$S_o = 5320\ \text{kg/d}$$

$$S = 5320(1 - 0.70) = 1596\ \text{kg/d}$$

$$S_o - S = 5320 - 1596 = 3724\ \text{kg/d}$$

$$P_x = \frac{(0.08)[(5320 - 1596)\text{kg/d}]}{1 + (0.03\text{d}^{-1})(15\text{d})} = 205.5$$

6. Compute the volume of methane produced per day at 35°C using Eq. (13–12) (conversion factor at 35°C = 0.40).

$$V_{\text{CH}_4} = (0.40)[(S_o - S)(Q)(10^3\ \text{g/kg})^{-1} - 1.42\ P_x]$$

$$V_{\text{CH}_4} = (0.4\ \text{m}^3/\text{kg})[(5320 - 1596)\text{kg/d} - 1.42(205.5\ \text{kg/d})]$$

$$= 1373\ \text{m}^3\text{d}$$

7. Estimate the total gas production.

$$\text{Total gas volume} = \frac{1373}{0.65} = 2112\ \text{m}^3/\text{d}$$

Table 13–28

Typical design criteria for sizing mesophilic high-rate complete-mix anaerobic sludge digesters[a]

	U.S. customary units		SI units	
Parameter	**Units**	**Value**	**Units**	**Value**
Volume criteria				
Primary sludge	ft^3/capita	1.3–2.0	m^3/capita	0.03–0.06
Primary sludge + trickling filter humus sludge	ft^3/capita	2.6–3.3	m^3/capita	0.07–0.09
Primary sludge + activated sludge	ft^3/capita	2.6–4.0	m^3/capita	0.07–0.11
Solids loading rate[b]	lb VSS/10^3 $ft^3 \cdot d$	100–300	kg VSS/$m^3 \cdot d$	1.6–4.8
Solids retention time[b]	d	15–20	d	15–20

[a] Adapted, in part, from U.S. EPA (1979).

[b] Based on combined primary and secondary sludges digestion without any pretreatment methods.

Loading Factors. One of the most common methods used to size digesters is to determine the required volume based on a loading factor. Although a number of different factors have been proposed, the two most favored are based on (1) the mass of volatile solids added per day per unit volume of digester capacity and (2) the mass of volatile solids added to the digester each day per mass of volatile solids in the digester. Of the two, the first method is preferred. Loading criteria are based generally on sustained loading conditions (see Chap. 3), typically peak 2-wk or peak mo sludge production with provisions for avoiding excessive loadings during shorter periods. Typical design criteria for sizing mesophilic high-rate anaerobic digesters are given in Table 13–28. The upper limit of volatile solids loading rates is typically determined by the rate of accumulation of toxic materials, particularly ammonia, or washout of methane formers (WEF, 2010a).

Excessively low volatile solids loading rates can result in designs that are costly to build and are troublesome to operate. In a survey conducted by Speece (1988) of 30 digester installations in the United States, one of the most significant observations was the relatively low solids content in the sludge feed to the digesters. The average TSS in the sludge feed was 4.7 ± 1.6 percent and the average volatile solids content was 70 percent. The average VSS value in the digesters was a dilute 1.6 percent. Dilute sludge feed causes low volatile solids loading leading to starving conditions within the digester, resulting in the following adverse effects in digester operation: (1) reduced τ, (2) reduced VS destruction, (3) reduced methane generation, (4) reduced alkalinity, (5) increased volumes of digested biosolids and supernatant, (6) increased heating requirements, (7) increased dewatering capacity, and (8) increased hauling cost for liquid biosolids. As a cautionary note, a potential problem with ammonia toxicity could occur if the waste activated sludge is thickened too much. Thus, in planning the design and operation of anaerobic digesters, consideration should be given to optimizing volatile solids loading to effectively utilize digester capacity. The effect of solids concentration and hydraulic detention time on volatile solids loading is reported in Table 13–29.

Estimating Volatile Solids Destruction. The degree of stabilization obtained is often measured by the percent reduction in volatile solids. The reduction in volatile solids can be related either to the SRT or to the detention time based on the untreated sludge feed.

Table 13–29

Effect of sludge concentration and hydraulic detention time on volatile solids loading factors[a]

Sludge concentration, %	Volatile solids loading factor							
	lb/ft³·d				kg/m³·d			
	10 d[b]	12 d	15 d	20 d	10 d	12 d	15 d	20 d
2	0.09	0.07	0.06	0.04	1.4	1.2	0.95	0.70
3	0.13	0.11	0.09	0.07	2.1	1.8	1.4	1.1
